The Impact of Increasing Food Supply on Human Nutrition—Implications for Commodity Priorities in Agricultural Research and Policy: Comment

Jon A. Brandt and Joseph B. Goodwin

In a recent article in this *Journal,* Pinstrup-Andersen, de Londoño, and Hoover (P-L-H) estimated demand price elasticities for Cali, Colombia, using the method developed by Frisch. From these estimates the authors proceeded to examine the changes in the nutritional levels (measured in calories and protein) of different population income strata from shifts in individual food commodity supplies. As with all studies, the conclusions and implications from the results are influenced by the choice of analytical method. This comment examines in somewhat greater detail (than did P-L-H) the Frisch method, its appropriateness, and its limitations. We contend that the selection of the Frisch method by P-L-H for estimating demand price elasticities for individual food commodities was inappropriate and that the calculated price elasticities are likely biased.

The authors note that the Frisch method allows for the estimation (calculation) of a complete price elasticity of demand matrix. They also note that this process is based on the assumption of want independence among the commodities or groups of commodities considered, and that this assumption is not valid for all goods. P-L-H (p. 133) incorrectly state that "it may be possible, however, to group the bundle of goods available to the consumer to obtain little or no want independence among the groups," whereas, in fact, the reason for grouping goods is to obtain little or not want dependence.

A review of the literature regarding the Frisch method leads to but one conclusion: the assumption of want independence is likely to be true only for broad aggregate groups. Deaton criticizes the Frisch method because of the restrictiveness of the want independence assumption, which implies direct additivity of preferences. Houthakker suggests that the additivity assumption is most likely applicable with large aggregate groups such as clothing and food. Barten (1968) uses the Frisch approach to estimate price elasticities for such broad groups as food, pleasure goods, and durables. None of these studies indicate that the method is applicable at the individual commodity level. In fact, Frisch did not suggest that the approach be used at the disaggregated level; rather he recommended its use to estimate elasticities for broad commodity groups where the assumption of want independence seems more valid.

Ayanian has shown that biased estimates of price elasticities will result if the want independence assumption is not applicable. The bias is due to the utility interaction of commodity i with all other goods for which i is non-want independent. This is illustrated starting with Frisch's (pp. 183, 4) formulas:

$$e_{ii} = \sigma_{ii} - W_i E_i\left(1 + \frac{E_i}{\phi}\right) \qquad (1)$$

$i = 1, \ldots, n$, and

$$E_i = \phi \sum_{k=1}^{n} \sigma_{ik}, \qquad (2)$$

where e_{ii} is the direct price elasticity for good i, σ_{ik} are the want elasticities defined by Frisch, W_i is the budget proportion for good i, E_i is the income elasticity for good i, and 0 is the money flexibility. Then rearranging equation (2),

$$\frac{E_i}{\phi} = \sum_{k=1}^{n} \sigma_{ik} = \sigma_{i1} + \sigma_{i2} + \ldots + \sigma_{ii-1} + \sigma_{ii} + \sigma_{ii+1} + \ldots + \sigma_{in}, \qquad (3)$$

$$\sigma_{ii} = \frac{E_i}{\phi} - \sum_{k,k \neq i}^{n} \sigma_{ik}. \qquad (4)$$

Substituting equation (4) into equation (1) obtains

$$e_{ii} = \frac{E_i}{\phi} - W_i E_i \left(1 + \frac{E_i}{\phi}\right) - \sum_{k,k \neq i}^{n} \sigma_{ik}, \qquad (5)$$

$$e_{ii} = -E_i\left(W_i - \frac{1 - W_i E_i}{0}\right) - \sum_{k,k \neq i}^{n} \sigma_{ik}. \qquad (6)$$

But the first term to the right of the equal sign in equation (6) is the same as P-L-H's (p. 132) equation (1) under want independence. With the assumption of non-want independence, the deviation

are considered rational since they depend on the same things as suggested by economic theory and incorporate available information. Our test of whether the market is efficient is conducted within the context of a specific model of price determination. The test of market efficiency with a specific model utilizing rational expectations is indeed a strong one. Both the model and test are based on sound theoretical structure.

The Norm

Substantial portions of Pasour's criticisms appear to originate with his erroneous reference to our model as an "ideal norm." Such an error would rightly lead one to make reference to the nirvana approach. However, our model is established only as a norm for comparison, and nowhere do we refer to it as an "ideal." The model's role as only a benchmark is clearly established. The model is simple in design and at the same time attempts to reflect the aggregate mental process of the market. Thus, the model and the market should perform similar roles in price formation.

In addition, the phrase "futures prices . . . accurately reflect subsequent spot prices" when stated out of context may convey a different meaning than intended as it apparently did to Pasour. It is not expected that futures markets should exactly predict subsequent spot prices. Errors are expected because of the lack of information and uncertainty. The question is: Do the markets in their price formation reflect at least the information currently available? The only way to examine that is with a norm. An efficient market needs only to reflect currently available information. Our performance norm is only relative, and it is difficult to imagine it as being ideal to the point of ensuring an "imperfect institutional arrangement" (Pasour). We make no claim as implied by both Pasour and Panton that our model is "efficient," only that it be considered a norm for comparison.

We do not compare the futures market to other institutional arrangements for relative efficiency. Buying and selling on the futures market by commercial firms may well be more efficient than, say, forward cash contracting. Small firms have difficulty in assessing local dealer offers because of the lack of comparison and high search costs. If survival is the only criterion, futures markets and many traders easily pass the test. But survival is a limited notion of efficiency and not directly applicable to evaluating forward-pricing abilities. Futures markets transmit information to economic agents, informed and uninformed alike (Danthine, Grossman), and the question is: How reliable is that information? Grossman suggests the appropriate test is the mean-squared prediction error conditional on available information, an approach similar to ours. Hamburger and Platt utilize the technique also.

Finally, Pasour concludes by suggesting that an "econometric model can be used to increase the accuracy of futures markets." How he obtained that implication from our study is a mystery. Our model is not designed to improve forward pricing on the futures market, and the statement only punctuates Pasour's misinterpretation of LH and the role the model played. He follows the above statement by saying, when referring to the trading capability of our model, that "the proof of the pudding is in the eating." Although not the designated purpose of our model, given the simulated trading results noted above, we offer the bowl of pudding to Pasour virtually free of charge and wish him "bon appétit."

after the sow-farrowing reports are released, an average return of 125% of the initial margin deposit after commissions over four-month holding periods could have been generated. If the decisions were made relative to the sow-farrowing intentions report, investment returns of 141% over seven-month periods were possible. This even assumes that on bad trades, additional margin money was deposited until the contract matured. Hence, the marginal benefits are substantial, and if anything on the conservative side because bad trades were held. Although costs will vary for traders, the benefit/cost ratio will certainly be positive for most.

Thus, Pasour's statement: "Use of a norm which fails to take account of [benefits and costs] is almost certain to lead to an incorrect assessment of the efficiency of real world economic activity" is interesting. He offers no proof, but as demonstrated here, the "incorrectness" may be an underestimation of the inefficiency involved if the benefits far exceed the costs for more information. The bias can go both ways.

These returns are probably "in excess of returns justified by risk" (Panton), although not formally tested. Panton's sole criterion for rejecting the EMH is for our pricing model to "systematically identify opportunities for excess returns." This suggests one procedure among several for judging market efficiency. Intuitively, the above results justify EMH rejection based on Panton's criterion, and serve to strengthen our original conclusions.

Finally, Pasour states we found in our study that "more or better informed traders could improve the forward-pricing accuracy of the futures market." As noted below, Pasour takes statements out of context and misinterprets. We found the market to be inefficient and suggest a possible resolution to this might be more or better informed traders. That, of course, depends upon costs and benefits.

In actuality, our study, like most empirical studies, is a partial analysis. We design a framework and test if the market appears to be using all the information available to it. Market inefficiency can occur for many reasons, and costly information (uninformed traders) is just one of them. Other causes for inefficiency in markets which can be examined include: (*a*) irrational traders, (*b*) wealth limitations, (*c*) risk aversion, (*d*) misinterpretation of information, (*e*) transaction costs, and (*f*) imperfect capital markets (Rausser and Just). A comprehensive theoretical framework for examining all these possibilities has not yet been developed.

Criteria for Market Efficiency

Pasour and Panton raise concern with how to evaluate market efficiency and the EMH. Pasour's only concern is the benefit/cost ratio, and Panton states that our model has no theoretical basis. We argue that our basic criterion is valid. As Fama states, an efficient market is one "in which prices provide accurate signals for resource allocation"; that is, where people can make decisions "under the assumption that . . . prices at anytime 'fully reflect' all available information" (p. 383). Just the existence of a market does not guarantee its efficiency. We established clearly when reviewing previous research in LH that futures prices are in fact used as signals when allocating resources, and the issue then is whether the prices are reliable.

Our model is a test of the expectations hypothesis that futures prices provide unbiased estimates of the market's expectation of future spot prices. Formally, the price expectations hypothesis can be represented as

$$(1) \qquad {}_{t+j}FP_t = E_t({}_{t+j}CP),$$

or the current period's futures price for a contract maturing in $t+j$ is the current expectation of the subsequent spot price in $t+j$. Under the assumptions of an EMH, the investors use all available information in forming expectations. It follows that

$$(2) \qquad E_{t+i}\,({}_{t+j}CP) - E_t\,({}_{t+j}CP) = u_{t,i},$$

where $u_{t,i}$ is a random number reflecting information regarding future spot price ${}_{t+j}CP$ available in $t+1$ but not available at time t. For $i = j$, the above equation reduces to

$$(3) \qquad {}_{t+j}CP - E_t\,({}_{t+j}CP) = u_{t,j}.$$

Substituting (1) into (3) yields

$$(4) \qquad {}_{t+j}CP - {}_{t+j}FP_t = u_{t,j}.$$

The expectations hypothesis and efficient market model imply that the difference between the futures price in t and the spot price that evolves at $t + j$ is a random number, representing the receipt of new information.

It is an empirical question if the hypothesis holds, and we test it with a model where expectations incorporate all publicly available information and prices reflect these expectations. Obviously, inaccuracies of market expectations will occur because not all future information is known. New information comes forth every day. Perfect expectations are unreasonable because of uncertain outcomes. This is referred to as "necessary inaccuracies" of market expectations. What we attempt to identify is any excess imperfection over this minimum, or "objectionable inaccuracies." These can be ascertained by determining if futures price changes are predictable, which we demonstrate clearly that they are with the likely benefit/cost ratio being positive.

This approach is well-grounded in theory, and does not condemn all inaccuracies in forward pricing, but only those in excess of the imperfections necessitated by lack of future information. Testing whether the market utilizes current information is an appropriate norm and is a meaningful point of departure. The expectations reflected by our model

A Semi-Strong Form Evaluation of the Efficiency of the Hog Futures Market: Reply

Raymond M. Leuthold and Peter A. Hartmann

Pasour and Panton question the procedures, results, and implications of our study (LH) of the forward-pricing ability of the hog futures market. Pasour contends "the finding of inefficiency on the part of live-hog futures traders is not warranted because [the model] does not take into account the costs and benefits of additional information to individual traders." Panton argues the efficient market hypothesis (EMH) does not suggest that "futures prices in an efficient market can be relied upon to reflect subsequent spot prices accurately." In our reply, we will discuss the benefit/cost issue, the criteria for testing market efficiency and the EMH, and the use of our model as a norm.

Cost and Benefits

Specific costs and benefits for acquiring additional information are not included explicitly in our model. We will examine each of them here to ascertain the seriousness of the omission and, thereby, the reliability of our tests. Both the costs and benefits are most likely perceived rather than carefully calculated, and they, especially costs, will differ for new or potential traders as opposed to existing traders.[1] The costs for acquiring information to trade successfully for a new trader can be substantial if the trader is going to make decisions without outside advice. The level of costs depends upon the initial base of knowledge. It is well rumored that in the futures markets a high proportion of the traders trade once or twice, lose some money, and never trade again. Certainly to them, the perceived costs exceed the perceived benefits, but it would be hard to argue that such traders operating on their own have a large impact on the forward-pricing ability of a market.

Alternatively, the inexperienced trader can turn investment money over to a commodity fund or follow the strict advice of an account executive, and the cost of additional information to this individual may approximate the cost of commissions. The burden for acquiring information and retaining the customer through successful trades lies with the brokerage house. It is here that we want to concentrate our attention. The people who have the greatest influence on price information are brokerage houses, consulting firms, commodity clubs, professional speculators, active public speculators, and commercial firms, either directly or indirectly. Although we discussed in LH alternatives for potentially improving forward-pricing efficiency, it is the above listed traders who must be evaluated *ex post* on their utilization of available information.

In building our econometric model, we deliberately kept it from being complex by utilizing just one supply equation and one demand equation. We incorporated only five economic variables, hog slaughter, sow farrowings, hog/corn price ratio, income, and the price of hogs, data which are readily available in free government publications. It is difficult to imagine any existing trader in the market with even modest experience not examining all or some of these variables before making a decision. The cost of acquiring them is extremely low. The real cost may come in assimilating the information in such a manner to obtain appropriate implications. Nevertheless, the marginal costs for additional information for existing traders in futures markets are low. With our model, it is not even necessary to gather information to "anticipate" government releases. However, the level of additional costs is important only relative to the marginal benefits.[2]

There are many potential benefits from acquiring more information relative to futures markets, but we will concentrate on just one, speculative profits. In LH we state, ". . . using the econometric model to indicate the direction of futures market price changes, and utilizing the naive trading strategy of buy-and-hold if the predicted price exceeds the futures price (if opposite, sell-and-hold), substantial trading profits could have been generated between 1971 and 1978 in the hog futures market" (p. 487). We did not consider the details sufficiently relevant to incorporate in the original paper, but they need reporting here. In fact, we now have additional results through 1979, giving us sixty-two different contracts for investment simulation. Using the above naive strategy and making trading decisions

[1] Pasour quotes Stigler on this latter point.

[2] It is not clear whether Pasour includes relative risks in his benefit/cost model.

A Semi-Strong Form Evaluation of the Efficiency of the Hog Futures Market: Comment

Don B. Panton

In a recent issue of this *Journal* (August 1979) Leuthold and Hartmann (LH) offered a methodology which was directed at evaluating the semi-strong form efficiency of the hog futures market. The authors employed an econometric model to forecast cash hog prices at contract maturity. Because the econometric model was observed to have greater forecasting merit than did the respective futures prices, the authors concluded that the hog futures market is semi-strong inefficient.

As LH observe, an efficient market has been defined by Fama as one in which prices fully reflect all available information. For any test of the efficient markets hypothesis (EMH) to be operational, one must identify relevant explanatory variables and the specific nature of the linking relation. Thus, any test of the EMH is, at the same time, a test of the postulated model. The LH model has little, if any, basis in theory; therefore, the model itself would be a prime suspect in any test of market efficiency.

LH state, "The hog futures prices cannot consistently be relied upon to reflect accurately subsequent spot prices, and thereby the market is not considered efficient." LH have destroyed a straw man; the EMH does not say, imply, or hint that futures prices in an efficient market can be relied upon to reflect subsequent cash prices accurately. Instead, the EMH does state that known information is impounded in current price, so that all desirable characteristics of the investment (usually expected return) are in equilibrium with all undesirable characteristics of the investment (usually covariance of return with that of the market portfolio).

Unless returns resulting from the use of a pricing model like that of LH are found to be in excess of returns justified by risk, the EMH cannot reasonably be rejected. Thus, for an appropriate test of market efficiency, it would be necessary to determine whether returns received from trading based on the econometric model exceed normal returns adjusted for risk. As Rendleman and Carabini (p. 913) state, "To determine the extent of the (Treasury Bill Futures) market, it is necessary to assess the significance of the quasi-arbitrage returns that could have been earned." If risk cannot be shown to vanish through arbitrage or diversification activities, one must compare realized returns to normal returns appropriately adjusted via a general equilibrium model. LH have not shown that their pricing model systematically identifies opportunities for excess returns; therefore, no justification exists for their statement: "We find that on occasion the econometric model provides more accurate forecasts of subsequent prices than does the futures market, implying that objectionable inaccuracies exist in the futures market. This means that the live-hog futures market is not performing efficiently. . . ."

Granted, a researcher may be dissatisfied with the applicability of currently available equilibrium models (e.g., the capital asset-pricing model) to futures trading. The point is, however, that the onus is upon the researcher to provide such a model if he proposes to determine whether a financial market is operating efficiently. An equilibrium model is a prerequisite to any empirical study of the EMH and risky markets.

Conclusions

Finally, and closely related, econometric models need not be viewed as an alternative to the futures market but rather (as the authors suggest) as a way to increase the forward-pricing accuracy of the futures market. LH find that for some time periods their econometric model provides more accurate forecasts of subsequent prices than does the futures market and on this basis conclude that the hog futures market is not efficient. In order to prove market inefficiency in the LH approach, it is necessary to find only one case in which some other model predicts better. Hence, to prove the inefficiency of the LH model, one presumably would need to find only one case where the futures market (or another econometric model) provides more accurate forecasts. It appears, therefore, that the econometric model developed by LH does not meet the efficiency criterion by which they judge the live-hog futures market, i.e., it does not "consistently and accurately" reflect subsequent spot prices. Much work remains to be done on this problem of market efficiency, but when it is realized that neither real world markets nor econometric models can consistently and accurately predict the future, no work is required to reject the criterion that an efficient futures market must accurately and consistently reflect subsequent cash prices.

The conclusion that better informed traders could improve the forward pricing accuracy of the futures market is unassailable and, if information were not scarce, it presumably would not be difficult to identify inefficient trading activities. Under real world conditions of uncertainty, however, an economically meaningful criterion of an efficient trader (or an efficient market) appears to be one with an "appropriate amount" of information and meaningful tests of efficiency are much more difficult. The Alchian "survival criterion" would seem to be the most appropriate test of whether any econometric model can be used to increase the accuracy of futures markets. In the futures market as well as the kitchen, "the proof of the pudding is in the eating."

trader. Expected benefits of acquiring knowledge about the futures market, for example, likely would be much different for a farmer nearing retirement (or planning to change careers) than for a farmer who anticipates that he will produce hogs for another twenty-five years. This suggests that it is economic for traders (and other decision makers) to devote different amounts of time (and effort) in acquiring knowledge (Stigler 1976, p. 215). Whether it is rational for a particular trader to acquire additional information hinges on a comparison of the expected benefits and costs.

Traders cannot rationally be expected to base their decisions on all publicly available information. As Stigler (1967 p. 291) states, "information costs are the costs of transportation from ignorance to omniscience and seldom can a trader afford to take the entire trip." It does not follow then that the level of knowledge held by current traders is inefficient unless the expected benefits of additional information exceed the costs. The identification and measurement of entrepreneurial inefficiency requires information concerning both the trader's knowledge and the optimal amount of knowledge that the decision maker should possess. The problem of identifying inefficiency on the part of market traders does not appear to be alleviated by defining an efficient market in terms of "necessary inaccuracy."[4] While imperfect knowledge is indeed a necessary fact of life, the amount of knowledge acquired by any trader, as suggested above, will hinge on the costs and benefits as he perceives them to be. The failure of market participants to become better informed suggests that the expected costs exceed the benefits.

A problem arises in identifying inefficient trading behavior under real world conditions because of the inability to define meaningfully the "optimal" situation in a world of uncertainty, imperfect knowledge, and costly information. Economic efficiency inevitably involves valuation by the decision maker. A situation would appear to be efficient when the entrepreneur has no preferred alternative, given the circumstances (Pasour and Bullock). Thus, to identify and measure inefficiency, the defined efficiency goal must correspond to that of the decision maker and it must account for uncertainty, costly information, and other aspects of the operating environment in which decisions are made.[5] Use of a norm which fails to take account of this environment is almost certain to lead to an incorrect assessment of the efficiency of real world economic activity.

Second, the fact that there is generally a difference between hog futures prices and subsequent spot prices does not imply market inefficiency.[6] Speculative error does not imply "objectionable inaccuracy." That is, the fact that futures market traders are sometimes "poor speculators" cannot appropriately be taken as an indication of inefficiency but suggests only that decision makers would make "better choices" if imperfect knowledge were not a fact of life. Because imperfect knowledge and uncertainty are facts of life and cannot be reduced at zero cost, then a truly efficient futures market appears to be different from the ideal norm assumed by LH, *viz,* that futures prices must consistently and accurately reflect subsequent spot prices. In dealing with the future, ignorance is unavoidable although an investment in knowledge can reduce its effects. However, even if it were possible to eliminate all the effects of ignorance, it would be uneconomic to do so.[7] Thus, the marginal rule applies to information just as it does to all other scarce resources. The profit-maximizing decision maker will attempt to acquire additional information only as long as the expected benefits exceed the costs.

If consistently accurate prediction of future price is the norm by which efficiency is judged, no market or econometric model will be efficient in a world characterized by change and uncertainty. This view of public policy, which represents the relevant choice as between an ideal norm and an existing imperfect institutional arrangement, has been characterized by Demsetz as the nirvana approach. In this approach, "those who adopt the nirvana viewpoint seek to discover discrepancies between the ideal and the real and, if discrepancies are found, they deduce that the real is inefficient" (Demsetz, p. 1).

The conclusion that the futures market is inefficient implies that an attainable alternative is better able to cope with price uncertainty. But, as the nirvana approach suggests, all institutional arrangements are imperfect when measured against an idealized norm. Whether the current hog futures market is inefficient hinges on whether there is an alternative institutional arrangement better able to cope with future price uncertainty. Moreover, any such alternative which improves the accuracy of forecasts represents an increase in efficiency only if the benefits exceed the costs.

---

[4] "An efficient market contains only necessary inaccuracy; price changes are due to new information. Any error beyond that is objectionable inaccuracy often termed as speculative error, and likely results from bad judgment of traders or from noncompetitive market situations" (Leuthold and Hartmann, p. 483).

[5] Alchian proposes firm survival as a criterion for evaluating entrepreneurial success. This approach avoids the problem of attempts to measure costs and returns which motivate entrepreneurial choice.

[6] "The hog futures price cannot consistently be relied upon to reflect accurately subsequent spot prices, and thereby the market is not considered efficient" (Leuthold and Hartmann, p. 488). If the econometric model is accepted as the performance norm, what does one conclude about the level of trader information for those time periods when the futures market provides a more accurate forecast than the econometric model? Do traders have too much information during these periods?

[7] "Ignorance is like subzero weather: by a sufficient expenditure its effects upon people can be kept within tolerable or even comfortable bounds, but it would be wholly uneconomic entirely to eliminate all its effects" (Stigler 1961, p. 224).

A Semi-Strong Form Evaluation of the Efficiency of the Hog Futures Market: Comment

E. C. Pasour, Jr.

In a recent study, Leuthold and Hartmann (hereafter LH) conclude that the live-hog futures market is not efficient. It is the purpose of this note to show that the findings of the LH study do not imply that the hog futures market is inefficient in an economically meaningful sense. The primary issue concerns the definition of efficiency. Although the "efficient market" criterion of the finance literature is the stated performance criterion in the LH study, the following analysis is directed specifically toward the alleged inefficiency of the hog futures market as identified by LH.[1] The major thrust of this comment is that the finding of inefficiency on the part of live-hog futures traders is not warranted because it does not take into account the costs and benefits of additional information to individual traders.

The comment is organized as follows. First, the criterion of market efficiency, procedure, and inefficiency findings of the LH study are briefly summarized. Second, the conclusion of the LH study that market traders have too little information in some years is challenged because the approach used does not consider the costs and benefits of information from the standpoint of individual traders. Third, the significance of the development of an econometric model with superior predictive power is briefly explored.

Approach of LH Study

Market efficiency in the LH study hinges on the extent to which the market utilizes all publicly available information.[2] The basic procedure and conclusions of the LH study are described in the following passage:

> An econometric model designed to forecast hog prices reflecting available public information is developed to act as the norm against which futures prices can be compared. Using alternative methods of evaluation, we find that on occasion the econometric model provides more accurate forecasts of subsequent prices than does the futures market, implying that objectionable inaccuracies exist in the futures market. This means that the live-hog futures market is not performing efficiently, presumably because of the markets inability to reflect fully all information. (p. 483)

In any time period when the econometric model provides a more accurate forecast, the futures market is assumed not to reflect fully available information and is held to be inefficient.[3] The study finds that traders have too little information in some years and that "more or better informed traders could improve the forward pricing accuracy of the futures market" (p. 487). Consequently, "educational programs designed to inform producers of the market's benefits" might be justified to "encourage a well-informed group of traders into the market" (p. 488).

The following section demonstrates the problems in identifying inefficient entrepreneurial behavior on the part of market traders when uncertainty and information costs are taken into account.

Efficiency and Information Costs

First, consider the problem of determining whether individual traders have too little information. Trading in the futures market requires an investment in knowledge. Whether traders would benefit from additional information hinges on the costs and benefits of such information. Moreover, the costs and returns of acquiring information vary from trader to

E. C. Pasour, Jr., is a professor of economics and business at North Carolina State University.

The author has benefitted from the comments of an anonymous *Journal* reviewer and from discussions with a number of colleagues in the Department of Economics and Business at North Carolina State University.

[1] No attempt in this paper is made to compare the "efficient market" approach of the LH study with that of related studies in the finance area. Hence, it is not clear to what extent the criticisms made here of the "efficient market" approach in the LH study apply generally to "efficient market" studies.

[2] "If prices reflect all publicly available information as it is released, the market is said to be semi-strong efficient" (Leuthold and Hartmann, p. 483). The semi-strong form test of the efficiency of the hog futures market in the LH study is purported to be the same as that used in the finance literature, i.e., semi-strong form tests of efficient market models are concerned with whether current prices "fully reflect" all "obviously publicly available information" such as stock splits, announcements of financial reports by firms, or new security issues (Fama, p. 404). In reality, it is doubtful that predictions from an econometric model based on publicly available information can also legitimately be considered "obviously publicly available."

[3] "Using an econometric forecasting model as a performance norm, the futures market by comparison has not at all times fully reflected the available information. This has allowed us to observe the presence of objectionable inaccuracies" (Leuthold and Hartmann, p. 488).

seller's sunk costs. The seller may be willing to accept a feeder sale price below that required to cover all sunk costs if he perceives that this price is the most buyers will be willing to pay. Alternatively, short-run seller reservation prices could more than cover total production costs in years of strong buyer demand.

$1.36 per hundredweight, but average 500-pound Choice feeder prices rose $0.10 per hundredweight more than average 600-pound Choice feeder prices. The coefficients of r suggest that rising corn prices not only diminish average Choice feeder prices but also decrease relative premiums on lightweight feeders. Every $1.00 per bushel increase in corn prices served to decrease overall average Choice feeder prices by $8.33 per hundredweight; at the same time, average 500-pound Choice feeder prices fell $1.11 per hundredweight more than average 600-pound Choice feeder prices. Coefficients of the Palmer soil moisture index and cattle inventory change may be interpreted similarly.

Coefficients of the sex dummy variables in each equation of table 3 (sex = 0 if a steer and 1 if a heifer) indicate that Choice heifers brought lower average prices than did Choice steers, and that dollar discounts on heavyweight over lightweight heifers were less than dollar discounts on heavyweight over lightweight steers. In 1977 dollars, Choice heifer prices averaged $46.55 per hundredweight and decreased an average $1.19 per hundredweight for every 100-pound increase in market weight. Choice steer prices averaged $54.68 per hundredweight and decreased an average $2.74 per hundredweight for every 100-pound weight increase.

A notable result was that interaction terms involving the sex variable and other explanatory variables were statistically significant in the model in which the dependent variable was average feeder price, but they were not significant in the model in which the dependent variable was the rate of feeder price change with respect to weight. Thus, corn price rises increase market price differentials between feeder steers and heifers at average weights; but they do not appear to affect the difference between steers and heifers in the rate at which market price changes with weight. In other words, buyers and sellers in the feeder markets analyzed behave as though expressions (ii) and (iv) in table 2 were negligible in magnitude.

Conclusions

The above results suggest that break-even analysis can be used successfully to clarify our understanding of market price differentials between different lots of feeder cattle. In general, the same variables that affect feeder price levels themselves also affect the price differentials observed between different classes of feeder cattle. Expected slaughter cattle prices, feed prices, soil moisture conditions, and rates of cattle inventory changes affect both average feeder prices and the rates at which feeder prices change with weight, although the directions of effect are opposite in sign.

The simulation-derived impacts of slaughter cattle and corn prices on feeder price-weight slopes agreed in sign with, but were considerably higher than, those estimated empirically. At a typical steer weight of 600 pounds, the simulated impact of an expected slaughter price increase on the rate at which buyer break-even feeder price changes with weight was three times that evidenced in the statistical results. One explanation for this discrepancy is that buyers are skeptical of the accuracy with which current slaughter cattle futures prices predict subsequent cash prices, and so react cautiously to changes in futures price levels.

Even in observed auction market transactions, buyer and seller profitability factors such as slaughter cattle price expectations have relatively stronger effects on feeder price-weight slopes than on average feeder prices. At sample mean variable values in table 3, a 1% rise in expected slaughter cattle price raises average feeder price by 1.36%, but it increases the premium on lightweight over heavyweight cattle (that is, the price-weight slope) by 2.62%. Similarly, a 1% increase in the corn price decreases average feeder prices by 0.4% but decreases premiums on lightweight over heavyweight cattle by 1.37%.

The estimated mean price-weight relationships, and impacts of buyer and seller profitability factors on these relationships, shown in table 3 represent linear approximations only and hence are strictly applicable only in the average weight ranges for steers and heifers (550–750 pounds and 450–600 pounds, respectively). Extension of the empirical analysis to nonlinear relationships can be approached by dividing the relationships into linear segments according to weight class, or by analyzing the second and higher derivatives of price-weight functions. Statistical results not reported in detail here did show that, among steers, market price-weight lines are generally convex from below, meaning that prices decrease at a decreasing rate as weight rises. Among heifers, market price-weight lines are usually slightly concave from below, if only because heifer prices often rise between the 300- and 400-pound weight levels before decreasing again. Only in some regression specifications slaughter cattle prices were found to affect significantly the curvature of feeder price-weight relationships. For example, increases in expected slaughter steer prices often were associated with increases in the rate at which feeder steer price-weight slopes diminish as weight rises.

A clear distinction should be made between the price-weight relationships observed at feeder cattle markets and the changes in per hundredweight price that occur when animals gain weight in the feedlot. High concentrate feeding may result in increasing an animal's grade as well as its weight, and price-weight trade-offs among slaughter cattle differ from those among feeder cattle.

Finally, it should be emphasized that break-even prices as defined here may not be used reliably to estimate short-run buyer or seller reservation prices. For example, in any particular sale period, weaned calf purchase value represents part of a

statistical analysis of actual feeder cattle markets. In long-run, perfectly competitive equilibrium, buyer and seller break-even price-weight relationships for a specific feeder type, and for a given time and place, are identical to one another and to market prices. Although due in part to the beef price-inventory cycle, this equilibrium is constantly shifting, and hence never achieved. Theoretically hypothesized signs should predominate if a sufficiently long time frame is observed. In order to provide statistical tests of the relationships developed above, twenty years of Virginia state-graded feeder cattle transaction data, involving 133,907 sale lots, were stratified by year, sex (steer and heifer), and season (spring and fall); and sale prices in each stratum were regressed against corresponding animal and market characteristics. The former characteristics included weight, breed, grade, and age; the latter included sales size, lot size, auction sale order, market location, and day. Interaction terms between weight and grade were used to isolate differences between feeder cattle grades in market price-weight relations. Weight variables themselves were employed alternately in linear and nonlinear form.

For each functional form fitted, this process generated eighty regression coefficients for each of the animal and market characteristics listed. For example, the eighty coefficients of the linear weight variables constituted a linear estimate for each year, sex, and season, of the marginal impact of feeder weight on feeder market price. These estimated linear price-weight slopes for Choice steers and heifers were then regressed against the revenue and cost factors hypothesized by the above conceptual model to affect them. Current live cattle futures prices (P) were used to represent buyers' expected slaughter prices and current Chicago No. 2 yellow corn prices (r) were used to represent feed price movements. The Palmer index of northern Virginia soil moisture conditions (PI) was included to represent changes in stocker grazing costs. Because the index varies directly with soil moisture, it should, with the exception of flood years, vary directly with pasture quality and inversely with grazing or hay costs.[4] Finally, annual rates of change in 1 January all-cattle inventories (ΔINV) were utilized to account for the effect of cattle inventory adjustments on feeder price formation.[5] Residual sex, season, and year effects also were tested, but only sex effects were statistically significant. All price and slope variables were inflated to a fall 1977 basis.

Results of the regression are shown in the Price-Weight Slope row of table 3. For purposes of comparison, average feeder steer and heifer prices in each year and season also are regressed against the above revenue and cost factors and the results given in the Average Price row of table 3. Taken together, these equations provide an estimate of the marginal impact of each revenue or cost factor on both average feeder price and the average rate of change of feeder price with respect to weight. For example, the coefficients for P indicate that rising slaughter steer prices not only increase average feeder prices but also increase relative premiums on lightweight feeders. For every \$1.00 per hundredweight increase in expected slaughter steer price, the overall average Choice feeder price rose

[4] Live cattle futures prices were, for spring observations on the dependent variable, mid-April quotes of October 1050–1200-pound Choice steer contracts and, for fall observations, mid-October quotes of April 1050–1200-pound Choice steer contracts (Chicago Mercantile Exchange). For years prior to the inception of a cattle futures market (1967), spring average and fall average cash prices of 900–1100-pound Choice Omaha slaughter steers were utilized instead. Corn prices used were, for spring observations, unweighted March-April-May averages of Chicago No. 2 yellow cash prices and, for fall observations, unweighted September-October-November averages (USDA). Palmer index data were taken from Smith.

[5] It is expected that rising cattle inventories are associated with more negative or less positive price-weight slopes since light calf prices are bid up relative to heavy stockers in the anticipation of higher prices for both feeder sexes. ΔINV is $INV_t - INV_{t-1}$, where t refers to the 1 January inventory following the time period of regression; this provides the best estimate we have of inventory changes the preceding year.

Table 3. Determinants of Feeder Cattle Price-Weight Slopes and of Average Feeder Cattle Prices, Virginia State-Graded Auction Sales, 1958–77.

	P	r	PI	ΔINV	SEX	$INTERCEPT$

[a] Marginal rate at which price changes, in $/cwt per 100-lb. weight increase, as evaluated at each weight shown.
[b] Marginal rate of increase in the price-weight slope, in $/cwt per 100-lb. weight increase, caused by a .10¢/Mcal. *ME* increase in feed price *r* or *s*. (If corn were the entire ration, a .10¢/Mcal. *ME* price rise would result from a 9.4¢/bu. increase in the corn price.)

over heavyweight cattle.[2] Interestingly, weight-by-weight comparison of steer and heifer values in the buyer's portion of column (4) suggests that feed price rises serve to increase algebraically a steer's break-even price-weight slope more than they do a heifer's. Because, in years in which buyers' break-even feeder prices decline with weight, break-even steer prices normally decline much more rapidly than they do for heifers, the implication is that increasing feed prices should serve to diminish the difference between steers and heifers in the rate at which price declines with added weight.[3]

Empirical Analysis

Simulations such as these not only may provide pricing guidance to individual firm operators, but also may represent a source of hypotheses for

[2] Entries in the seller portion of column (4), table 2, are positively biased because reliable estimates of the effect of grazing costs on weaned calf prices, $p^*_s(s, D)$, were not obtained.

[3] Despite this, there is good theoretical reason and statistical evidence that increasing feed prices tend to increase premiums of steer prices over heifer prices at any given weight (Buccola and Jessee).

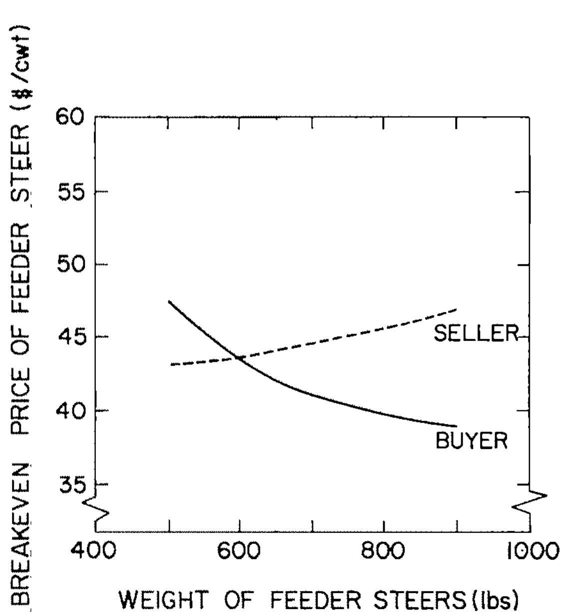

Figure 1. Simulated break-even price-weight lines for feeder steers, buyer and seller, 1977

Table 1. Impact of Feed Prices and Feeder Cattle Characteristics on Rate At Which Break-Even Feeder Prices Change with Weight

	(a) Impact of Feed Price Change on Break-Even Feeder Price-Weight Slope[a]	(b) Effect of Feeder Characteristics on Relationship in Column (a)
Buyer	(i) $f(w,D\|GF,W)W/w^2 - f_w(w,D\|GF,W)\ (W/w - \ )$	(ii) $f_d(w,D\|GF,W)W/w^2 - f_{w,d}(w,D\|GF,W)\ (W/w - 1)$
Seller	(iii) $-p^*_s(s,D)w^*/w^2 + i(w,D\|GP,w^*)w^*/w^2 + i_w(w,D\|w^*)\ (1-w^*/w)$	(iv) $-p^*_{s,d}(s,D)w^*/w^2 + i_d(w,D\|GP,w^*)w^*/w^2 + i_{w,d}(w,D\|GP,w^*)\ (1 - w^*/w)$

[a] In the notation employed in this table, $f_d(w,D|GF,W)$ represents the difference between two classes of animals in average feed efficiency, given a constant purchase weight. Term $f_{w,d}(w,D|GF,W)$ represents the difference between the two classes of animals in the rate of average feed efficiency loss as purchase weight rises. Terms $i_d(w,D|GP,w^*)$ and $i_{w,d}$ $(w,D|GP,w^*)$ are defined in a parallel way for grazing efficiency. Other notation is as defined and used previously.

values, leave indeterminate whether rising feed prices increase or decrease the difference between these two classes of cattle in the rate at which break-even prices change with purchase weight.

Simulation of Price Differentials

Thus, signs and magnitudes of expressions (3), (4), and the terms in table 1 require an understanding of the feed conversion functions f, i; daily-basis nonfeed cost functions g, j; per-head-basis nonfeed costs $h(D)$, $k(D)$; slaughter and weaning weights W, w^*; weaned calf price p^* and expected slaughter-weight prices P; daily gains GF and GP; and feed prices r and s. To gain better insight into these relationships and their changes over time, a hypothetical buyer's and hypothetical seller's break-even feeder prices were simulated at selected weights and, for both steers and heifers, for each fall sale during the period 1968–77.

Parameters, feed requirement functions, and cost functions employed in the simulation corresponded to a Virginia stocker operator and Corn Belt feedlot operator. Estimates of feed efficiency functions f and i were derived from National Research Council data (National Academy of Sciences, pp. 22–25). In these estimates, the following were assumed: GF = 2.4 pounds per day (steers) and 2.0 pounds per day (heifers); GP = 1.0 pounds per day (steers) and 0.8 pounds per day (heifers); W = 1,050 pounds (steers) and 840 pounds (heifers), both Low Choice; w^* = 450 pounds (steers) and 400 pounds (heifers). Daily-basis nonfeed feedlot cost function g (machinery, labor, death loss, depreciation, interest) and per-head-basis feedlot cost $h(D)$ (hauling and marketing, veterinary) were adapted from Crickenberger and Black (1976, pp. 57–71). The feed ration employed consisted of 53% corn silage, 44% cracked corn, and 3% soybean meal, ME basis. Feed and slaughter cattle price expectations were represented by August through October price averages (USDA).

In eight of the ten years simulated, the feeder buyer's break-even purchase prices for both steers and heifers declined with increases in purchase weight; that is, equation (3) was negative. The two fall seasons for which break-even prices increased with weight (1974 and 1976) were the only falls in which slaughter cattle/corn price ratios fell below 17.0; this had the effect of diminishing the negative first term in (3) relative to the positive second term. Third and subsequent terms in (3) were less important, though not negligible, in magnitude.

On the seller side, break-even steer prices declined with weight during every year except 1976 and 1977, implying that the first and last terms in (4) were normally greater in absolute value than all other terms combined. For heifers, however, break-even sale prices increased with weight in four of the ten years studied and were nearly invariant with respect to weight in two additional years. The tendency of heifer break-even sale prices to increase with weight owes partly to the greater grazing nutrient requirements per pound gain in heifers than in steers, and hence the greater relative importance to heifers of the second term in (4). Third and subsequent terms in (4) were less important in magnitude.

Simulation results for the year 1977 are shown in table 2. The buyer's and seller's break-even feeder steer price-weight relations for 1977 are illustrated in figure 1. Column (4) of table 2 provides data for evaluating the expressions in table 1 which, lacking feed price or feed cost coefficients, are invariant from year to year. Simulated values of expression (i), table 1, are given in the buyer portion of column (4), and simulated values of expression (iii) are given in the seller portion of column (4). Simulated values of expressions (ii) and (iv) are evaluated for the sex characteristic by subtracting steer entries from heifer entries at constant weights, for example by subtracting .292 from .351 at the 500-pound market weight level.

The fact that all entries in column (4) of table 2 are positive signifies that increasing feed prices should diminish the relative premiums that buyers would offer, and sellers demand, for lightweight

hand side of (1), then, consists, respectively, of expected per-head slaughter animal revenue, feed cost, daily-basis nonfeed cost, per-head-basis nonfeed cost, and feeder animal cost.

Similarly, consider a farmer who sells a feeder animal which he has purchased (from himself or another) as a weaned calf and grazed for a variable period. Defining w^* as the weight of calf at weaning, in hundredweight; s as price or value of pasture or hay nutrients, in \$/Mcal ME; GP as average daily gain on pasture, in hundredweight per day; $i(w,D|GP,w^*)$ as average efficiency of grass/gain conversion, in Mcal/cwt gain; $j(w,D|w^*)$ as average daily-basis nonpasture cost of animal maintenance on farm, in dollars per day; $k(D)$ as per head cost of animal maintenance on farm, in dollars; and $p^*(s,D)$ as price of calf at weaning, in dollars per hundredweight, the per head profits (π_s) faced by the feeder cattle seller are

(2)
$$\pi_s = pw - p^*(s,D)w^* - s(w - w^*)i(w,D|GP,w^*) - (w - w^*)[j(w,D|w^*)/GP] - k(D).$$

The right-hand side of (2) consists respectively of per-head feeder animal revenue, weaned calf cost, pasture cost, daily-basis nonpasture cost, and per-head-basis nonpasture cost.

The buyer's and seller's break-even prices for a lot of feeder cattle are found by setting (1) and (2) equal to zero and solving each for per hundredweight feeder price p. The impact of a marginal change in feeder sale weight, for example, on these break-even prices can then be determined by differentiating the resulting equations with respect to w. Defining the buyer's break-even price for a particular sale lot as p^b and the seller's break-even price for this lot as p^s, and denoting first derivatives with respect to weight by w subscripts, the impacts are

(3)
$$\begin{aligned} dp^b/dw = {} & -P(W,D)W/w^2 + rf(w,D|GF,W)W/w^2 \\ & - rf_w(w,D|GF,W)(W/w - 1) \\ & + [g(w,D|W)/GF]W/w^2 \\ & - [g_w(w,D|W)/GF](W/w - 1) \\ & + h(D)/w^2, \end{aligned}$$

(4)
$$\begin{aligned} dp^s/dw = {} & -p^*(s,D)w^*/w^2 + si(w,D|GP,w^*)w^*/w^2 \\ & + si_w(w,D|GP,w^*)(1 - w^*/w) \\ & + [j(w,D|w^*)/GP]w^*/w^2 \\ & + [j_w(w,D|w^*)/GP](1 - w^*/w) \\ & - k(D)/w^2. \end{aligned}$$

In equation (3), one may assume that slopes $f_w(w,D|GF,W)$ and $g_w(w,D|W)$, respectively representing marginal losses in average feed efficiency and marginal increases in average daily nonfeed costs as feeder sale weight rises, are positive (National Academy of Sciences). Hence, the first right-hand-side term in (3) is negative and the rest alternate in sign; the net sign and value of the entire expression depend upon the relative absolute values of these terms. The sign of equation (4) is similarly indeterminate: the first and last right-hand-side terms are negative, but the others are nonnegative since $i_w(w,D|GP,w^*)$, like $f_w(w,D|GF,W)$, is positive, and $j_w(w,D|w^*)$ is probably close to zero.

Expected slaughter cattle prices and current feed and pasture costs are the principal factors affecting the rate at which a buyer's or seller's per hundredweight break-even prices rise or fall with feeder animal sale weight. The degree to which slaughter cattle or feed prices affect this rate depends in turn on the characteristics of the feeder animal considered: its grade, breed, sex, frame size, and age. This may be seen by first differentiating equations (3) and (4) with respect to per hundredweight slaughter cattle price P and feed or pasture nutrient prices r or s, then differentiating the resulting equations with respect to feeder animal description D. Slaughter cattle prices apply, of course, only to the buyer's profit function (3). The derivative of (3) with respect to P, that is W/w^2, is negative, meaning that rising slaughter cattle price expectations cause buyers to bid up per hundredweight prices of lightweight feeders relative to heavyweight feeders. Derivatives of (3) and (4) with respect to feed prices present a more complex picture and are shown in table 1.

Expression (i) in table 1 represents the effect of a unit change in feed price on the buyer's price-weight slope, the rate at which the buyer's break-even feeder price changes with feeder purchase weight. Expression (ii) simply shows the difference we expect in this effect between two animals with distinct sex, grade, or other characteristics. Expressions (iii) and (iv) are defined similarly for the seller of feeder calves. Like the price-weight slopes in equations (3) and (4), each of the expressions in table 1 is indeterminate in sign without information on the feed efficiency functions $f(w,D|GF,W)$ and $i(w,D|GP,w^*)$ and without knowledge of the rate at which weaned calf prices vary with grazing costs.

For example, the first term in expression (i), reflecting the average quantity of feed required per pound gain (weighted by W/w^2), is positive whereas the second term, reflecting the rate at which average feed quantity per pound gain rises with feeder purchase weight (weighted by $[W/w]-1$), is negative. Hence, rising feed prices increase the algebraic value of the buyer's price-weight slope; that is, they decrease the buyer's willingness to offer premiums on lightweight over heavyweight feeders only if the first term is greater in absolute value than the second. To interpret expression (ii) in table 1, let $D = 0$ when describing the more feed-efficient of two classes of feeder cattle, and $D = 1$ when describing the less feed-efficient. For the likely case in which less feed-efficient cattle also lose efficiency more rapidly under weight gain, the first term in expression (ii) is positive and the second negative. This would, in the absence of specific coefficient

However, these functional dependencies are taken into account in the model evaluations in the following section.

An Approach to the Analysis of Feeder Cattle Price Differentials

Steven T. Buccola

One of the difficulties faced by agricultural economic price analysts is the great variety of subclasses identifiable within commodity categories. Beef cattle price analysts face a particularly difficult problem in this regard. In addition to spatial, temporal, grade, and variety distinctions inherent in most agricultural commodities, cattle markets often discriminate sharply on the basis of weight, age, and sex. Most feeder cattle demand, supply, or price studies focus on a representative steer or heifer defined by an explicit set of characteristics that remains invariant across the data set (Maki). Readers are left to draw inferences for other sets of characteristics. Considerable attention has been devoted to identifying the causes of price differentials observed among lots of feeder cattle sold in a given trading period. But in these studies, readers are left to draw inferences as to how the differentials would change under alternative supply and demand conditions (James and Farris). The intention of the present paper is to provide a general model of break-even feeder cattle prices faced by feeder buyers and sellers, and to utilize the model to investigate the influence of important supply and demand factors on feeder cattle price differentials. Emphasis is placed on price differences by weight and sex category.

Conceptual Basis of Price Differentials

In the United States, prices paid for feeder cattle are established by competitive buyer bidding on successive lots of animals. If prospective buyers view profits as their success indicator, none will pay more for an animal, in the long run, than the difference between its expected sale value and its expected handling and feeding costs. Similarly, although sellers are passive agents in the auction process, few would accept less for an animal, in the long run, than its estimated total cost of production. Thus, break-even prices of buyer and seller define the long-run limits of price bidding. In turn, break-even prices differ according to animal characteristics; that is, according to weight, breed, grade, age, sex, frame size, or other description, because both expected slaughter cattle revenues and animal production costs vary according to these characteristics. Because expected slaughter cattle prices and feed and nonfeed resource prices affect expected feedlot or farm revenues and costs, they also may affect differences in prices realized for different lots of feeder cattle.

To allow more detailed development of this concept, consider a feedlot operator who buys a feeder animal and expects to feed it to slaughter weight and grade. Where W, w are weights of slaughter and marketed feeder animal, respectively, in hundredweight (cwt); r is the price of a prepared feed ration, in dollars per megacalorie ($/Mcal) of metabolizable energy (ME); GF is average daily gain under feed, in hundredweight per day; D is a discrete breed, grade, age, sex, and frame description; $f(w,D|GF,W)$ is average feed efficiency, in Mcal per hundredweight of gain; $g(w,D|W)$ is average daily-basis nonfeed cost of animal maintenance in feedlot, in dollars per day; $h(D)$ is per head cost of animal marketing, in dollars; $P(W,D)$ is slaughter cattle price, in dollars per hundredweight; and p is feeder cattle price, in dollars per hundredweight, expected per head profits (π_b) faced by the feeder cattle buyer are

$$(1) \quad \pi_b = P(W,D)W - r(W-w)f(w,D|GF,W) - (W-w)g(w,D|W)/GF - h(D) - pw.$$

Where appropriate, variables contained in parentheses for this and subsequent equations are assumed to be as function arguments. For example, slaughter cattle price P is a function of slaughter weight W and a set of discrete animal descriptions D. Feed efficiency function $f(w,D|GF,W)$ represents the average feed/gain ratio achieved when a feeder animal of description D is placed on feed at weight w, achieves average daily gain GF, and is sold at preassigned slaughter weight W and slaughter grade. A similar interpretation applies to daily-basis nonfeed cost function $g(w,D|W)$.[1] The right-

The author is an assistant professor, Department of Agricultural Economics, Virginia Polytechnic Institute and State University.

Helpful suggestions on earlier drafts of this paper have been made by Paul Hasbargen, Department of Agricultural and Applied Economics, University of Minnesota; by David Kenyon, Department of Agricultural Economics, Virginia Tech; and by three anonymous reviewers. Fiona Carmichael, now with the Esso Corporation, London, assisted with the computer programs used in the analysis.

[1] If all cattle represented in functions f and g achieve an identical slaughter grade, slaughter weight W must vary according to characteristic set D. Furthermore, feasible average daily gains on feed (GF) often also vary by characteristic. I here avoid the notational complication of expressing W and GF as functions of D.

has quadratic terms for all variables. This creates a large matrix, for which eigenvalues are needed—perhaps difficult in itself. Further, the approximation ends up with an LP larger in dimension than the Kuhn-Tucker system of the original problem. Thus, if suitable software is available, direct solution by quadratic programming may be better.[2]

Third, eigenvalue-vector programs are available on virtually any computer system that will do the calculations and identify problems in existence (Bellman). Partial diagonalization may be done over small parts of quadratic matrix when the eigenvalues do not exist or when only part of the variables exhibit off-diagonal terms.

Fourth, in the separable programming formulation, grid endpoints for the separable program can be set by approximating all variables with numerical endpoints ranging between plus and minus the square root of a maximum for the quadratic term divided by the eigenvalue. Trial solutions also may be used. The number of grid points depends upon available computer capacity and the magnitude of the eigenvalues.[3] Fifteen points seemed to be reasonable for the various experiments done by the authors. (Error was generally less than 3% in variables, shadow prices, slacks, and objective function prediction.)

Finally, the approximation is numerically sensitive and it appears desirable to use at least six significant digits for the eigenvectors. A slight allowance for error may also be desirable in the equation $\mathbf{X} - \mathbf{QZ} = 0$, when many variables are present (as in Tice, where $-10^{-5} \leq \mathbf{X} - \mathbf{QZ} \leq 10^{-5}$).

Concluding Comments

An exact transformation based upon eigenvalues is discussed above that provides a mechanism for transforming well-formed quadratic programs into separable programs which may then be approximated. The separable programs will have a concave objective in most practical problems and therefore may be solved by linear programming. Using these techniques, the authors have solved a number of problems and contend that the approximation works well, particularly for problems with a low proportion of quadratic variables.

[Received August 1979; revision accepted January 1980.]

[2] Further, in the case of E-V problems (where the authors feel that this case would arise most often), the Hazell approximation could be used.

[3] The larger (in absolute value) the eigenvalues, the more points needed for a good approximation.

$$(6)\qquad Q = \begin{pmatrix} \frac{1}{\sqrt{2}} & \frac{1}{\sqrt{2}} \\ \frac{1}{\sqrt{2}} & \frac{-1}{\sqrt{2}} \end{pmatrix}.$$

Then the problem becomes

$$\max\ (100\ 90)\begin{pmatrix} X_1 \\ X_2 \end{pmatrix} + (Z_1 Z_2)\begin{pmatrix} -.25 & 0 \\ 0 & -1.75 \end{pmatrix}\begin{pmatrix} Z_1 \\ Z_2 \end{pmatrix}$$

$$(7)\qquad X_1 + X_2 \le 100$$

$$X_1 - \frac{1}{\sqrt{2}} Z_1 - \frac{1}{\sqrt{2}} Z_2 = 0$$

$$X_2 - \frac{1}{\sqrt{2}} Z_1 + \frac{1}{\sqrt{2}} Z_2 = 0$$

$$X_1 \ge 0,\ X_2 \ge 0.$$

A grid of points may then be chosen for Z_1 and Z_2 via separable programming and the problem solved as a linear program.

Comparison with Alternative Approximations

The fundamental question regarding the above approximation is: So what—why should I use it? The approximation needs to be placed in context. Namely, its adequacy must be assessed versus other approximations. A complete comparison of possible approximations is beyond the scope of this paper. Rather, the only approximations addressed will be those developed in Thomas et al., and in Duloy and Norton (1975) and Hazell.

Thomas et al. presented an approximation procedure for the E-V problem, that could easily be applied to the general quadratic program above, which is an application of the separable transformation given in Hadley (p. 119). The approximation adds two new variables which then are separable and two constraints for each cross-product term. The Thomas et al. case clearly deals with the above QP problem in its full generality. General separable programming rather than linear programming is required because the cross-product terms can be either positive or negative.

Duloy and Norton (1975) also provide an approximation procedure that uses separable programming to approximate a quadratic problem. This procedure is most suitable for a diagonal quadratic matrix, although Duloy and Norton discuss how to handle substitution. The procedure, however, does not easily handle the general problem outlined above. Hazell provided the MOTAD approximation for the E-V problem. MOTAD uses the data directly, from which the variance-covariance matrix would normally be formed. MOTAD, in using this data, solves a problem related to, but different from, the E-V problem.

Fundamentally, the eigenvalue transformation is not an approximation; rather, it is an exact transformation. However, when the terms $Z'\Omega Z$ are computed via separable programming, then this scheme becomes an approximation. Implicit, therefore, in the above approximation descriptions are some of the answers to the question on why use this approximation. Specifically:

(*a*) The eigenvalue-based approximation is good for quadratic matrices which are not diagonal (or for nondiagonal parts of quadratic matrices). Diagonal parts can be handled more directly via separable programming (Miller) as in Duloy and Norton (1975).

(*b*) The eigenvalue-based approximation uses linear programming and adds one separable variable (which is approximated via a grid) and one constraint for each variable in the quadratic matrix. If there are many interactions, this would be a smaller problem than the Thomas et al. problem.

(*c*) The eigenvalue approximation solves the quadratic program directly and not a different problem, as in Hazell. This may be desirable if one wishes to maintain correspondence with a theoretical utility function as in Freund.

Further Comments

Relative to the approximation, let us make several further comments. First, a feature of quadratic programming is that when a variable with a quadratic objective term enters what ordinarily would be a linear program, then the whole problem has to be dealt with as a quadratic program. Normally, if one is not using decomposition, as in Polito, McCarl, and Morin, then one would apply a quadratic programming algorithm that would work on the Kuhn-Tucker conditions of the problem (as in Wolfe or Lemke). This leads to a larger system of equations and also requires the complementary conditions to be dealt with. Efficient software for large problems of this sort is not widely available. The approximation above then may be desirable for large problems that are to a great extent linear with a few quadratic variables. Such formulations occur repeatedly in the literature (see, for example, [*a*] spatial equilibrium problems in Takayama and Judge, Duloy and Norton (1975), and Plessner and Heady; and [*b*] the theoretically derived E-V problems in Cocks, Rae, and Tice). The approximation would work well in these cases as long as the quadratic matrix is symmetric and not diagonal. This, in fact, is the problem for which the approximation was developed (Tice) and where it would appear to be most desirable.

Second, as is implicit in the paragraph above, the approximation is not at its best for a problem which

Linearizing Quadratic Programs through Matrix Diagonalization

Bruce A. McCarl and Thomas F. Tice

Quadratic programming formulations are common in applied agricultural economics research. Important problems portraying behavior in the face of risk (e.g., E-V analysis as discussed in Anderson, Dillon, Hardaker) and market equilibrium (Takayama and Judge) have been formulated as quadratic programs. However, quadratic programming problems are more difficult to solve than linear programs and software is not generally available for large quadratic programs. Consequently, many approximations have been proposed (and in many practical applications have been substituted) for quadratic formulations (e.g., Duloy and Norton 1975; Hazell; Chen and Baker; Thomas, Blakeslee, Rogers, Whittlesey). The purpose of this paper is to introduce yet another approximation procedure for quadratic programs, briefly contrast this scheme with other common approximations, discuss its properties, and discuss the cases under which use of this approximation appears desirable. The approximation (developed and applied in Tice) is based upon matrix diagonalization.

Background and Approximation Development

For a symmetric matrix (**A**), where the eigenvalues and vectors exist, then pre- and post-multiplication of the original matrix (**A**) by matrices found from the matrix (**Q**) composed of the eigenvectors (as columns) results in a diagonal matrix with the eigenvalues on the diagonal, i.e.,

$$\mathbf{Q}'\mathbf{A}\mathbf{Q} = \Omega, \tag{1}$$

where **Q** is the matrix of the eigenvectors; **Q**′ is its transpose and Ω is a matrix with elements equal to the eigenvalues on the diagonal, zero elsewhere:

$$(\Omega)_{ii} = \lambda_i;\ \mathbf{Q}(\Omega)_{ij} = 0_{i \neq j}.$$

Using these results an approximation may be formulated. Given a quadratic program with linear (**Y**) and quadratic (**X**) components,

$$\begin{array}{lll} \text{maximize } \mathbf{CX} + \mathbf{X}'\mathbf{AX} + \mathbf{dY} & & \\ \mathbf{FX} & + \mathbf{GY} \leq \mathbf{b} & \\ \mathbf{X}, \mathbf{Y} & \geq \mathbf{0}, & \end{array} \tag{2}$$

where **A** is symmetric[1] and negative definite, introduce new variables so that

$$\mathbf{X} = \mathbf{QZ}, \tag{3}$$

where **Q** is the matrix of eigenvectors of **A**. Substituting for **X**, the quadratic term above becomes $\mathbf{Z}'\mathbf{Q}'\mathbf{AQZ}$ which is diagonal and equals **Z**. The quadratic program then becomes

$$\begin{array}{ll} \max & \mathbf{CX} + \mathbf{Z}'\,\Omega\,\mathbf{Z} + \mathbf{dY} \\ & \mathbf{FX} \qquad\qquad + \mathbf{GY} \leq \mathbf{b} \\ & \mathbf{X} - \mathbf{QZ} = 0 \\ & \mathbf{X}, \mathbf{Y} \geq \qquad \mathbf{Z} \gtrless \mathbf{0}, \end{array} \tag{4}$$

The term $\mathbf{Z}'\,\Omega\mathbf{Z}$, however, can be written as $\sum_{i=1}^{n} \mathbf{Z}_i^2\lambda_i$, which is separable and allows approximation via separable programming—grid linearization (Miller or as in Duloy and Norton). Further, the eigenvalues of a negative definite matrix are all negative; thus, if the original problem is well-formed, the term $\mathbf{Z}\,\Omega\,\mathbf{Z}$ is concave and, following Hadley, the separable problem may then be solved as a linear program (p. 124).

Example

Given the problem

$$\max\ (100\ 90)\begin{pmatrix} \mathbf{X}_1 \\ \mathbf{X}_2 \end{pmatrix} + (\mathbf{X}_1\mathbf{X}_2)\begin{pmatrix} -1 + & .75 \\ .75 & -1 \end{pmatrix}\begin{pmatrix} \mathbf{X}_1 \\ \mathbf{X}_2 \end{pmatrix}$$

$$\begin{array}{l} \mathbf{X}_1 + \mathbf{X}_2 \leq 100 \\ \mathbf{X}_1 \geq \mathbf{0};\ \mathbf{X}_2 \geq 0. \end{array} \tag{5}$$

The eigenvalues are $(-.25\ -\ 1.75)$ and the associated matrix of eigenvectors is

[1] **A** will ordinarily be symmetric in most applications as (*a*) **A** is symmetric for variance matrices in E-V formulations, or (*b*) **A** can be made symmetric simply by averaging the cross products. In supply-demand type problems, asymmetric matrices must be handled carefully as the discussion in McCarl and Spreen points out.

tween the two models. The chi-square statistics testing this hypothesis for both pairs of equations are given in table 3. These statistics are significant, indicating that in both models distinctly different forces affect the amount of the loan granted by lenders in the liberal group versus those in the conservative grouping.

Summary

The results of this experiment indicate that the surveyed lenders (as a group) were responsive, in terms of the amount of the loan approved, to the borrower's financial position (table 2). Further, these results suggested that the amount of land owned, even though that land was appreciating in value, was not necessarily a good indicator of nonreal estate credit capacity.

The loan responses were more intensively analyzed using an estimation technique which incorporates the doubly truncated nature of the dependent variable, the amount of loan received. The dependent variable has two points of truncation in that negative loans are not possible and the maximum amount of loan requested was $60,000. Preliminary analysis of these data suggested that the lenders tended to respond as two separate groups. A secondary purpose of the research then became to test if these two groupings of lenders responded differently to changes in the firm's financial structure.

Analysis of lender responses indicated that both lender groupings considered the borrower's net worth and income-generating potential as major determinants of credit-generating capacity. The two groups of lenders differed in their view as to the importance of short-term equity and the value of the farmer's leverage ratio. Lenders in the conservative grouping were very responsive to changes in short-term equity, whereas lenders in the liberal grouping were not responsive to changes in this variable. Lenders in both groupings responded to changes in the leverage ratio, but a given increase in that ratio would reduce credit availability by a much greater amount for conservative lenders than it would for lenders in the liberal grouping. These differential responses between the two lender groupings were found to be significant using a chi-square test.

	(−1.44)	(4.04)	(−.035)	(1.51)	
	$\chi^2_8 = 99.0$				

where:

STE is current assets less current liabilities (in thousands of dollars); LEV, debt/net worth; INC, income for past year (in thousands of dollars); EXP, experience of lender, in years; BUSS, percentage of institution's loans which are agricultural; and NW, net worth (in thousands of dollars).

Note: Numbers in parentheses are the ratio of the estimate to its standard error. The chi-square statistics test the hypothesis that the respective slope coefficients, intercepts, and standard errors are different for the paired relationships. Hence, the degrees of freedom in each test are the number of slope coefficients estimated plus two.

variations in financial structure. Therefore, a large-sample likelihood ratio statistic was used to test if all of the parameters in each pair of equations are identical. Because the impact of the independent variables on expected loan and probability of a loan is nonlinear, the intercept term and the variance of the disturbance term also are included under the null hypothesis of parameter equality be-

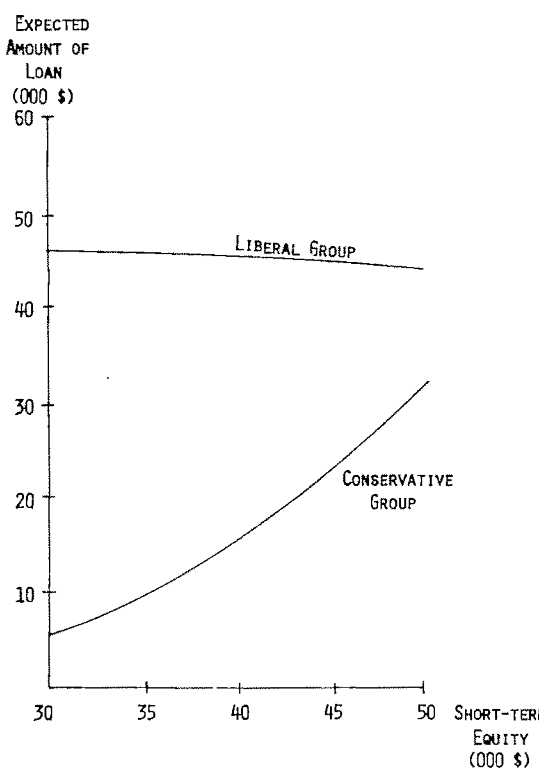

Figure 1. Effect of amount of short-term equity on expected amount of loan

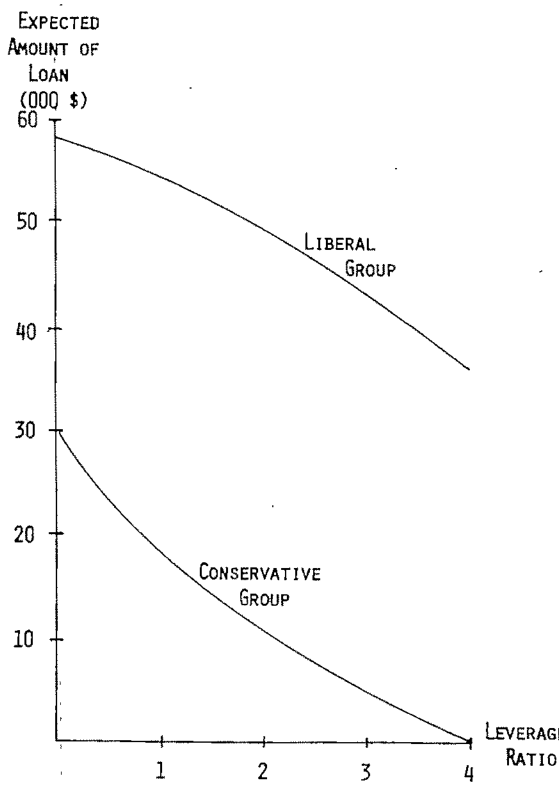

Figure 2. Effect of leverage ratio on expected amount of loan

Factors Affecting Credit Responses of Lenders

Agricultural finance texts suggest that three factors are important in credit analysis: repayment potential, expected returns, and risk-bearing ability (Hopkin, Barry, and Baker). Therefore, specific models were formulated to determine if these factors also are regarded as significant by the lenders involved in this experiment.

To test the importance of the above factors in credit analysis, two regression models are estimated by the ML procedure described, with amount of borrowed funds obtained as the observed dependent variable (W_t). In each model selected variables representing the credit factors previously specified are included in the regression equation. The first model focused on the role of the income-generating capacity of the firm. The second utilized the leverage variable to represent risk-bearing capability. Both models include net worth to indicate the repayment capacity of the borrowing firm. In addition to the variables just discussed, other farm financial and institutional variables were considered in each regression equation, and those that exhibited substantial explanatory power were included.

During preliminary model construction and data analysis, it became apparent that there was considerable variation in individual lender response. For example, two lenders may have responded in a similar fashion to variations in the financial position of the applicant, but one lender consistently would loan a greater quantity of funds than the second for each of the five experimental situations. This variation between lenders did not prove to be strongly related to relevant lender or lending institution characteristics.

To provide a better basis for evaluating this variation, the average loan amount granted over the five loan situations was computed for each of the thirty-three institutions. Examination of these average loan amounts indicated that the lenders' responses tended to fall into two groups with respect to the absolute size of loan granted. One of these groups, which we call the liberal group, was composed of twenty lenders whose average loan response was in excess of $30,000. The remaining thirteen lenders, whose average loan response was less than $30,000, are called the conservative group. To reduce this variability associated with the lender groupings, separate regression equations—one for the liberal and one for the conservative group—are estimated for both of the models discussed previously.[3] A secondary purpose of the analysis then became to assess the extent to which the lenders in each of these groups differed in the manner they responded to the firm's financial structure.

Estimation results of the four regression equations (two for each model) are presented in table 3.[4] Equation (C1) relates to the conservative grouping of lenders and (L1) refers to those in the liberal group. These results indicate that lenders in both groupings regard both the income-generating potential and the net worth of the prospective borrower as important factors in determining the amount of loan to approve. For both lender groupings a $1,000 increase in net worth of the prospective borrower would generate approximately $400 in additional credit capacity (all other variables at sample mean levels). Those in the liberal grouping, however, tended to be more influenced by the income-generating potential of the firm than were those in the conservative group. A $1,000 increase in income potential expanded the potential loan by about $2,200 and $1,800, respectively.

A major difference between the lenders in the two groupings is reflected in their response to the level of short-term equity the borrower possesses. This relationship is illustrated graphically in figure 1. Those lenders in the conservative groupings were willing to increase loan amounts by about $1,400 for each $1,000 increase in short-term equity. In contrast, liberal lenders regarded short-term equity as an unimportant factor (as long as other financial variables remained constant).

Equations (C2) and (L2) relate to the conservative and liberal groupings, respectively. Again the two groupings concur in the crucial role of net worth as a measure of the applicant's collateral position. Both groupings also regard the risk-bearing capacity of the firm, as measured by its leverage ratio, as a significant variable. However, the rate at which the loan amount decreases as the leverage ratio increases is sharply different between the two groupings. This differential, and the disparity in the absolute amount of the loan, is shown in figure 2. Whereas an increase of 0.5 in the leverage ratio reduces the loan received by about $2,700 for the liberal grouping (in the range of ratios from 0.5 to 3.0), this same increase would reduce the loan amount by $3,900 for lenders in the conservative grouping.

As noted previously, dividing the lenders into two groupings precipitated the question of whether the lenders in each group respond differently to

[3] An alternative to estimating two separate equations would have been to use dummy variables to allow intercept and slope coefficients to vary according to whether a lender was classified as liberal or conservative. However, that specification would make σ constant for both groups. Specification of separate equations for the two lender categories was felt to be more appropriate. In both models the estimated standard deviations (σ) were different at about an 88% level of significance.

[4] The observations in each estimated regression clearly are not independent because five observations are drawn from each lender and all five observations for a given lender are included in the same equation. However, to get a comparable sample size from separate lenders, it would have been necessary to contact 165 lenders, an option beyond the limitations of the study. The implied loss of independence is ameliorated by the inclusion in each model of two variables (*BUSS* and *EXP*) characterizing the lending institutions. Thus each variable has identical values for all five observations. These variables purge u_t of variation unique to a given institution relating to *BUSS* and *EXP*.

age ratios of Situations 4 and 5 relative to Situations 2 and 3, respectively. The loan responses of these lenders are consistent with those found by Smith and Baker indicating that debt commitments associated with the purchase of land can reduce the availability of non-real estate credit. They also underscore the need for evaluating the conditions under which increases in net worth resulting from appreciation in land values provide additional capacity to generate debt-financed expansion of the farm firm (Plaxico and Kletke).

Estimation of a Model Explaining Lender Responses

The responses of table 2 provide insights as to the effect of debt structure on credit reserve but do not give estimates of quantitative relationships between financial variables and lender responses. Therefore, a second phase of this analysis was to estimate these relationships utilizing an estimation procedure appropriate for the particular situation under analysis.

Because the hypothetical borrower could not receive more than the amount requested and negative loans are disallowed, the dependent variable in this analysis, the amount of the loan received, is truncated at both tails of its distribution. Such a model is simply a more general model of the one discussed by Tobin, where the dependent variable is truncated only at the lower end of its distribution. As discussed in Tobin, multiple regression is not appropriate when there is a concentration of observations at a limit for the dependent variable. If our concern were only with whether a loan of some amount would be granted, probit or logit analysis would be appropriate. However, these latter approaches deprive the economic analysis of an estimate of the size of expected loan given a specific set of values for the independent variables. Therefore, an estimation approach which incorporates the doubly truncated nature of the dependent variable is utilized. This approach is a special case of a general model with numerous discontinuities in the observed dependent variable (Nelson).

The proposed model may be written as

$$
(1)\quad \begin{aligned} W_i &= 0 \text{ when } Y_i \leq 0 \\ W_i &= 60, \text{ when } Y_i \geq 60 \\ W_i &= Y_i, \text{ when } 0 \leq Y_i \leq 60, \end{aligned}
$$

where Y_i is a linear combination of the independent variables, X_i, plus an error term and is defined as:

$$
(2)\qquad Y_i = \beta' X_i + u_i,
$$

where β is an unknown coefficient vector to be estimated. The u_i are normally and independently distributed error terms with mean zero and variance σ^2. The variable W_i is the observed amount that would be loaned in thousands of dollars. (The constraint value, 60, correlates to the maximum loan amount requested, \$60,000.) The independent variables, X_i, indicate characteristics of the given loan application as well as attributes of the individual lender and lending institution considering the loan. Thus, the Y_i can be interpreted as latent indicators of how much should be loaned given the specific application and lender. The actual amount loaned, W_i, is determined according to how Y_i is classified in (1).

In their seminal article on models with doubly truncated limited dependent variables Rosett and Nelson recommend estimation of β and σ by maximum likelihood (ML) methods.[2] The system of equations which results with the maximum likelihood method is nonlinear and must be solved by iterative methods. Thus initial values for the parameter estimates are required. Rosett and Nelson propose using OLS estimates of those observations where $W_i = Y_i$. Monte Carlo results presented in their article suggest that such an approach likely will yield reliable final estimates. Hence, that method was employed in this analysis. Statistical inference in this study is performed on the estimated parameters by the use of likelihood ratio statistics and the assumption that the estimates are asymptotically normally distributed.

Given the estimated parameters, $\hat{\beta}$ and $\hat{\sigma}^2$, the model in (1) and (2) can be used to predict the probability of a loan being extended and the expected value of loans for given levels of the independent variables. Letting $\hat{Y}_i$ be the predicted value of Y_i given X_i and $\hat{\beta}$, the probability of a loan being extended is simply the probability that $\hat{Y}_i$ is greater than zero where $\hat{Y}_i$ is normally distributed with mean $\hat{Y}_i$ and variance $\hat{\sigma}^2$. The expected value of W_i given X_i is computed as

$$
(3)\qquad E(W_i|X_i) = \int_{-\infty}^{\infty} \frac{1}{\sigma} Z\left(\frac{y - \hat{\beta}' X_i}{\sigma}\right) g(y)\,dy,
$$

where $g(y) = 0$ for $y \leq 0$, $g(y) = y$ for $0 < y < 60$, and $g(y) = 60$ for $y \geq 60$. ($Z[\cdot]$ is the standard normal density function.)

An important implication of (3) is that in general a unit increase in an independent variable does not result in an increase in expected value equal to that variable's slope coefficient. Instead, the impact of a unit increase in an independent variable on expected loan is a function of the level of that variable and the other independent variables in the model. The closer the expected loan is to either the upper or lower limits, the less the impact of a unit change in an independent variable.

---

[2] The likelihood function, L, is defined as

$$
L = \prod_{s_1} P\left(\frac{-\beta' X_i}{\sigma}\right) \prod_{s_2} \frac{1}{\sigma} Z\left(\frac{W_i - \beta' X_i}{\sigma}\right) \prod_{s_3} \left\{1 - P\left(\frac{60 - \beta' X_i}{\sigma}\right)\right],
$$

where s_1, s_2, and s_3 denote the number of observations where $W_i = 0$, $W_i = y_i$, and $W_i = 60$, respectively, $P(\cdot)$ denotes the standard normal cumulative probability distribution function, and $Z(\cdot)$ is the standard normal density function.

[c] Total liabilities divided by net worth.

tionally, considerable production and financial data were available to the lender. However, only those items the lender requested were supplied. Available financial statements included past and projected income, net worth, and cash flow statements.

Many farm operators considering a decision to invest relatively large sums of money in fixed assets are concerned that such a commitment will have an adverse effect on their ability to generate borrowed funds to continue operation of their business. In this study, therefore, five loan situations were devised in which the borrower was said to have recently purchased farmland and now desired intermediate credit. In each of these situations the borrower requested $60,000 to replace a crucial piece of machinery, the combine, and to establish a grain storage and drying facility. If the original loan request was thought to be too high, the lender was requested to make a loan for the maximum amount feasible.

Selected financial data for the five simulated loan situations are given in table 1. In the first three situations the applicant had recently purchased 40 acres and in the last two situations had purchased 80 acres of his 400-acre, predominately cash grain farm. As shown in table 1, these five situations were structured to represent varying degrees of financial stress for the hypothetical farmer borrower.

For each financial situation, the average amount which would have been loaned by the lenders surveyed is presented in table 2. These average responses vary from $20,000 in Situation 3 to over $47,000 in Situation 1. An applicant with the relatively strong financial characteristics described in Situation 1 would have received a loan, but of varying amounts, from all thirty-three lenders. The minimum which would have been provided in this instance was $20,000, sufficient for purchasing a used combine but not for erecting any grain-drying and storage facilities.

For Situations 3 and 5, the comparatively weaker financial position of the borrower resulted in average loans of about $20,000, sharply lower than in the other three circumstances. A considerable number of lenders indicated they would have refused to grant any loan (13 and 15 lenders, respectively). These responses indicate that the concept of credit reserve, i.e., the capacity to borrow, should be of concern to farm operators. Potential borrowers with financial characteristics as depicted in Situations 3 and 5 may have so diminished their credit reserve that their ability to borrow in order to survive adverse occurrences would be jeopardized.

The loan responses of table 2 also indicate that the amount of land owned by the potential borrower, by itself, is not a good indicator of loan response. For example, the loan responses of Situation 2 and Situation 4 are nearly equal, even though the prospective borrower in Situation 4 was described as owning twice as much land as the applicant of Situation 2. (A similar comparison is possible between Situations 3 and 5.)

One positive aspect of the larger land purchase is reflected by the larger net worths of Situations 4 and 5. These expanded net worths are in large part due to inflation in land values subsequent to the land purchase. A negative aspect of the larger land purchase, however, is reflected in the higher lever-

Impact of Farm Financial Structure on the Credit Reserve of the Farm Business

S. T. Sonka, B. L. Dixon, and B. L. Jones

The concept of credit reserve and its interaction with other firm decisions has become particularly important to the farmer because of two factors recently affecting American agriculture. One of these is the greater price variability associated with many agricultural products. The second is the recent escalation of farm input prices, particularly with respect to major asset items such as farmland (Melichar, Scott). In adjusting to such changing operating conditions, farm operators have substantially increased their use of borrowed funds. Between 1970 and 1977, liabilities of the farming sector increased by over 90% (U.S. Department of Agriculture). Although borrowing has been historically an important source of capital for farmers (Brake and Melichar), this expansion in the use of borrowed funds makes understanding the ramifications of debt use a high priority information need.

The credit reserve concept, i.e., the individual's unused capacity to borrow funds (Baker), is a central feature in the process of understanding the use of debt capital. If an individual farmer chooses to maintain a credit reserve, this decision is not without costs and benefits. The costs of this decision are the foregone expected net benefits of utilizing additional borrowed funds. The intangible benefits associated with a reserve result from maintenance of firm liquidity. Therefore we can think of the decision to maintain a credit reserve as a form of risk-averse behavior in response to uncertainty (Barry and Baker). This response would be expected to become more important as farmers perceive the conditions in which they operate as being increasingly uncertain (Kadlec and Jones).

For a specific farm operator, a quantitative expression for credit reserve can be described as the difference between capital limits imposed by external credit rationing and the amount actually borrowed by that individual (Barry and Baker). Describing credit reserve in this manner specifies the two parties involved in determining the size of the credit reserve. The first party is the farm operator and the second is the lender who decides upon the level of external credit rationing.

Past research has shown that farmer actions, such as the order in which loans for particular items are requested or forward contracting a portion of a crop, can affect the amount of credit available (Irwin and Baker; Barry and Willmann). An additional set of farmer-controlled variables which should have an impact on the level of external credit limits is reflected in the asset structure of the farm business (Hopkin, Barry, Baker). This paper reports on an experiment conducted to estimate quantitatively the relationship between the asset structure of the farm firm and its credit reserve for a specific agricultural situation.

Soliciting Lender Responses to Farm Financial Structure

To assess quantitatively the impact of the firm's financial structure on its external credit limits, information was needed which related lender credit reactions to variations in the components of a farm's financial position. In early 1977, a simulated borrowing experiment was conducted with thirty-three agricultural lenders in east central Illinois.[1] At each of these institutions (thirty commercial banks and three Production Credit Associations), an agricultural credit officer was asked to evaluate loan requests of hypothetical farm operators and to indicate the loan response that such requests would receive.

Several items of information were made available to each loan officer as he requested them. One item was a detailed biography of the borrower. This biography described the borrower as a college graduate in agriculture with four years experience as an independent farmer. The applicant was said to have dealt with that institution for the entire time he had farmed and to have a good credit history. Addi-

S. T. Sonka, B. L. Dixon, and B. L. Jones are associate professor, assistant professor, and research assisant, respectively, in the Department of Agricultural Economics, University of Illinois.

[1] As detailed by Baker, observation of lender responses to the financial condition of prospective borrowers is a subtle problem. Utilization of an attitudinal survey of lenders may result in conditioned responses by lenders rather than responses indicating their actual behavior. Examination of actual loans, on the other hand, will only provide information on loans granted and would exclude conditions where loans are refused. These concerns plus positive experiences with the experimental approach by other researchers (Barry and Willmann, Irwin and Baker, and Smith and Baker) indicated that a simulated experiment would be most appropriate in this instance. In order to assure as realistic an experimental situation as possible, the financial situations specified were pretested with a small number of individuals with lending experience in the geographical area. After adjustment, these individuals indicated that the financial conditions developed for the experiment would be representative of actual farm firms of the type specified.

However, the aggregate response is the net response of many decision makers. It is possible that certain categories of farmers do not respond as hypothesized. This phenomenon could not be captured with aggregate data. Also we have focused more on the direction of the response than the magnitude of the response. Differential magnitudes in response may be associated with various characteristics such as risk aversion (Gabriel), farm size, or farm type. In short, the extent of the response for any given farm could be expected to be greater or less than the one displayed in the aggregate model.

Although the empirical test of the existence of risk balancing as described in this paper is far from conclusive, owing to the obvious problems associated with aggregation and the possibility of autocorrelation, the results are consistent with the hypothesis. Adequate testing of the risk-balancing hypothesis would require detailed observations of how individual decision makers respond to changes in business risk over significant periods of time. This data requirement may be difficult to satisfy.

The finance activity of the farm firm is a critical and pervasive one which should not be ignored in attempts to model the decision-making process at the farm level. It has been shown that the financing decision is an important consideration in determining total risk, whether risk is defined in terms of income variability or as the probability of the occurrence of a dread event such as cash insolvency.

The importance of the relationship between business and financial risk lies in the resultant link between investment and financing decisions. Investment and financing decisions must be made simultaneously, maintaining a balance between risk exposure and expected returns. This relationship also is important when estimating the potential effects of policy-induced alterations in business risk with respect to farm finance.

Preliminary Empirical Evidence

In an attempt to verify the risk-balancing activity described above (i.e., the financial adjustment to changes in business risk), linear regression was used to estimate the coefficients of variables explaining changes in the ratio, $I/(\bar{c}x - I)$. This ratio is the component of financial risk in which the balancing response takes place.

The data used in the regression equation were aggregate income, balance sheet, and farmland price data provided by U.S. Department of Agriculture (USDA) publications, *Farm Income Statistics, Balance Sheet of the Farming Sector,* and *Farm Real Estate Market Developments.* While the various definitions which follow are straightforward, some clarifications are in order. Although cash rental obligations increase financial risk, the available figures on rental payments are "contaminated" with share-type rental payments which do not affect financial risk. Consequently, rental obligations were excluded as an element of financial risk. In addition, data on principal payments on debt are not available, so that the net operating income definition of financial risk was employed.

Although the conceptual framework presented in this paper is micro in nature, we have attempted a preliminary test of the risk-balancing hypothesis using aggregate data. The reason for this is that it was felt that it would be difficult to obtain adequate farm-level data (i.e., a long enough time series for enough farms) to facilitate a test of the hypothesis. Thus, the aggregate results would describe the behavior of the "aggregate of decision makers." We believe that, although inconclusive in itself, this approach may provide a point of departure for future research on the topic.

Factors other than business risk are assumed to influence the decision makers' ability and/or willingness to make adjustments in the firms' financial risk. Among those factors are the average cost of debt capital and the profitability of assets. In addition, changes in the price of land are assumed to affect firm liquidity as credit adjusts to new equity values. Recall that firm liquidity was shown to be instrumental in the risk management of the farm.

Using nationally aggregated data for the period 1949–76, the following model was estimated:

$$FR_t = f(CV_{t-1}, (I/D)_{t-1}, (NI/A)_{t-1}, \%CH\ LND_{t-1}),$$

where CV_{t-1} is a five-year moving coefficient of variation of net operating income for the farm sector of the United States; (CV_{t-1} is based on net operating income for years $t-1$, $t-2$, $t-3$, $t-4$, and $t-5$.); $(I/D)_{t-1}$ is the ratio of total interest payments to total debt in year $t-1$; $(NI/A)_{t-1}$, the ratio of net income to total assets in year $t-1$; $\%CH\ LND_{t-1}$, percent change in the land price index from March year $t-1$ to March year t; and FR_t, the ratio $I/\bar{c}x - I$ in year t.

The regression results (see table 1) indicate an inverse relationship between business risk (CV_{t-1}) and $I/(\bar{c}x - I)$. That is, in the aggregate, there appears to be a financial response to changes in business risk which tends to support the risk-balancing hypothesis.

While the other explanatory variables are of secondary interest here, we will look briefly at their role in explaining changes in the dependent variable. The coefficient for $(I/D)_{t-1}$ is positive and significant, which indicates, as one might expect, that high (low) debt capital costs lead to high (low) financial risk, *ceterus paribus.*

The variable $(NI/A)_{t-1}$ displays a coefficient with the expected sign as well as a high level of significance. All things otherwise the same, greater asset profitability should lead to high debt coverage ratios and lower financial risk.

Finally, as stated earlier, land values influence credit availability positively, increasing liquidity and allowing financial risk also to increase. This relationship is supported by the positive and significant coefficient associated with *%CH LND.*

Summary and Conclusion

The results of this empirical analysis have shown that in the aggregate, farmers make financial adjustments leading to decreased (increased) financial risk in response to a rise (fall) in business risk.

the release of internally rationed debt capital. Once again, the response to the exogenously induced decline in business risk could involve production or investment decisions, financing decisions, or a combination of the three.

Liquidity and Risk Management

The previous discussion ignores the role that liquidity reserves play in risk management. Baker, along with others, has emphasized the importance of liquidity management in the management of risk on the farm (Baker and Bhargava, Baker and Hopkin, and Barry and Baker). In addition to the liquidity embodied in the tangible assets of the farm, one must consider the liquidity characteristics of a somewhat less tangible asset, credit or borrowing capacity.

It is clear that the level of liquidity reserves exerts at most a small explicit effect on the variability of income or cash flows. However, most of its influence is implicit in that it affects the production organization as well as the financial organization of the farm. That is, if the decision maker regards his reserves of liquid assets as a tool in risk management, used to offset cash deficiencies resulting from an adverse outcome in an uncertain market or production process, the size of these reserves will influence his investment and financing decisions. The larger the reserves of liquid assets, the more willing he will be to select riskier investment alternatives and financial plans.

One method of incorporating this liquidity management dimension into an overall risk management framework is to look at risk in a probabilistic sense. Let us redefine total risk as the probability, α, that one will be unable to generate a minimum level of funds needed for home consumption as well as business requirements after having serviced debt. This can be expressed as

$$(8)\qquad P(cx + \mu - I \leq z) = \alpha,$$

or, as an upper bound,

$$(9)\qquad P(cx + \mu - I \leq z) \leq \alpha.$$

Following Roy and Kennedy and Francisco (pp. 133–35), we can state:[3]

$$(10)\qquad P(cx + \mu - I \leq z) \leq \frac{\sigma_s^2}{[(\bar{c}x + \mu - I) - z]^2},$$

where cx is the random variable, net cash flow; $\bar{c}x$ is expected net cash flow; μ is the liquidity reserve; I is the fixed debt-servicing obligations (i.e., interest and principal); z is the lower limit described above; and σ_s^2 is the subjective variance of net cash flow.

Restricting total risk to be no greater than α, where α is the probability that some critical cash demand cannot be met amounts to the restriction,

$$(11)\qquad P(cx + \mu - I \leq z) \leq \frac{\sigma_s^2}{[(\bar{c}x + \mu - I) - z]^2} \leq \alpha.$$

In other words, the condition prescribed by equation (9) will be met if

$$(12)\qquad \sigma_s \leq \sqrt{\alpha}\,[(\bar{c}x + \mu - I) - z], \text{ or,}$$

dividing both sides of (12) by $\bar{c}x$,

$$(13)\qquad \frac{\sigma_s}{\bar{c}x} \leq \sqrt{\alpha} + \frac{\sqrt{\alpha}\mu}{\bar{c}x} - \frac{\sqrt{\alpha}I}{\bar{c}x} - \frac{\sqrt{\alpha}z}{\bar{c}x}.$$

Moving the terms involving μ, I, and z to the left side of (13) and factoring $\sqrt{\alpha}$,

$$(14)\qquad \frac{\sigma_s}{\bar{c}x} + \sqrt{\alpha}\,\left(\frac{I}{\bar{c}x} + \frac{z}{\bar{c}x} - \frac{\mu}{\bar{c}x}\right) \leq \sqrt{\alpha}\,.$$

The implications of this risk constraint are clear: $\sigma_s/(\bar{c}x)$ is equal to the coefficient of variation of net cash flow and is an index of business risk; $I/(\bar{c}x)$ is the ratio of financial risk to total risk under the variability criterion discussed earlier;[4] $z/(\bar{c}x)$ is the ratio of the critical cash requirement to the expected net cash flow and $\mu/(\bar{c}x)$ is the liquidity reserve divided by expected net cash flow. These items can be considered components of total risk in that if total risk, α, were allowed to vary unrestricted it would be positively related to $\sigma_s/(\bar{c}x)$, $I/(\bar{c}x)$, $z/(\bar{c}x)$ and inversely related to $\mu/(\bar{c}x)$.

It is important to note, in equation (14), that each of the components involving I, z, and μ is weighted by $\sqrt{\alpha}$. Because α necessarily must be a number between zero and one, depending on the decision maker's risk preferences, the impact of changes in these components on total risk can be considerably less than that of business risk, $\sigma_s/(\bar{c}x)$. This phenomenon should be expected, however, since business risk is the underlying source of all risk.

The risk constraint shows that the importance of liquidity reserves as a method of managing risk becomes negligible as business and financial risk approach zero. This is clear since liquidity reserves tend to offset the various sources of risk indicated in equation (14). Also, exogenously based changes in the value of equity, through capital appreciation and/or depreciation, affect the farmer's ability to bear risk. This results from the alteration in liquidity reserves, μ (particularly credit), which occurs as capital appreciates or depreciates in value.

---

[3] Roy and Kennedy and Francisco have shown, using Tchebycheff's theorem, that

$$P[cx \leq z^*] \leq \sigma_s^2/(\bar{c}x - z^*)^2,$$

where z^* is a disaster outcome, and cx, $\bar{c}x$, and σ_s^2 are defined as in the text above. In this paper we have defined z^* (which is a constant) to equal $z - \mu + I$ (also all constants). Hence we are able to write equation (11).

[4]
$$\frac{\text{Financial risk}}{\text{Total risk}} = \frac{\dfrac{\sigma_1 I}{\bar{c}x(\bar{c}x - I)}}{\dfrac{\sigma_1 \bar{c}x}{\bar{c}x(\bar{c}x - I)}} = \frac{I}{\bar{c}x}.$$

$$(2)\qquad FR = \frac{\sigma_2 - \sigma_1}{\bar{c}x - I} + \frac{\sigma_1}{\bar{c}x}\,\frac{I}{\bar{c}x - I}.$$

Consider the case where leverage does not induce a change in the variability of net cash flows (i.e., where $\sigma_1 = \sigma_2$). When $\sigma_1 = \sigma_2$, the σ_1 first term of the right side of equation (2) becomes zero, leaving equation (3):

$$(3)\qquad FR = \frac{\sigma_1}{\bar{c}x}\,\frac{I}{\bar{c}x - I}.$$

We see that financial risk is determined by the degree of business risk inherent in the firm $\sigma_1/(\bar{c}x)$, and the relation $I/(\bar{c}x - I)$ which is determined by the financing decision.

Equation (2) reveals the effects of leverage-induced changes in the variability of net cash flows. If the variability of net cash flows declines with use of debt financing because, for example, the decision maker alters his marketing strategy, (i.e., $\sigma_2 < \sigma_1$) financial risk will be lower than if no change in variability occurred. The difference would be determined by the value $(\sigma_2 - \sigma_1)/(\bar{c}x - I)$. Conversely, if variability increased ($\sigma_2 > \sigma_1$), financial risk would be greater than would have been the case had no change taken place: by the amount, $(\sigma_2 - \sigma_1)/(\bar{c}x - I)$.

Risk Balancing

If it is assumed that the decision maker has identified both firm survival and profit maximization as goals, where survival is of primary importance, a lexicographic utility function exists and the decision maker will maximize net returns subject to the constraint that total risk does not exceed a specified level (see Encarnatión and Halter and Dean, pp. 54–57). Risk balancing refers to the adjustment in the components of total risk (i.e., business and financial risk) that results from an exogenous shock to the existing balance. This shock is to be represented by a change in business risk and is viewed within the context of a total risk constraint.

Assuming that there are no leverage-induced changes in business risk (i.e., that $\sigma_1 = \sigma_2$) total risk (TR) is defined as

$$(4)\qquad TR = \frac{\sigma_1}{\bar{c}x - I}, \text{ or}$$

$$(5)\qquad TR = \frac{\sigma_1}{\bar{c}x}\,\frac{\bar{c}x}{\bar{c}x - I}.$$

A total risk constraint can be formed if the maximum tolerable total risk (β) can be identified by the decision maker. Hence, the total risk constraint could be written,

$$(6)\qquad \frac{\sigma_1}{\bar{c}x}\,\frac{\bar{c}x}{\bar{c}x - I} \le \beta.$$

Suppose that, due to a change in an exogenous source such as price support policy or foreign trade policy, σ_1 declines, leaving all the other variables unchanged. Total risk will have declined proportionally, leaving slack in the risk constraint specified in (6). Financial risk also will have fallen proportionally. Because financial risk contributes to the total risk of the firm and is a function of the financing decision, internal capital rationing may occur in order to comply with the risk constraint. Therefore, one might expect debt use and, consequently, financial risk, to adjust to changes in the level of business risk.

It is important to observe at this point that the ratio, FR/TR, is invariant to changes in business risk (assuming a change only in σ_1). Financial risk as a percentage of total risk might change, however, as investment and financial responses to this modification in business risk take place.

The response to a decline in business risk may involve an investment decision as well as a financing decision. If the decision maker maximizes profit subject to a risk constraint, he will search for investment opportunities that increase the value of the objective function. Simultaneously, however, he may be expected to consider the effects of financing alternatives on cash flow, profitability, and overall risk. The process is a complex one, entailing the interaction of the components of risk (i.e., the risk which originates in the investment decision and that which originates in the financing decision). A balance must be met between the effect that the investment has on overall business risk as well as its effects on financial risk.

For a more complete understanding of the role of business and financial risk in the determination of total risk, the expression for total risk, defined as total variability, can be shown to consist of the sum of business and financial risk. If $\sigma_1 = \sigma_2$, and some upper limit, β, is placed on total risk we have

$$(7)\qquad \frac{\sigma_1}{\bar{c}x} + \frac{\sigma_1 I}{\bar{c}x(\bar{c}x - I)} \le \beta.$$

Because the expression for financial risk involves that of business risk, its level is dependent upon the degree of business risk. Let there be an exogenously induced rise in σ_1, and thus a rise in business risk. Assuming there is no slack in the risk constraint, financial risk also will rise, forcing a subsequent risk adjustment in order to comply with the constraint. This adjustment may involve a production or an investment decision, a financing decision, or all three. For example, a strictly financial response would be to refinance some existing debt with either a debt with longer maturity (and thus lower periodic debt service requirements) or with equity capital. Alternatively, a reorganization of farm assets and investments could take place, lowering business risk.

Similarly, if σ_1 were to decline due to some exogenous force, such as a change in foreign trade policy, both business and financial risk would decline leaving slack in the risk constraint. This would allow the introduction of more risky, higher return activities into the production process in addition to

Concepts of Business and Financial Risk

Stephen C. Gabriel and C. B. Baker

There is considerable current interest in methods of limiting the business risk to which farmers are exposed. Some approaches to business risk modification involve insurance, government programs, weather modification, and innovations of individual farmers: technological, to limit the probability of disease and insect damage; and market, to limit the probability of adversity through price fluctuations.

It is recognized that the introduction or modification of risk in the production process affects the pattern of resource allocation and in turn the level of production (Dillon, pp. 102–48, Just, Wiens, and Wolgin). We suggest that there is also a financial response to business risk modification. The differentiation is important in that business risk and financial risk may well be trade-offs in the risk behavior of farmers. Thus, a decline in business risk would lead to the acceptance of greater financial risk, reducing the effects of the diminished business risk on total risk.

In this paper we present a conceptual framework for linking production and investment decisions to the financing decision via a risk constraint. While most of the literature on risk and risk response treats only production and price risk (i.e., business risk), we intend to introduce the notion of financial risk explicitly into the decision-making process.

Business Risk

Business risk is defined to be the risk inherent in the firm, independent of the way it is financed (Van Horne, pp. 207–8). Business risk generally is reflected in the variability of net operating income or net cash flows. A high (low) coefficient of variation of net cash flows, for example, would indicate high (low) business risk. Business risk may be evaluated at a point in time based on the probability distribution of net cash flows.

There are two major external sources of business risk in the agricultural firm. One is the market which produces price variability for both outputs and inputs and uncertain availability and quality of the latter. The other source is the biophysical environment which produces yield or production variability. These elements combine to form the bulk of business risk on the farm. The level of business risk also is influenced by internal factors such as investment decisions and management skills.

Financial Risk

Following Barges (p. 16), financial risk is defined to be the added variability of the net cash flows of the owners of equity that results from the fixed financial obligation associated with debt financing and cash leasing.[1] Also, as mentioned by Van Arsdell (p. 304) and Van Horne (p. 252), financial risk encompasses the risk of cash insolvency. However, this notion will be expanded to include the risk of being unable to meet prior claims with the cash generated by the firm, which is determined by the dispersion of net cash flows and the level of fixed obligations, as well as the firm's pool of liquid resources. Focusing initially on the variability aspects, financial risk (FR) can be specified as:

$$FR = \frac{\sigma_2}{\bar{c}x - I} - \frac{\sigma_1}{\bar{c}x}, \tag{1}$$

where σ_1 is the standard deviation of net cash flows without debt financing; σ_2, the standard deviation of net cash flows with debt financing but before the deduction of debt servicing payments; $\bar{c}x$, expected net cash flows without debt financing; and I, fixed debt servicing obligations.[2]

Equation (1) reflects the change in the coefficient of net cash flows which results from debt financing. Standard deviations of net cash flows without financing and with financing (σ_1 and σ_2, respectively) have been specified since it is possible that lenders or indeed the farmer himself may impose marketing and/or production restrictions which may alter the dispersion of net cash flows owing to the use of debt financing. Also, leverage-induced scale effects may influence the variability of net cash flows. Expected net cash flows may be altered because of scale effects. However, for the sake of simplicity we hold it constant in this analysis. Equation (1) may be rewritten, allowing us to divide financial risk into its components:

The authors wish to acknowledge the helpful comments of Peter Barry, Bruce Dixon, Charles Linke, David Lins, Steven Sonka, and two *Journal* reviewers on a previous draft of this paper.

[1] For the balance of this study only debt financing will be referred to as a source of financial risk for purposes of simplicity.

[2] Financial risk could be defined in terms of net operating income or net cash flows. The fixed debt-servicing obligations would involve only interest under the former definition and both interest and principal under the latter.

larger farms are more diversified. Wealthier and less experienced farmers are more specialized. Finally, there is also evidence that corporations are more specialized than farms with other organizational forms.

Evidence reported here suggests that diversification and size (or growth) may be positively linked. Hence, there may not be sufficient economies of scale in a particular commodity to warrant specialization. In general, the results here are consistent with risk theories. That is, the firm diversifies to spread risk and wealthier farmers have fewer incentives to spread risk. However, as with all cross-section studies, questionable causation and the myriad of forces at work lead one to be cautious when interpreting results. The essential point is that these results may be cause for reservation for those supporting policies which are tied to diversified farms that are presumed to be relatively small. Raup and others have suggested that larger farms may be in relatively poorer risk posture than smaller farms. However, the results reported here may not support his hypothesis. The conclusions reached in the analysis here must be tempered by the lack of nonfarm income-generating activities and possibly any unique characteristics specific to the geographical setting. These considerations indicate that positive economic analysis of diversification needs further research in order to delineate more fully the economics of activity choice and the ability of farms to self insure through diversification.

[b] Indicates farm is located in Madera County, California.
[c] Indicates farm is located in Kern, Merced, San Joaquin, or Tulare County, California.
[d] Indicates whether or not farm is irrigated, $D_4 = 1$, if irrigated.

are more specialized, *ceteris paribus*) for all diversification measures in table 1. These results would be consistent with a decreasing (in wealth) type risk aversion in a cross-sectional sense. That is, wealthier farms are less risk averse and less diversified—other things equal.

Another surprising result concerns the experience variable. Table 1 indicates that younger or less experienced farmers are more specialized. One might speculate that younger farmers are less risk-averse. But, more plausibly, young farmers may start small and specialized and perhaps become more diversified as they expand their operation. This may be indicative of capital shortages for young farmers. Also, it may be difficult for less experienced farmers to manage diverse activities.

Concluding the discussion of results from table 1, "significance" levels vary with the measure of diversification for the organizational dummies. Further, the signs among the different measures are not consistent. However, the evidence suggests that corporate farms are more specialized than other farms.[6]

Table 2 presents results for measures M_1, M_3, and M_4, when these measures are defined over net revenue (M_2 remains unchanged). Net revenue is defined as sales less variable costs. Here it is noted that all "significance" levels are low for variables representing organizational form. This is in contrast to evidence presented in table 1. However, again there is strong evidence that larger farms are more diversified than smaller farms (*ceteris paribus*). Again, the results indicate that more experienced farmers are more diversified than those with less experience, and wealthier farmers are more specialized (*ceteris paribus*). Therefore, on the basis of this sample, evidence suggests that the results stated above are fairly robust with respect to the diversification measure used.

Summary and Conclusions

Using alternative measures of diversification, a sample of California farms revealed evidence that

[6] The rankings in terms of diversification are M_1: $Z_3 < Z_2 > Z_1$; M_2: $Z_3 < Z_2 < Z_1$; M_3: $Z_3 < Z_2 > Z_1$; M_4: $Z_3 < Z_1 < Z_2$, where the Z's represent the sum of the estimated constant plus the dummy coefficient.

analyses of diversification. A priori, one cannot expect the various measures to yield identical results.

Define A_i as the crop acreage in activity i, and ΣA_i as total farm acreage cropped; and let $p_i = A_i / \sum_{i=1}^{N} A_i$ denote proportions. Then the following measures are considered (White and Irwin, Berry, Hackbart and Anderson).

$M_1 = \max_i p_i$ (index of maximum proportion);

$M_2 = \sum_{i=1}^{N} I(p_i)$, (number of enterprises);

where I denotes a zero-one indicator.

$M_3 = \sum_{i=1}^{N} p_i^2$ (Herfindahl index);

$M_4 = \sum_{i=1}^{N} p_i \log \frac{1}{p_i}$ (entropy index).

When M_1 through M_4 are defined for net income, p_i is the proportion of income from crop i. All measures except M_2 can be computed such that they are bounded by zero and one. For increasing diversification, M_1 is generally decreasing, M_2 is increasing, M_3 is decreasing, and M_4 is increasing. This statement is apparent for M_1 and M_2. For M_3 and M_4 (see Berry, Hackbart and Anderson, or Theil).

We shall comment briefly on some of the properties of the measures M_3 and M_4. The Herfindahl index takes a value of 1 when there is complete specialization and approaches 0 as N gets large. That is, if diversification is "perfect," such that

$$A_i = \frac{1}{N} A \text{ and } N \to \infty, \text{ the } \sum_{i=1}^{N} p_i^2 = \frac{1}{N} \to 0.$$

The M_4 is the entropy measure popularized in economics by Theil. It possesses several desirable properties (see Hackbart and Anderson). For our purposes, it is important to note that M_4 approaches its maximum when $p_i = \frac{1}{N}$, or when diversification is "perfect." Recalling Samuelson's theorem, the entropy index is maximized when optimal diversification is undertaken by a risk averter when returns are independent and have equal means. It approaches zero when a farm is specialized.

The Empirical Model

On the basis of theory, one can derive few (if any) firm hypotheses regarding diversification, scale, constraints, organizational form, and other relevant factors. The essential point is that the theory does suggest that these could be important elements in diversification decisions. As limited by our sample, we shall investigate the following relationship:

$$\begin{aligned} M_{jt} = a_0^j + a_1^j \mathbf{Z}_t + a_2^j \mathbf{D}_t + a_3^j S_t \qquad & t = 1 \ldots T \\ + a_4^j W_t + a_5^j E_t + \epsilon_t \qquad & j = 1 \ldots 4, \\ \epsilon_t \sim N(0, \sigma^2), E(\epsilon_t \epsilon_{t'}) = 0 \text{ for } t \neq t', & \end{aligned}$$

where M_{jt} is the jth diversification measure on the tth farm, $\mathbf{Z}_t$ is a vector representing organizational forms (dummy variables for partnership, family corporation, and corporation; family farms are represented by the constant term). $\mathbf{D}_t$ is a vector of locational dummies; S_t (farm size) is acres cropped; W_t (wealth) is net worth per acres cropped; and E_t (experience) is the year the farmer started farming.[3]

The sample consists of data obtained from financial institutions on over 1,000 crop farms in the San Joaquin Valley in California. Most of these farms are not monocultures, and the potential to grow a number of crops is great.[4] This area seems well-suited for the study. We note that we know of few other large microsamples that would allow one to investigate the above relationships (it is particularly difficult to obtain net worth figures).

The Empirical Results

The regression results via ordinary least squares for the four measures computed on crop acreages are given in table 1.[5] At once it is clear that various null hypotheses on the coefficients may be sensitive to the measure of diversification used. However, all of the results suggest that farm size has a positive effect on diversification. This is in contrast to the meager and/or inconclusive evidence computed from the U.S. census by White and Irwin. These results shed some light on the nature of the trade-offs between scale economies and risk reduction mentioned above. That is, if there are large-scale economies in an enterprise, then one might expect larger farms to be more specialized. Clearly our results refute this hypothesis.

The net worth variable shows a significant negative effect on diversification (i.e., wealthier farms

[3] Assets are measured at current market value. Net worth is then calculated as assets minus liabilities. These calculations include all assets (including nonfarm) and all liabilities for each entrepreneur.

[4] Though there is some opportunity for complementary land-use cropping patterns, it is almost always the case that farms have a choice between crop patterns of varying degrees of complementarity. Not only do complementary cropping patterns (e.g., spring and fall vegetables) affect risk but they also reduce cash flow problems. Thus, increased liquid reserves may serve to reduce diversification.

[5] Because most of the diversification measures are bounded by zero and one, one may be suspicious of the assumption of normality. Further, one may wish an estimator which ensures that predicted values of M_j are in the interval (0, 1). A popular transformation to alleviate these problems is the logit transformation (Theil) where the dependent variable becomes $\ln[M_j/(1 - M_j)]$. However, such transformations are used for M_j in the open positive unit interval. Here, $M_j = 1$ is not only possible, but occurs more than 100 times in the data. Hence, ordinary least squares estimators will be presented.

relationship. It also is determined that there is a "significant" negative relationship between diversification and measures of financial "well-being." Finally and somewhat unexpectedly, farmer experience or age exhibits a positive effect on diversification (*ceteris paribus*). That is, younger or less experienced farmers are less diversified.

Theoretical Considerations

Certainty theory gives little explicit insight as to predicted diversification patterns unless three facts are known: (*a*) the nature of the production possibility curve, (*b*) the nature of constraints on firm choice, and (*c*) the prices of inputs and outputs. However, it is well known that increasing returns to scale may promote specialization by reducing the concavity of the transformation surface—or making it convex (White and Irwin).

When uncertainty is introduced, the model becomes more complex and diversification is usually promoted if the decision maker is risk-averse and the covariance of enterprise returns is zero or negative. For later reference, we shall state briefly the results of several theorems assuming stochastic linear technology and risk aversion.

The basic theorem is that if returns in two activities are independently and identically distributed, then diversification is optimal with equal proportions in each activity (Samuelson). Hadar and Russell have generalized Samuelson's results for a number of cases. The result of interest here is that diversification (not necessarily equal proportions) is optimal when returns have equal means but covariances are negative. These results suggest that diversification is likely to be optimal for a risk averter. However, large positive covariances, large disparities in mean returns (e.g., scale economies) or resource constraints may provide incentives for specialization. For example, assuming independence of returns, it can be shown that under risk aversion, optimal production levels of crop activities are found by weighing marginal increases in expected profits against marginal increases in risk (variance). Further, as farm size increases, all activity levels increase if there are sufficient increases in the marginal expected return with respect to the marginal increases in variance. (Therefore, if diversification were measured by the number of active enterprises, diversification would increase with size.) These results emphasize the potentially crucial nature of the trade-off between scale economies and benefits from diversification.

Aside from farm size, a number of potentially interesting variables may affect diversification choices. These include net worth, experience of the farm operator, form of ownership (e.g., family farm, corporation), and dummy variables which delineate the activity choice set (primarily variables that indicate geographical location and the extent of irrigation). Net worth, experience, and organizational form may be rationalized to affect diversification in a risk-preference framework as well as alternative models of behavior. For example, learning by doing may lead to incentives for specialization or, greater experience may change risk preferences. Also, one might expect wealthier farmers to be less risk-averse, if the concept of decreasing risk aversion is applied in a cross-sectional sense, and perhaps less diversified (Markowitz).

Scalar Measures of Diversification

Because the primary purpose of this study is to conduct an inductive inquiry concerning diversification and the above socioeconomic variables in a cross-section of crop farms, it is now necessary to become more precise regarding measures of diversification. Because of data limitations, it is necessary to restrict the indices to include only on-farm agricultural production activities.[2] Two measures typically used are the number of crops grown and the maximum over-crop proportions of sales of a particular crop (see White and Irwin). For the cross-sectional analysis, it is argued that both net income and crop acreages are potentially interesting variables over which to define diversification. The disparity between these two approaches can be illustrated with two examples. If a farm grew 10 acres of strawberries and 1,000 acres of wheat, with each activity yielding $50,000 net income, then clearly, for many uses, acreage proportions may be a deficient measure of diversification. Similarly, suppose a farm grew 505 acres of wheat and 505 acres of tomatoes; yet, due to random forces, income on tomatoes was $5,000 and income on wheat production was $100,000. In such case, income proportions may be a poor measure of diversification (see also Gardner and Pope).

A great deal of research on diversification has been directed toward single-valued measures. However, when a vector of information is collapsed into a scalar, problems can arise (see, for instance, Scherer, pp. 67–69). Clearly, the propriety of a diversification measure depends on the nature of the problem studied. A central question posed here is, "Are larger farms more specialized than smaller farms and is there a systematic relationship between diversification and other farm characteristics?" The approach taken is to utilize a wide variety of diversification measures in order to ascertain if the answer to this question is robust to the diversification measure used. Hence, four measures of diversification are considered: each has desirable properties and is defined over net income and acreage proportions and has been used in empirical

[2] Roughly speaking, the farm in this study is defined legally. If a limited partnership held farming enterprises in three locations, these would be listed as a single farm; similarly for corporate interests. However, when the farming enterprises are not in the general study area, they are excluded in the farm definition and its associated acreages.

Diversification in Relation to Farm Size and Other Socioeconomic Characteristics

Rulon D. Pope and Richard Prescott

Interest by agricultural economists in farm diversification is evident in published research. Since the early work of Markowitz and Heady, attention has focused mainly on mean-variance portfolio approaches (Johnson; Stovall; Carter and Dean; Greve, Plaxico, Lagrone). These studies generally focus on the normative issue of optimal diversification under uncertainty. In the present paper, a positive examination of diversification using detailed microdata is undertaken.

There are several fundamental reasons why diversification may be of interest. First, the relationship between diversification and farm size is an indicator of trade-offs between risk reduction and possible economies of size in a particular activity. That is, if there are substantial economies of scale in a particular activity, one clearly gives up a large expected return in order to insure against risk through diversification. Second, there is policy interest in promoting diversified small farms. In a recent paper prepared for the Congress by the Congressional Budget Office (*Public Policy and the Changing Structure of American Agriculture*), several policy tools were proposed to "discourage the expansion of family-size farms into larger-than-family-size farms" (p. 63). Two such proposals which are particularly relevant here are as follows.

(*a*) "Commodity program benefits could be targeted to small, diversified farms. This could be accomplished by gearing program payments to farm size or existing ownership patterns, and by requiring two or three enterprises per farm for program eligibility" (p. 63).

(*b*) "Public research and information could be aimed exclusively at small and part-time farmers. Diversified farming, labor-intensive production practices, organic farming, and direct marketing would be key research topics" (p. 64). The implication appears to be that a negative correlation exists between size and diversification.

Finally, the relationship between diversification and the form of ownership, wealth, and other variables of interest has policy significance as well. For example, it is of interest to determine whether corporations are more specialized because of the risk-spreading nature of the corporate form of ownership.

Among the most prominent and recent studies of diversification and size is that by White and Irwin. Using aggregate U.S. Census data and comparing diversification across farm classes, they conclude that "Census data have suggested some connection between size and specialization in the past" (p. 210). Generally, the data suggested that larger farms are more specialized, but the data are not conclusive for all farm types and classes. Furthermore, the measure of diversification used was "Sales of Primary Product as a Percent of Total Sales by Farm Class" (pp. 196–7).[1] Given the level of aggregation and the rough measure of diversification used, it would seem beneficial to further study diversification at the microlevel.

The purpose of this paper is to examine the relationship between farm size and other socioeconomic variables and diversification in a large cross-section of California crop farms. As in the White and Irwin study, the diversification measures are limited to farm production activities and do not include income from nonfarm sources or other farm sources such as custom hire. Though some information is available from the Census regarding the general nature of the relationship between farm and off-farm income, it seems as though less is known regarding off-farm or "other" activities as compared to farm production activities. However, it is known that smaller farms generally have a larger proportion of their income from nonfarm sources (U.S. Department of Agriculture). This is particularly true of farms with less than $40,000 of sales. Although a majority of farms in our sample exceed this figure, it is not known how much income is derived from various other sources and how this income may vary with farm size and other variables of interest. Given this limitation of the data employed here, diversification in production is examined using measurements on both net income and acreage.

Contrary to earlier research findings, it is found that, using any of four measures of diversification considered, there is a strong indication of a positive relationship between diversification and size. Further, some evidence suggests that the form of ownership and diversification exhibit a "significant"

Rulon D. Pope is an associate professor of agricultural economics, Texas A&M University, and Richard Prescott is an economist with the U.S. Department of Agriculture.

The views expressed in this note should not be attributed to the USDA.

[1] Primary product includes broad crop classifications, e.g., cash-grain, cotton, vegetable, fruit and nut, poultry, dairy, livestock, and other field crops.

risk premiums of farm and nonfarm investors are influenced by tax, credit, and farm policies, and resulting implications for farm size, ownership, and control (Raup, Carter and Johnston).

region to .36 in the Lake region. While the R^2 values appear rather low, they generally are consistent with values reported elsewhere for individual securities (Sharpe 1978, Modigliani and Pogue).

Implications and Limitations

The low beta values imply that investment in farm real estate at national or regional levels contributes little systematic risk to a well-diversified portfolio. The remaining nonsystematic risk that is attributed to unique supply and demand conditions of agriculture largely could be eliminated by effective diversification. Resulting rates of return required to hold a claim on U.S. farm real estate in a well-diversified portfolio of stocks and bonds are only slightly above the rate on an asset like nine- to twelve-month government securities. For example, the risk premium required for a claim on farm real estate at the national level given a beta of .19, a risk-free rate of 8% and an expected rate on the market portfolio of 12%, is 0.76% = .19 (.12 − .08). The required return then is 8.76%. The highest regional risk premium (1.16%) occurs in the Corn Belt, with the highest beta value.

Besides the low-systematic risk, positive alpha values imply that farm real estate has offered substantial premiums above those for systematic risk. Hence, for this historic period, returns data, and market index, investments in farm real estate by well-diversified investors appeared to outperform the market and most individual assets too.

Evaluating these CAPM results involves how well the CAPM assumptions correspond to the characteristics of farm real estate investors and markets, and how well the results accord with intuitive judgments about risk and return from farmland. Impacts of inflation are especially perplexing and not well-developed in CAPM analyses. For example, a possible reason for low beta values on farm real estate is greater unanticipated inflation in the latter part of the sample period. Following evidence cited by Lintner (1975), in periods of a year or less unanticipated inflation may lower returns to stocks and bonds, while raising returns to farmland. Moreover, if investors in farm real estate correctly anticipated the inflationary increases in farm returns, then the own-variance and CAPM risk measures reported here are overestimated because of the CAPM's failure to reflect this expectations phenomenon. Risk associated with farm real estate investments would then be related to variance about the anticipations rather than about actual values. How returns for real estate, stocks, and bonds respond to inflation and the implications for risk modeling are important areas needing further study.

Real estate generally is considered a relatively illiquid asset caused by high transactions costs, tax obligations, indivisibilities, and thin markets with less than 5% of total farmland changing hands annually. Hence, the CAPM's failure to account for these effects may bias upwards the resulting returns to farmland. Farmers also are not considered well-diversified with farm ownership resting heavily in rural areas (USDA). Hence, following Levy about the effects of limited diversification, these CAPM results for farm real estate may understate the true beta values and overstate the true alpha values. Finally, the historic analysis raises numerous concerns about effects of data quality, aggregation levels, and imputation of returns to unpaid farming resources.

Despite these shortcomings, the CAPM offers reasonable evidence that farm real estate has low risk relative to other assets and is a promising candidate for risk reduction in well-diversified portfolios. Moreover, the CAPM systematically treats risk pricing in an equilibrium framework that, in turn, yields important insights about the effects of investor behavior and market characteristics. It also broadens the framework for evaluating how

Table 1. Summary Statistics for Rates of Return on Farm Real Estate and the Market Indexes

[a] Standard deviation.
[b] Coefficient of variation.

viations were calculated from the annual time series of each measure.

Among regions, the mean excess return ranged from 5.70% in the Southern Plains to 8.76% in the Northeast. The Southeast also exhibited a high mean rate of return while relatively low rates of return occurred in the Appalachian and Great Plains regions. Coefficients of variation for excess returns were highest in the Corn Belt, Great Plains, and Appalachian regions and lowest in the Pacific and Northeast regions.

The excess rate of return on the stock, bond, and farm real estate index averaged 4.74% over the period with a standard deviation of 8.67, giving a relatively high coefficient of variation of 1.83. Mean excess rates of return for the stock and stock-bond indexes alone are 7.44% and 4.31%, respectively, with standard deviations of 14.42 and 10.33. Hence, based solely on their own standard deviations relative to mean returns, farm real estate exhibits lower variation relative to mean returns than does the market index and its stock and bond components. Kost obtained similar results for the stock index using an earlier time period. Moreover, the higher variation for the market index arises from the greater variation in annual change in value. For example, the coefficient of variation for the value-return to the market index (1.88) is much greater than the coefficient for farm real estate (.71) at the national level and for all regions. In contrast, the "production return" on the market index and its components has a higher mean and lower standard deviation than does farm real estate at national and regional levels.

Initial regression results for the CAPM using equation (3) have Durbin-Watson values falling below the lower boundaries and high first-order correlation coefficients among successive disturbances. As a result, regressions were reestimated using the Cochrane-Orcutt iterative method (Kmenta, p. 287). Results in table 2 for the national model show a beta value of .19 for farm real estate which is not significantly different from zero at the .01 level. Results for regional models also indicate consistently low beta values ranging from .10 in the Northeast, Great Plains, and Mountain regions to .29 in the Corn Belt. None of the beta estimates differ significantly from zero. However, standard errors are relatively high and sample values of confidence intervals are relatively wide, so that the sample estimates leave much uncertainty about values of beta. This may be due in part to the relatively small sample size, although the data period already is rather long. Still, beta values appear to fall in the zero to .5 range, which makes them comparable to betas for long-term bonds and lower than betas for most common stocks which fall in the .5 to 1.5 range (Sharpe 1978). Moreover, betas calculated from annual returns likely are less than those calculated from monthly returns, as usually occurs for common stocks, perhaps because annual periods give more time for nonsystematic effects.

The national model shows an alpha value of 4.78, which differs significantly from zero. Alpha values also are high in all regions, ranging from 3.91 in the Southern Plains to 7.62 in the Northeast. Only the Corn Belt, Great Plains, and Lake regions show values that do not differ significantly from zero, although they still are relatively high. An R^2 of .26 for the national model, which differs insignificantly from zero, indicates that about 26% of the variation in national farm real estate returns is associated with changes in returns of the market index. Values of R^2 range from a low of .04 in the Appalachian

Data and Estimation Procedures

Risk premiums on farm real estate are estimated by regressing a time series of excess annual rates of return on farm real estate against excess annual rates of return of a market portfolio. The 1950 through 1977 period is free of dominating events like World War II and the Great Depression. The risk-free asset is investment in nine- to twelve-month U.S. government securities with average annual yields obtained from the *Federal Reserve Bulletin*.

In principle, the market portfolio contains values of all assets that contribute to wealth. Because the true market portfolio and its rate of earnings are virtually impossible to measure, CAPM applications use various indexes as market proxies. The index used here is a combined stock, bond, and farm real estate index with annual returns to each asset weighted by their outstanding market values in each year. The stock index is the widely known Standard and Poors 500, a value-weighted average of 500 stocks, mostly traded on the New York stock exchange. Annual rates of return are measured as the sum of the annual dividend rate on the Standard and Poors (SPP) index, plus the annual percentage change in value of the index.

Annual holding period yields for three types of bonds are measured using price indexes for corporate bonds (industrial, utility, and railroad), domestic municipal bonds, and taxable U.S. Treasury bonds as the sum of (*a*) the coupon rate for each bond index divided by the beginning-of-year bond price, and (*b*) the annual percentage change in value of each bond's price index as reported in the *Survey of Current Business* (U.S. Department of Commerce) and *Trade and Securities Index* (SPP). The measure of annual returns to farm real estate at the national level for use in the index is described below. Annual outstanding values used as weights in forming the stock and bond portion of the market index were obtained from flow of funds data reported by the Federal Reserve Board of Governors, and farm real estate values were from the U.S. Department of Agriculture's (USDA) *Balance Sheet of the Farming Sector*.[2]

Annual rates of return on farm real estate are estimated at the continental U.S. level and for ten farm production regions used in *Farm Real Estate Market Developments* (USDA). Those levels of aggregation are used because data are available and for regional comparisons. Annual rates of return are the sum of annual percentage changes in the index of farm real estate values (1 February) per acre plus annual rates of return to land from farm production.

For the national model, annual percentage changes in the index of farm real estate values are obtained from selected issues of *Farm Real Estate Market Developments*. For regional models, annual percentage changes of farm real estate values are estimated by deriving a weighted average of individual state index values, using each state's value of land and buildings as weights. These indexes primarily reflect changes in real estate values, although annual improvements are included too.

Annual rates of return from farm production result from dividing an estimate of returns to farm real estate in each year by the beginning-of-year (1 January) farm real estate value as reported in the *Balance Sheet of the Farming Sector*. Annual returns to farm real estate are estimated with an approach formerly used by USDA. This approach first estimates net income from production as total net income of farm operators from farming plus cash wages and perquisites of hired labor, interest on real estate and non-real estate debt, and net rent to landlords, minus the imputed portion of rental value of farm dwellings. Net income from farm production then is reduced by imputed returns to total farm labor, management, and non-real estate assets to yield a residual return to farm real estate. Annual returns to non-real estate assets are estimated as the sum of interest paid on non-real estate debt and opportunity costs on equity in non-real estate assets charged at the three-month U.S. Treasury Bill rate.[3]

For the regional models, estimates of annual net income from production were obtained by summing individual state data taken from *State Farm Income Statistics* (USDA). Because no state estimates of imputed returns to labor, management, and non-real estate assets are available, regional estimates reflect proration of national figures among regions in proportion to their contribution of net income from production to the national total.

Results

Results first are reported as means, standard deviations, and coefficients of variation for various return measures for farm real estate and the market index during the 1950–77 period, and then as estimates of beta values and other regression measures for the CAPM. Results in table 1 indicate that the mean annual excess rate of return on farm real estate at the national level over the time period was 6.60%, with a standard deviation of 6.31. This excess return measure is the sum of the annual change in the index of farm real estate values (7.70%) plus the mean annual rate of return to real estate from production (3.06%) less the mean annual rate of return on the risk-free asset (4.16%). Standard de-

[2] Averages of annual weights for each type of asset in the market index during the 1950 to 1977 period are stocks 54.8%, corporate bonds 10.6%, municipal bonds 8.5%, U.S. Treasury bonds 8.2%, and farm real estate 17.8%. The annual proportion of Treasury bonds declined through the period while proportions of corporate and municipal bonds increased. The proportion of farm real estate was higher in early and later years of the period.

[3] This imputation procedure ignores any risk premium on equity in non-real estate assets which likely understates their returns and overstates resulting returns to farm real estate.

Capital Asset Pricing and Farm Real Estate

Peter J. Barry

Increasing interest in and policy concerns about agricultural investments by nonfarm investors, especially in farm real estate, and consideration by trust firms and other investment companies of mechanisms for channeling outside equity capital into agriculture make it important to evaluate agriculture's risk-return characteristics relative to those of other investments. Accordingly, this paper uses the capital asset pricing model (CAPM) to estimate risk premiums required to hold farm real estate in a well-diversified market portfolio. Risk premiums are estimated for farm real estate at the national level and for ten farm production regions of the United States. CAPM results then are evaluated in light of farm real estate's unique characteristics.

Capital Asset Pricing Model

As originated by Sharpe (1964) and Lintner (1965), the CAPM shows that equilibrium rates of return on individual assets adjust to levels that reflect the risk which each asset contributes to a market portfolio of all assets. Investors holding such portfolios need only require compensation for the total market, or systematic, risk that is common to all assets in the portfolio and that cannot be diversified. Consequently, premiums ascribed to individual assets need only compensate for their systematic risk.

In market equilibrium the CAPM expresses the relationship between an asset's expected return and its systematic risk in a linear fashion as the sum of a risk-free rate and a risk premium reflecting the product of the price and quantity of risk:

$$R_j = i + \left[\frac{E(R_m) - i}{\sigma_m^2}\right] c\sigma_m\sigma_j, \tag{1}$$

where R_j is the expected return of asset j, i is a risk-free interest rate, $E(R_m)$ and σ_m^2 are the expected return and variance, respectively, of a market portfolio, and $c\sigma_m\sigma_j$ is the covariance of returns between asset j and the market portfolio, with σ_j as the standard deviation of returns for asset j and c as the correlation coefficient.

In empirical analysis, the model is modified to the familiar beta (β) approach:

$$R_j - i = [E(R_m) - i]\beta_j, \tag{2}$$

where $\beta_j = (c\sigma_m\sigma_j)/\sigma_m^2$. Now excess returns (above i) on asset j are expressed as a function of excess returns on the market portfolio where β_j measures asset j's systematic risk.[1] In the absence of data on expectations, CAPM relationships usually are estimated by regressing a time series of excess returns for individual assets against a time series of excess returns for a market portfolio:

$$R_{jt} = \alpha_j + \beta_j R_{mt} + e_{jt}, \tag{3}$$

where R_{jt} and R_{mt} are excess rates of return on asset j and the market portfolio, respectively, in period t, and e_{jt} is the error term. The anticipated value of alpha is zero, and nonzero estimates imply returns or losses in excess of those needed to compensate for systematic risk.

Proponents of CAPM cite its microfoundations, relative simplicity, and potential testability for a wide range of applications, while skeptics are concerned about the model's restrictive assumptions on characteristics of asset markets and investors. Markets are assumed highly efficient so that expected returns quickly and fully reflect available information; no transaction costs, tax obligations, or indivisibilities exist; and, for risk-free financial assets, lending and borrowing rates are equal. Investors are assumed risk-averse, well-diversified and to hold homogenous expectations that are fully characterized by means and variances over single-period horizons.

Much attention has been given to the CAPM's explanatory capacity and to the consequences of modifying these assumptions (Sharpe 1978, Jensen, Modigliani and Pogue, Ross). Appraisals are mixed, caused, in part, by problems with data and estimation procedures. However, empirical tests appear to support the view that beta is a useful risk measure and that high beta securities are priced to yield high rates of return. Levy also provides important insight into pricing relationships for assets held by relatively few investors who have relatively undiversified portfolios. He shows theoretically that an asset's equilibrium price is determined by a weighted average of the systematic risk it contributes to the portfolios of each of its investors; and that, for undiversified investors, the asset's own variance contributes importantly to this systematic risk relative to its covariance with other assets.

Peter J. Barry is a professor of agricultural economics at the University of Illinois.

The author gratefully acknowledges the review comments and suggestions provided by C. B. Baker, David Lins, and two *Journal* reviewers.

[1] Systematic risk of asset j equals β_j times σ_m. However, since σ_m is common to all assets, β_j itself shows an asset's systematic risk.

[b] The numbers listed here reflect the average percentage rate of price appreciation over the decade.

did plan on intensive development, their properties would have a lesser value to prospective buyers. For other parcels, the Plan indicated land uses and intensities that were more flexible relative to current and expected development expectations. If these direct impacts were all that influence values, the resultant changes in property values would be relatively easy to predict. Unfortunately, the real estate market is not so simply analyzed: properties have values not only from direct uses but also from the enjoyment of neighborhood amenities. If the Plan could protect these amenities by preventing some of the adverse impacts of future development, land values in the park could have been enhanced. Thus, one could reasonably anticipate several separate forces resulting from enactment of the Plan. Some forces acted to shift relative values of properties classified into different use categories, while others acted on entire neighborhoods within the park. Some forces even may have acted on the park as a whole, shifting values there relative to values in adjoining areas.

The empirical evidence marshaled for this study suggests that the Plan did affect relative values for different land use classifications. Following the enactment of the Plan, relative prices for the five nonindustrial, private, land use categories shifted, with the less restrictive classifications showing the better relative price performance.

Land values within the park were largely unaffected relative to those in the out-of-park control area. In-park properties, taken as a whole, were estimated as having risen approximately 4% less per year than the out-of-park sample following the enactment of the Plan, but this is a small difference relative to historical fluctuations in the regional real estate market. Further testing of this conclusion could be obtained by increasing the sample size and by extending the period of analysis into the future. Only with an expanded effort could shifts in relative values of in-park and out-of-park land be definitively measured.

The empirical analysis presented here represents a promising method for evaluating the price impacts of alternative land use schemes. The ability of the technique to show the relative price impacts of land use programs, while holding other price-influencing variables constant, is not just of academic interest, but of a more general importance. Properly used, it can provide answers to questions often asked in the political arena concerning, for example, the equity implications of a zoning program that shifts land from one use classification to another. The measurement of yearly percentage increases in land values can help focus public perceptions and clarify the ultimate impact of land use schemes, thereby becoming a valuable tool for state and local planning officials.

assessors were used to identify properties for which significant improvements had been made in physical structures. Improvements to properties also were indicated by excessively high implicit rates of price appreciation over short periods. The rule of thumb used in the latter criterion was that an observation was deleted if the sale price increased 100% during a one-year holding period, 200% during a three-year holding period, and 300% after five years.

Other reasons for dropping observations were: transactions between individuals with the same surname, the prices for which may not reflect the true market values; missing information; and, because property values were trending upward during the period of analysis, observations where the sale price was less than 75% of the purchase price. In total, after deleting observations, there were 471 in-park observations and forty-five out-of-park observations. Of the total in-park observations, 278 were in the hamlet classification; seventy-one in moderate intensity; sixty-seven in low intensity; twenty-seven in rural land; and twenty-eight in resource management.

Model Results

The estimated yearly percentage rates of price appreciation for all in-park land, all out-of-park land, and in-park land by land use classification are presented in tables 1 and 2. For all regressions, the years 1950–69 were separated into five-year groups except where the total number of observations was less than sixty, in which case the years 1950–69 were separated into ten-year groups. The statistical significance is indicated for all the regression coefficients.

The wide fluctuations in the out-of-park estimates, due mainly to the small data set, make comparison of in-park and out-of-park land value changes, shown in table 1, difficult. Summary data for the period immediately following the passage of the Plan, 1973–75, show that the sample of in-park properties, taken as a whole, appreciated at the somewhat greater rate of 22.9% per year for the same period. Statistically, however, the difference in rates of appreciation is not significant. One interesting comparison is between the price appreciation in the pre-Plan years, 1970–72, and the post-Plan period, 1973–75. Prices during the former period appreciated more slowly than in the latter period. This may be explained, in part, by the uncertainty surrounding the final outcome of the master plan for management of the Adirondack that was being prepared from 1971 to 1972. While land buyers knew that some form of regulation probably would be imposed on land transactions within the park, they did not know the specifics of the Plan, and may have been hesitant to enter into the market. This dampening of demand for land is a natural result of buyers not wanting to purchase land when the development possibilities for the land are not certain.

Table 2 portrays rates of yearly price change by land use classification within the park. Averages of the point estimates for the years 1970–72 and 1973–75 also are reported. Because of the relatively small sample sizes for some of the land use classifications, these averages should be more representative of actual rates of price change than the individual price estimates. Using these averages, land use groups can be ranked by their price changes subsequent to passage of the Plan. Hamlet parcels showed the greatest relative price increase (19.0%) followed by light intensity (15.1%), moderate intensity (10.7%), rural land (2.8%), and resource management (−3.8%). This ranking tends to provide empirical support for the theoretical impacts predicted earlier—that hamlet land and already existing small parcels should increase the most in relative value. The resource management classification actually showed a decline in value, although the erratic pattern of price behavior makes any interpretation of the estimates for these lands questionable.

Conclusions

That the broad set of land use controls in the Adirondack Park Plan affected expected future land use decisions is certain. Specific properties were severely limited as to potential future uses and development intensity. The owners of many of these parcels no doubt were disappointed, for even if they

measure the appreciation of land values in the park relative to land values outside the park.

The virtue of the methodology described below is that it allows the researcher to hold the sample constant over the period of the analysis. As will be discussed later, this is accomplished by carefully scrutinizing the data before applying them to the regression model. If additional data were available, another technique, hedonic analysis, which has been used to measure the value of environmental benefits as well as the value of different characteristics of land parcels, could have been used (Abelson). The technique described here is useful for its simplicity and can be used when little interest is attached to the value of specific site characteristics.

The Model

The derivation of the regression model for estimating the yearly percentage rates of price appreciation is developed below. Let B_t equal the percentage increase in price during year t, and $U_{itt'}$ equal an error term signifying the amount by which the given observation deviates from the prediction of the rate of price appreciation. The ratio of the final price of property i in year t' to the initial price in year t, $R_{itt'}$, can be expressed as

(1)

$$R_{itt'} = (1 + B_t)\ (1 + B_{t+1})\ .\ .\ .\ (1 + 1B_{t'})\ (U_{itt'}).$$

Taking natural logarithms of (1), gives

$$r_{itt'} = b_t + b_{t+1} + \ .\ .\ .\ + b_{t'} + u_{itt'}, \tag{2}$$

where the lower case letters denote natural logs of the expressions in parentheses on the right-hand side of (1).

Date Exchanged	Price	Date Exchanged	Price	Classification
30 June 1966	2.20	28 April 1976	\$4.50	Hamlet

An equation for estimating $r_{itt'}$, given observations of percentage increases in price and the length of time a parcel was held, can be developed by letting x_t equal 1 if the property was held during year t, a fraction of 1 if it was held for a fraction of year t, and 0 if the property was not held at all during year t. Thus,

$$r_{itt'} = b_t x_t + u_{itt'}. \tag{3}$$

Equation (3) is more readily visualized as a linear equation if expressed in matrix terms.

$$\mathbf{R} = \mathbf{X}B + \mathbf{U}, \tag{4}$$

where $\mathbf{X}$ is a $N \times T$ matrix of observations on the independent variables, the x_t's; $\mathbf{R}$ is a $N \times 1$ vector of observations on the dependent variables, the $r_{itt'}$'s; $\mathbf{B}$ is a $T \times 1$ vector of parameters to be estimated, the b_t's; and $\mathbf{U}$ is a $N \times 1$ vector of disturbance terms, the $u_{itt'}$'s.

Using (4), the ordinary least squares (OLS) estimate, $\mathbf{B^*}$, of the $\mathbf{B}$ matrix is given by

$$\mathbf{b^*} = (\mathbf{X'X})^{-1}\mathbf{X'R}. \tag{5}$$

The estimates of the b_t's contained in the $\mathbf{B^*}$ vector can be found by solving for the yearly rates of price appreciation in (1) by calculating

$$\hat{b}_t = e^{b^*}(t) - 1, \tag{6}$$

where $\hat{b}_t$ is the estimate of the percentage increase in price in period t and the $b^*(t)$ is an individual element in the $\mathbf{B^*}$ vector.

The data required for the application of this model to the assessment of the price impacts of the Plan are pairs of transaction prices for the same parcels of land and the dates of the transaction. To this end, land deeds for five towns with the Adirondack Park and one town outside the park were examined for the years 1950–76, and the appropriate data obtained. The five in-park towns (Cargoa, Webb, Fine, Harrietstown, and Westport) were chosen as a cross-section of the entire park and represent, as closely as possible, five distinct geographical regions in the park (Champlain, High Peak, southeast central, southwest central, and northwest). The out-of-park town (Redfield) is located in the Tug Hill region of New York and was chosen as a comparable resort area. Although the deeds did not contain the actual purchase or sale prices for the parcels, they did contain the tax paid on the transaction, recorded as the value of the tax stamps for the sale or purchase. Because only relative price changes were to be measured, tax stamp information would adequately reflect true relative market prices.[2]

An example of a typical observation is

In the few instances when one parcel changed hands three times within the period of the test years, the transactions were included as two observations.[3]

With the data arranged as above, inconsistent observations were dropped from the data base. Data were deleted if property improvements had been made during the holding period; inclusion of these observations would have violated the assumption of constant quality of the land parcels. Visual inspections and interviews with the town

[2] Because the stamps record only value increments of \$500, use of the stamp data could lead to the overstatement of prices on an unknown number of properties. Depending upon whether the initial, final, or neither price in a pair was overstated, the relative prices on a given observation pair could be understated, overstated, or accurate. This may be interpreted statistically as an error in variables problem in the dependent variable.

[3] As Baily, Muth, and Nourse note, this introduces a slight bias to the estimates.

of potential development options of parcels within the park. By limiting the development alternatives of any particular lot, the Plan, in some cases, also affected the characteristics attributed to adjoining parcels which were not restricted or were less restricted than the controlled areas. For example, such characteristics as view or aesthetics may be enhanced in parcels adjacent to sites where minimum acreage restrictions are in effect.

The direct impact of development size limitations can be hypothesized as almost certainly negative for all but the hamlet use classification (where no site restrictions were imposed) because minimum size guidelines restrict rather than enhance the range of potential development options. With no restrictions, the range of options is greatest and the value of individual development size can be maximized. Relative impacts for different parcels will depend upon the magnitude of the adjustment in development expectations. The indirect impacts of size limitations are not easily diagnosed. Limits on the minimum acreage for development should protect both views and aesthetics derivable from adjoining parcels. In economic terminology, this reduces the likelihood of externalities which might otherwise occur were adjacent property owners free to develop as they see fit.

It should be noted that there are a number of additional complications as to the final effect of land use classifications on site values. In a region where land planning and use control were virtually nonexistent, there is now one of the most comprehensive systems in the country. But land buyers and sellers have little precedent from which to predict the Plan's impact on land values. Developers have little basis for judging the most profitable way of packaging and developing the regulated land. Furthermore, although the partial impact of a single regulatory strategy (e.g., lot size limitations, permits, or grandfather and children's clauses) on a single site characteristic (e.g., view, lot size, etc.) may be predicted reasonably well, the overall combined impact on property values is far less easily determined. Many of the impacts tend to be offsetting and of unknown relative magnitudes. Moreover, the timing of the effects is highly speculative. The Plan introduced a new element of uncertainty into the Adirondack land market, and it may take several years before the participants in the market feel confident that they know how all of the regulations will be interpreted and enforced. As a result, land market values will almost certainly move slowly to new equilibrium levels.

Despite these caveats it is possible to develop some tentative hypotheses concerning the land price impacts of the Plan's land-use intensity guidelines. Among the separate regulations of the Plan, the restrictions on lot size are likely to be the most significant in affecting relative land values between the different land use classes. Based on the previous discussion, the following two hypotheses can be formulated: (*a*) Hamlet land and already existing small parcels should increase the most in relative value as the expected supply of these parcels decreases. (*b*) Relative values for large parcels, particularly in the most restrictive use classifications (such as rural or low intensity land) should fall as development expectations are revised downward. In addition to these hypotheses, it is likely that the value of park land relative to nearby land outside the park would change, especially in the short run. Although no specific hypothesis is developed for this impact, an assessment of its magnitude and direction would be useful.

The remainder of this paper is devoted to an empirical assessment of the actual price impacts, and the extent to which these tentative hypotheses are supported by the evidence.

Price Estimation Methodology

While there have been several previous studies on the economic effects of the Plan that help shed some light on the probable price impacts, these analyses stand on weak methodological grounds and do not provide any information on the relative price impacts among different land use classifications. One of the most glaring problems is the failure to isolate price effects due to the Plan from price effects caused by other influences. For example, the New York State Board of Equalization and Assessment found that during the first eleven months following the enactment of the Plan, average per acre sales prices for parcels of Adirondack land rose at a higher rate than land prices throughout New York State (21.4% vs. 14.8%). Although this finding might suggest that the Plan benefited the Adirondack region relative to the rest of the state, the analysis did not take into account the possibility that average parcel size in the sales and transactions may have changed or that property improvements within the park may have exceeded those outside the park. Both of these factors may have caused prices in the Adirondacks to experience relatively higher rates of increase.

The technique used in this paper is designed to cope, at least partially, with the sort of problems described above, through the use of more detailed information on land values. The intent is to estimate the yearly rates of price appreciation for land located both within and outside the park boundaries using an approach suggested by Anderson for measuring price appreciation for art. For in-park land, separate price series were estimated for parcels in each of five private, residential land use classifications used by the Adirondack Park Agency.[1] By comparing the estimated rates of price appreciation, one can test the hypothesis that land appreciated differently among the five land use categories. In addition, this approach can be used to

[1] Values for lands classified as industrial were not included in the analysis.

Land Price Impacts of the Adirondack Park Land Use and Development Plan

Robert C. Anderson and Roger C. Dower

The enactment of any ambitious land use control system raises a variety of concerns about the effects of the system on land values. Restrictions on allowable use typically are opposed by the affected landowners in that such controls may depress market value. Owners of land not encumbered by controls may be far more sanguine, believing the demand for developable parcels will be enhanced. These concerns are likely to be expressed whenever land use controls are imposed. A particularly strong reaction followed the legislation that created the Adirondack Park Agency in New York State. The 1973 enactment of the Adirondack Land Use and Development Plan by the agency introduced sophisticated land use controls where virtually no regulation on private land had existed previously. One key policy issue that arises is the impact of this new set of controls on property values. The need for empirical answers to this issue is prompted by concerns over the equity of the program. Land value changes determine, in part, who pays and who benefits from the program. This concern is certainly not unique to the Adirondack land use control case, but has been raised in the context of economic evaluation of land use controls in other regions as well (Kneisel).

This paper addresses the issue of land price impacts. Specifically, a technique is described for measuring the price impacts of land use control systems and is applied to the Adirondack Park Land Use and Development Plan.

New York's Adirondack Park contains some six million acres, three-fifths of which are now in private ownership and two-fifths in state ownership. Although efforts to manage this collection of private and public holdings of mountains, lakes, forests, and villages date at least to the creation of the State Forest Commission in the 1800s, a fully comprehensive plan was not enacted until 1973. In that year the Adirondack Land Use and Development Plan (hereinafter referred to as "the Plan") was signed into law. The Plan separated the park into several land use intensity zones. These were, ranging from lowest to highest permitted intensity of development: resource management, rural, low intensity, moderate intensity, hamlet, and industrial. The most critical restriction on residential development is the intensity guideline for each of these classes. In general, moderate intensity land cannot be developed with a density greater than 1.28 acres per house; low intensity land must allow 2.3 acres per house; rural land 8.5 acres per house; and resource management 42.0 acres per house. No intensity guidelines apply in the industrial and hamlet areas.

In addition to the intensity guidelines, the Plan also created a permitting authority for many projects to be exercised by either the park agency or the appropriate local government. Permit authority can be used to veto certain projects, but the more common usage is to impose conditions on development. Typical conditions include architectural standards, erosion control measures, screening and planting requirements, and prevention of view disruption. Another provision of the Plan granted through a "grandfather clause" the rights to develop subdivided but as yet undeveloped parcels. Furthermore, under the "children's clause," owners of large parcels may split off smaller sites for their children.

The following discussion presents a methodology for estimating how such a system of land use intensity controls would affect market values of the different classifications of land. Other regulatory aspects of the Plan will not be addressed except to the extent that they affect the price impacts of the land use intensity provisions.

Estimation of Price Impacts

It is established theoretically that public programs directed at controlling the uses of land tend to shift values within the controlled area as well as lands adjacent to that area (Ministry of Working and Planning). The value of a particular parcel of land is derived from the marketplace valuation of the characteristics that describe the site, such as size, views, access, site flora and fauna, and adjoining ownership. The imposition of a land use control scheme alters buyers' and sellers' expectations concerning individual site characteristics and therefore the value of the land.

The Adirondack Park Plan contracted the range

rise. High inflation has a clear effect in all projections by shifting the supply curve to the left, and thus decreasing output and increasing prices received. Prices received do not increase as fast as prices paid, however, so real prices fall.

Projections of Future Farmland Needs

Agricultural land needs are defined here in terms of cropland because it is clearly the most productive farmland use. Cropland is used not only for the direct production of food for human consumption, but it also indirectly supports much (if not most) of the United States' meat production.

The output projections in table 3 can be converted to cropland requirements through projections of future agricultural yields. In the optimistic projection, agricultural yields (agricultural output per acre of cropland) are expected to increase at an average annual rate of 1.75% from today to the year 2000, while in the pessimistic projection, agricultural yields are expected to show no increase (from the trends for the 1960s and 1970s, see table 2). In 1977, an agricultural output of 121 was supported by 413,000 acres of cropland (ratio = 0.293), so in the year 2000 the output-to-cropland acre ratio is expected to range from 0.293 (pessimistic projection) to 0.437 (0.358 in the middle range projection).

From table 3, it can be seen that, in the optimistic projection, rapid increases in yields and relatively low output will make it possible to retire about one-third of the present cropland base from production by the year 2000. In the pessimistic projection, however, substantially more cropland will be needed in order to support the large increases in farm output in the years ahead. In the most pessimistic case, the nation will need 154 million acres of additional cropland by the year 2000. This is more than the 135 million acres of potential cropland currently available.

It should be noted, however, that there may be an important limitation in this part of the analysis. In estimating future agricultural yields, it has been assumed implicitly that the present "mix" of agricultural output will be maintained in the future. However, under high demand pressures, it may be possible to shift some cropland away from the indirect to the direct production of food for human use. Such a shift could increase agricultural yields and substantially reduce the possibly high demand pressures on our land resources.

Implications for the Future

Our estimates of cropland needs in the year 2000 delineate a wide range of possible situations. In the optimistic projection, it will be possible to retire up to one-third of the present cropland base from production over the next quarter century, and, in this case, the urbanization of farmland is probably not of national concern. In the pessimistic projection, however, American agriculture may need more additional cropland by 2000 than the 135 million acres of currently available potential cropland. Here, the continued urbanization of farmland could seriously constrain future increases in agricultural production.

Such a wide range of estimates of future cropland needs may not seem particularly useful, but actual conditions probably will fall somewhere in between. And unless the most favorable circumstances prevail, it will be necessary to bring some additional cropland into production to support future agricultural output. The urbanization of farmland serves only to exacerbate this problem, because, in order to expand the cropland base, it is necessary to replace that farmland lost to urbanization plus bring some nonfarmed land into production. Present trends indicate that urban expansion may effectively reduce the present cropland reserve by more than 10% and the present reserve of prime agricultural land by almost one-half by the end of the century.

We do not want to suggest that there will be an absolute shortage of farmland in the future. Clearly, under heavy demands for agricultural output, the price of farmland will be bid up and less productive land will be pushed into agricultural production. However, such a shift will decrease productivity and yields, further increase output prices, and increase erosion and other environmental costs. In addition, continued urbanization is not the only factor affecting future farmland availability. The agricultural land base may be reduced further in the future because of the continuing loss of topsoil to erosion, the depletion of groundwater and surface water supplies in the Southwest, and a possible reduction in the growing season in the northern perimeter of the country due to climatic shifts (Pimentel et al. 1975, 1976).

production, (*c*) a slowdown in technological advances in the agricultural sector and in the mechanization of agriculture, and (*d*) a return to the "usual" more variable weather pattern in the United States (Crosson 1977, National Academy of Sciences, Schneider). It is suspected that the 1967 price weights, which are used to measure the level of farm inputs in the productivity series for the 1970s, may not reflect the relative input prices that have existed in the agricultural sector since the rapid increase in energy prices in 1973. Barton and Durost, for example, have shown that the USDA farm input series is fairly sensitive to shifts in the underlying price weights. It thus appears to be prudent to project future agricultural output with a lower productivity estimate than that indicated by currently published figures. One percent per year seems to be a reasonable lower estimate of future increases in agricultural productivity.

Table 3 shows the results of the optimistic and pessimistic projections and also of a "middle-range" projection where demand and productivity are expected to increase as annual rates of 1.97% and 1.33%, respectively. In the optimistic projection, future agricultural output is expected to remain at about its current level of 121 (1967 = 100), while real prices (prices received divided by prices paid) will decline markedly (from 91 in 1977). In the pessimistic projection, however, agricultural output will increase substantially and real prices will also

Table 3. Alternative Projections of Agricultural Output, Prices, and Cropland Needs in the Year 2000

Scenario	Agricultural Output (1967 = 100)	Agricultural Prices (1967 = 100): Prices Received	Agricultural Prices (1967 = 100): Real Prices (*PR*/*PP*)	Cropland Needs (millions of acres)	Additional Cropland Needs Compared to 1977 (millions of acres)
1. Optimistic projection: demand up 1.17% per year; productivity up 1.66% per year; yields up 1.75% per year:					
Low inflation (4% annually)	127	380	73	291	−122(29.5%)
High inflation (8% annually)	111	739	62	254	−159(38.5%)
2. Pessimistic projection: demand up 2.77% per year; productivity up 1.00% per year; yields up 0.00% per year:					
Low inflation (4% annually)	166	621	120	567	154(37.3%)
High inflation (8% annually)	144	1207	101	492	79(19.1%)
3. Middle range projection: demand up 1.97% per year; productivity up 1.33% per year; yields up 0.88% per year:					
Low inflation (4% annually)	145	486	94	405	−8(1.9%)
High inflation (8% annually)	126	944	79	352	−61(14.8%)

unlikely to be challenged by 1985" (p. 47). This finding, however, has been vigorously challenged by Crosson (1978).

The plan of this part of the paper is simple. First, the NIAP system is used to predict equilibrium levels of farm output and prices in the year 2000 under alternative sets of future conditions. Second, these output predictions are combined with estimates of future agricultural yields in order to estimate future farmland needs.

The NIAP System

The NIAP demand-supply system as presented by Yeh is

(1) Demand: $$\ln Q_{d,t} = \ln\alpha_d + \beta_d \ln PR_t + (1 - \delta_d)\ln Q_{d,t-1} + \delta_d \sum_{t=to}^{t-1} g_{d,t} + g_{d,t};$$

(2) Supply: $$\ln Q_{s,t} = \ln\alpha_s + \beta_s \ln(PR_t/PP_t) + (1 - \delta_s)\ln Q_{s,t-1} + \delta_s \sum_{t=to}^{t-1} g_{s,t} + g_{s,t}; \text{ and}$$

(3) Market Equilibrium: $Q_{d,t} = Q_{s,t}$,

where $Q_{d,t}$ and $Q_{s,t}$ are the quantities of agricultural output demanded and supplied in year t (measured by the USDA index of agricultural output), PR_t is the USDA index of prices received by farmers in year t, PP_t is the USDA index of prices paid by farmers in year t, and $g_{d,t}$ and $g_{s,t}$ are the proportional shifts in demand and supply in year t (due to exogenous factors).

From other studies, Yeh found that the following figures provide reasonable estimates for the parameters in the system: β_d (the short-run elasticity of demand) equal to -0.15, β_s (the short-run elasticity of supply) equal to 0.20, δ_d (the adjustment parameter in demand) equal to 0.70, and δ_s (the adjustment parameter in supply) equal to 0.20.

At this point, it is important to discuss how the exogenous shifts in demand and supply are calculated in these equations. To calculate the annual shift in demand for agricultural products, the following equation is used:

(4)
$$g_{d,t} = (1 - w)[(\Delta p/p) + 0.14\,(\Delta y/y)] + w\,(\Delta E/E),$$

where $\Delta p/p$ is the rate of increase in the U.S. population during the year, $\Delta y/y$ is the rate of increase in real per capita disposable income during the year, 0.14 is the income elasticity of demand for agricultural products at the farm level (from Yeh), $\Delta E/E$ is the rate of increase in agricultural exports during the year, and w is the proportion of agricultural output that is exported. The supply equation, on the other hand, is subject to two exogenous shifts—a shift to the right due to productivity increases in agricultur ($g_{s,t}$) and a shift to the left due to inflationary increases in input prices (prices paid by farmers).

Using the above parameter estimates, equations (1), (2), and (3) were combined in order to find reduced form equations for farm output and prices. These equations were then fit to data for the period 1960–77 to find estimates of the constant terms. Using our constant terms, the mean absolute percentage errors in predicting output and prices during 1960–77 were 2.6% and 7.0%, respectively.

Projections of Future Agricultural Output and Prices

Agricultural output and prices are projected under two sharply different future scenarios: (*a*) a pessimistic projection, which assumes a continuation to the year 2000 of the demand and productivity trends of the 1970s, and (*b*) an optimistic projection, which assumes that there will be a return to the demand and productivity trends of the 1960s in the future. Prices paid by farmers are assumed to increase at a relatively low rate of 4% per year to a relatively high rate of 8% per year in both sets of projections. Increases in input prices are, of course, due to general inflation in the economy, which is assumed to be exogenous to the system.

The future demand and productivity shifts were obtained as follows. Demand is expected to increase from 1.17% to 2.77% per year. The optimistic (low) demand shift is based on average annual increases in (*a*) the U.S. population of 0.55% (from the Census Bureau's Series III population projections), (*b*) real per capita disposable income of 1.73% (the 1970s trend, see table 2), and (*c*) agricultural exports of 3.33% (the 1960s trend, see table 2). The pessimistic (high) demand shift is based on the following average annual increases: (*a*) the U.S. population—1.16% (from the Census Bureau's Series I population projections), (*b*) real per capita disposable income—2.94% (the 1960s trend, see table 2), and (*c*) agricultural exports—7.37% (the 1970s trend, see table 2). The percentage of agricultural output which is exported is expected to range from 14.8% (the average for the 1960s) to 20.6% (the 1970s average).

Agricultural productivity, which shifts the supply curve to the right, is expected to increase from 1.00% to 1.66% in the future. The optimistic (high) figure is based on the trend for the 1960s (table 2), but the pessimistic (low) figure is based on a less hopeful judgment.

Table 2 shows that, rather surprisingly, agricultural productivity (measured as farm output per unit of inputs) has been increasing at about the same rate during the 1970s as during the 1960s. This is despite a sharp drop in agricultural yields and the widespread belief that agricultural productivity is slowing down because of (*a*) high prices for fertilizer and other energy intensive inputs, (*b*) diminishing returns to nonland inputs in agricultural

Table 1. Projected Urbanization of Rural Lands from 1977 to 2000 Assuming the Continuation of Present Trends

Land Use	Stock in 1977 (1000 of Acres)	Conversion/Year (1000 of Acres)	Percentage of Stock Converted 1977–2000	Reserve in 1977 (1000 of Acres)	Percentage of Reserve Converted 1977–2000

[a] Excludes federally owned land and Alaska.

may overestimate the loss of rural land to urbanization because of a classification problem. In 1967, urban areas of less than 10 acres were classified as "other land" by the SCS. Other land accounted for 4% of the nonfederal rural land in 1967; but, according to the PCS, 25% of the land converted to urban uses during 1967–75 was formerly "other land." Thus, the rapid growth of small rural areas in recent years may have resulted in a reclassification of many of these areas from "other land" to urban and built-up uses (Lee, p. 16). See also Vining, Plaut, and Bieri for a further discussion of the PCS estimates.

Putting the Estimates into Perspective

Are these estimates of the national loss of farmland to urbanization large or small? Some perspective on the magnitude of these figures can be obtained by relating them to the stock and the "reserve" of agricultural land in the country (the latter concept will be defined shortly).

From table 1, it can be seen that in relation to its stock, the loss of agricultural land to urbanization does not appear to be overly alarming. By assuming that the present losses will continue into the future, it is calculated that no more than 3% to 7% of the land in any of the four rural land uses will be converted to urban uses by the year 2000.

However, these comparisons may be misleading. Rather than view the loss of agricultural land in relation to its stock, perhaps we should relate it to the reserve—that is, to the amount of agricultural land that is currently not being farmed but could be brought into agricultural production, if needed, at relatively low cost. (Note that the term "reserve" does not refer to a conscious government effort to keep land out of production.) In other words, one could ask: For every acre of farmland lost to urbanization, is there another acre of equally productive nonfarmed land that could easily be brought into agricultural production?

The 1977 *National Resource Inventories* have identified about 135 million acres of land not currently being cropped and with a high or medium potential for conversion to cropland (under 1976 commodity prices, development costs, and production costs). Of this total, about 47 million acres is prime agricultural land. This land is assumed to constitute the country's reserve of potential cropland. According to the 1975 PCS, 74% of our potential cropland is currently used for pasture and range.

From table 1, it can be seen that, in relation to the reserve, the loss of farmland to urbanization appears to be more disturbing. With present trends, the amount of cropland urbanized by the year 2000 will be equal to over 10% of the cropland currently available in reserve, and the urbanization of prime agricultural land will equal almost one-half of the current reserve.

Future Farmland Needs

Current estimates of the loss of farmland to urbanization suggest that the continued loss of farmland to urbanization could have a constraining effect on future increases in agricultural output if it is necessary to bring more agricultural land into production. Thus, it is important to estimate how much additional land will be needed in order to support agricultural output in the future and see if these land needs will exceed the amount of land that will be readily available for agricultural use.

Here, future farmland needs are estimated by using the National-Interregional Agricultural Projections (NIAP) system developed by the Economic Research Service (now the Economics, Statistics, and Cooperatives Service) of the U.S. Department of Agriculture (Yeh; and Yeh, Tweeten, Quance). Yeh, Tweeten, and Quance, in particular, have developed several output and price projections from the NIAP system and have argued that "long-run U.S. farm production capacity is

Urban Expansion and the Loss of Farmland in the United States: Implications for the Future

Thomas R. Plaut

As our cities and towns grow and decentralize, farmland and other rural lands are converted to urban uses. The loss of agricultural land to urbanization in this country has evoked little concern in the past. Because of the recent period of food price inflation and agricultural shortages across the world, however, some observers have begun to worry that the continued loss of farmland to urban uses may interfere with the United States' long-run ability to produce food and fiber for itself and for the rest of the world. (See Brubaker, Crosson 1977, Pimentel et al. 1975, 1976, Schiff. For alternative views, see Heady and Timmons, Gardner, and the U.S. Department of Agriculture 1974.) This concern becomes even more serious if one expects that, in the future, energy and other nonland inputs to agricultural production may become very expensive (and/or be in short supply) and the country may be forced to return to a more land-based form of agriculture. Because of the high costs associated with "reconverting" land back from urban to agricultural uses, it is important to consider if the continued loss of farmland to urbanization could exacerbate a possible shortage of productive agricultural land in the future.

The above concerns point out the need to relate systematically the urbanization of farmland to future farmland needs and to analyze whether or not a future conflict is probable. In this paper, we begin to explore this question.

It should be noted that this paper considers only the most direct effect of urbanization on agricultural production—the conversion of agricultural land to urban uses. However, the negative externalities caused by nearby urban development can also have important indirect effects on agricultural production. These include: (*a*) the idling of farmland in areas under extreme urban pressures (Berry 1976, Plaut, pp. 176–82) and over a wider geographic area, (*b*) the switchover to less capital-intensive forms of farming (Berry 1978, 1979). Thus, even though agricultural land is not converted to urban uses, potential agricultural production is lost. The reason for not including this loss in our analysis is that, presumably, under high demand pressures much of this idled and less intensively farmed land could be brought back into intense farm production.

The Urbanization of Agricultural Land

Two recent studies by the Soil Conservation Service have provided some up-to-date estimates of the national loss of rural lands to urban and built-up uses.[1] Based on a subsample of the points used in the 1967 *Conservation Needs Inventory*, the 1975 *Potential Cropland Study* (Dideriksen, Hidlebaugh, Schmude) found that the national loss of agricultural land to urbanization is much higher than previous studies have suggested. In particular, the study reports that the annual urbanization of rural land increased from 1.2 million acres during 1958–67 (Hart) to 2.1 million acres during 1967–75. The PCS estimates also indicate that 36% of the land lost to urbanization is prime farmland (soil capability class I and II). This last figure is somewhat surprising since only 23% of U.S. nonurban, nonfederally owned land is in prime soils.

The 1977 *National Resource Inventories* are based on a much larger sample of 200,000 points (41,000 points were used in the PCS). Preliminary results from this study indicate that the average annual loss of rural land to urban and built-up uses during 1967–77 was 2.9 million acres. This figure may be a little high, however, because it is based on the direct comparison of the estimated urban and built-up areas in 1967 and 1977; the 1967 figure might be too low.[2] Estimates of the urbanization of rural land by previous use are not available because the sample points are different from those used in the 1967 CNI. Thus, the estimates of rural land conversion shown in table 1 were obtained by (*a*) using an intermediate estimate of the urbanization of all rural land (2.5 million acres per year) and (*b*) assuming that the proportion of land converted in each use is the same as reported by the PCS.

It should be noted that the recent SCS studies

Thomas R. Plaut is a research associate, Bureau of Business Research, University of Texas.

[1] Urban uses include residences, commercial establishments, industrial sites, institutions, airports, public recreational areas, roads, highways, and railroad acreages.

[2] Telephone conversation with Raymond Dideriksen, Director of the Inventory and Monitoring Division, Soil Conservation Service, on 26 October 1979. According to Dideriksen, the 1967 estimate of urban and built-up area may have been influenced partially by the Census figure, which includes only urbanized areas of SMSAs.

Table 1. Comparison of Route Development Results Using the Clarke-Wright Method and Districting Analysis for One Week's Delivery to Customers of Wholesale Milk Processor

Route Characteristics	Clarke-Wright	Districting
Number of routes	38	38
Distance traveled (miles)		
Total	1,090.5	1,168.1
Average/route	28.7	30.7
Standard deviation	6.6	7.1
Time required (hours)		
Total	275.4	282.2
Average/route	7.2	7.4
Standard deviation	1.9	1.7
Stops served	1,033	1,033
Average/route	27.2	27.2
Standard deviation	11.8	10.0

proved routing network required 34% fewer travel miles and 29% less travel time than the existing network.

Data presented in table 1 give the results for the Clarke-Wright and the districting analyses. The data indicate that both procedures give similar results. Each requires the same number of routes to serve the firm's 1,033 weekly customers. Total distance traveled and time required are slightly higher for districting, 7.1% and 2.5%, respectively.

Standard deviations are also similar; however, the values for travel time and stops served per route are lower for districting analysis. This would be important to route management in their attempts to balance the work loads of their drivers.

each service point i, S_j is the maximum capacity of each district j, T_j is the minimum capacity of each district j, and K is the number of districts to be established.

Equations (1) through (6) indicate that the districting procedure could be formulated as a zero-one, mixed-integer programming problem. As indicated earlier, however, most techniques which attempt to find optimal solutions to combinatorial problems, such as those seen in the vehicle routing and scheduling context, take excessive amounts of computer time. Hypothetical problems using the above model were run with the IBM MPSX mixed integer package on an IBM 370/158. A small model with twenty-five stops and two districts took two minutes and fifteen seconds of CPU time. A larger model with fifty stops and fourteen districts did not reach an optimal solution after two hours.[1]

Because of the computational time difficulties, a heuristic procedure was developed to complete the districting analysis. The procedure uses the combined logic of location-allocation models and the conventional transportation model of linear programming in an iterative fashion to divide a given service area into a set of districts. The steps in the technique are as follows:

(*a*) Select an initial set of district centers. The number of centers is dictated by the total demand in the service area and the number of vehicles available. This step is similar to facility location problems in which an objective function based on the weighted spatial distances or costs connecting each service point to each potential center is minimized (Hardy). It may be expressed as follows:

$$\text{(7)} \qquad \text{Minimize} \sum_i \sum_j A_{ij} C_{ij} M_j,$$

subject to

$$\sum_j A_{ij} = D_i \text{ for all } i, \text{ and}$$

$$\text{(9)} \qquad \sum_j M_j = K,$$

where the variables have the same definitions as in equations (1) through (6). The only difference between this model and the zero-one, mixed-integer programming model presented earlier is the absence of the capacity constraints.

(*b*) Assign all service points a center, thereby forming service districts. This is the conventional capacitated transportation problem which may be stated as

$$\text{(10)} \qquad \text{Minimize} \sum_i \sum_k C_{ik} A_{ik},$$

subject to

$$\text{(11)} \qquad \sum_i A_{ik} \leq S_k \text{ for all } k,$$

$$\text{(12)} \qquad \sum_i A_{ik} \geq T_k \text{ for all } k,$$

$$\text{(13)} \qquad \sum_k A_{ik} = D_i \text{ for all } i, \text{ and}$$

$$\text{(14)} \qquad A_{ik} \geq 0 \text{ for all } i \text{ and } k.$$

(*c*) Measure the compactness of the derived districts. Compactness is defined as the maximum distance separating any service point from its district center, the maximum distance between the most extreme points in each district, the weighted total distance from all points to their respective center (the value of the objective function in step *b*), and so forth.

(*d*) Determine a new center for each district using the technique described in step (*a*) with the value of K equal to 1. These centers may or may not be the same as those used to develop the districts initially.

(*e*) Using these new centers, follow the procedure in (*b*) to reassign service points to the set of capacitated districts. Districts may or may not change from the previous stage.

(*f*) Measure the compactness of these districts. If compactness has improved over the last measure, return to step (*d*). If there is no improvement, then take previous results as best and proceed to step (*g*).

(*g*) Examine the final compact districts and manually determine the path for vehicles to travel in serving all points. The number of stops to be served per district should be small enough so that most feasible routing alternatives could be examined and evaluated manually. In addition, hard-to-quantify variables, such as one-way streets, railroads, busy thoroughfares, and steep grades, could be handled with ease.

Empirical Results

The urban delivery network of a wholesale milk processor was analyzed to permit a comparison of routes developed using the Clarke-Wright method with those generated through districting analysis. Previous research results (Murphy and Hardy) indicated that significant improvements in routing efficiency for this distribution system could be realized from routes developed by the Clarke-Wright method. The analysis revealed that the im-

[1] Recent advances in computational technology and computer software (Glover, Hultz and Klingman; Glover, Hultz, Klingman and Stutz; Mulvey and Crowder) permit certain types of large-scale, mixed-integer programming problems to be solved quickly and efficiently. These techniques, however, are proprietary and as such are not readily available to the general researcher. Also they are somewhat difficult to use because programs, or at least subroutines, must be developed for each individual application. The districting heuristic model presented in this report is based upon the IBM MPSX program package which is found at many computer installations.

Vehicle Routing Efficiency—A Comparison of Districting Analysis and the Clarke-Wright Method

William E. Hardy, Jr.

Continued cost increases associated with the transportation of raw materials and final products are forcing management to examine more closely the economic efficiency of their operations. A basic problem facing the transportation manager is to schedule and direct a fleet of vehicles to a set of stops or destinations, such that only one vehicle visits each stop. The objective is to minimize the total cost of delivery. Normally, travel distance is used as a surrogate measure of cost, or it is assumed that cost is proportional to distance. Most analyses attempt to satisfy this minimization objective while being constrained by such variables as vehicle capacity, maximum route length, maximum route time, and special customer service time constraints.

Both heuristic procedures and models that will give optimal solutions have been used extensively to solve routing problems (Turner, Ghare, Fourds). Most emphasis in the literature and in practical industrial applications has been placed on heuristic techniques, because computational time increases exponentially with problem size. This computational problem is particularly evident in models which seek optimality. In most cases, the additional accuracy obtained by using these models does not justify the added time and expense required.

One of the first and most often referenced heuristic techniques was developed by Clarke and Wright. Their procedure, or modifications and extensions of the technique, has served as the basis for many successful applications (Hallberg and Kriebel 1972, 1979; Hardy and Grissom; Murphy and Hardy; Russell and Igo; Schruben and Clifton).

Routing analyses of the Clarke-Wright type give definite, explicit routes that should be followed in satisfying the demands of the specified service area. The apparent rigidity and inflexibility of these research results has led to some reluctance on the part of route managers to implement the findings of detailed routing analyses. Some feel that their decision-making powers are being replaced or, at best, supplanted by the quantitative analysis. A more valid complaint often expressed is that there are objectives and constraining variables which should be considered in establishing routes that are not quantifiable and thus cannot be included in the analyses.

William E. Hardy, Jr. is an associate professor in the Department of Agricultural Economics and Rural Sociology, Auburn University.

Research on which this report is based was supported by federal and state research funds under Hatch Project Alabama 638.

Districting for Route Development

An alternative quantitative method which would be of assistance to a route manager in developing efficient route systems without dictating the specific paths the vehicle would follow is the concept of districting. This technique has been used successfully in delineating compact and balanced districts for schools, political boundaries, and planning regions (Thoreson and Liittschwager; Weaver and Hess). It also has been used to a limited extent in developing transportation systems (Berlin).

There is a single basic difference between the results of a Clarke-Wright analysis and those provided by a districting analysis. The Clarke-Wright technique specifies the exact sequence of stops, permitting little room for management discretion. Districting analysis, however, simply groups the demand points of the total service area into a specified number of compact service districts. Actual route design for each of these smaller districts is left to management. The number of stops in each district should be small enough so that most reasonable routing alternatives should be obvious.

Mathematically, the districting problem may be expressed as follows:

$$\text{(1)} \qquad \text{Minimize} \sum_i \sum_j A_{ij} C_{ij} M_j,$$

subject to

$$\text{(2)} \qquad \sum_i A_{ij} \leq S_j \text{ for all } j,$$

$$\text{(3)} \qquad \sum_i A_{ij} \geq T_j \text{ for all } j,$$

$$\text{(4)} \qquad \sum_j A_{ij} = D_i \text{ for all } i,$$

$$\text{(5)} \qquad \sum_j M_j = K, \text{ and}$$

$$\text{(6)} \qquad A_{ij}, M_j \geq O,$$

where A_{ij} indicates whether the demand from service point i is served in district j, C_{ij} is the cost or distance between service point i and district center j, M_j is a zero-one variable indicating whether point j is a district center, D_i is the service requirement of

Table 2. Determinants of Relative Breeding Effects

	Profit-ability (*P*)	Growth Rate (*G*)	Vari-ability (*V*)
Coefficients in 1974 (table 1)	4.07	56.24	5616
Orange crop parameters	171.5	1.0	0.26
Percentage of income change from percent change in parameter	2.32	28.77	1.11

creases in average grower income. In particular the regression coefficients suggest that a 1% increase in crop profitability (for example through a small increase in labor productivity) would yield an increase in grower income of about 2%. A 1% increase in the logistic constant of growth (for example an orange tree that matured about a month earlier) would yield an income increase of around 29%. A 1% decrease in crop variance (for example through a crop resistant to perhaps 5% of local diseases on Atiu) would yield an income increase of about 1%.

Of course nothing can be said about the relative merits of different breeding strategies without knowing how difficult it is to obtain each of these improvements. To investigate this it might be possible to use an approach like that of Liyanage. He estimated the expected genetic progress of a series of traits in the progeny of an adult plant. His work with coconuts, for example, suggested that despite improvements already attained, it was still easier to achieve a given percentage change in crop yield than in fruit-maturing time.

Despite this observation and our ignorance of the breeding performance of orange trees, it seems safe to conclude that a suboptimal approach was taken in the breeding of improved orange trees for Atiu: the ideal tree should have been above all fast growing. It is more difficult to confidently rank variability, profitability and other design characteristics.

This leaves an important question unanswered: most of the interest in new varieties is centered not on tree crops but on cereals, where speed to maturity is less crucial than variability and yields. The general evidence here is that high yields may have been overrated at the expense of low risk. To test this more precisely requires knowledge of the different components of these two aggregated design traits. For example, Pinstrup-Andersen, de Londoño, and Infante suggest a method to estimate the extent of different causes of yield variance in crops. With knowledge of these disaggregated subparameters, it is possible to conduct simple genetic experiments to investigate directly the tradeoffs involved, and the optimal design strategies.

Another question of practical relevance is whether it is necessary to have detailed records of past grower participation as in the special case of Atiu in order to estimate likely future responses. A recent study by Dillon and Scandizzo suggests that it may after all be possible to gather sufficient meaningful information (about risk preferences for example), by careful survey work before a project is designed.

In making policy recommendations from this analysis, the limiting statistical assumptions made, the quality of the data used, and the ignorance about relative breeding costs, all must be remembered. But although it may not be possible to obtain estimates of absolute gains from breeding, the formulation does highlight a number of things: just what "improved" crop varieties are likely to involve; how dependent choice of ideal crop technique is on the particular attitudes of a grower community (and, hence, how site-specific crop design may have to be); and the significance of the relative costing decisions that are all the time being made implicitly by crop breeders.

dently of managed inputs. Again, there are a number of subparameters of interest: the changing pattern of returns over time, the time taken to maturity, etc. The potential (not necessarily achieved and not observable) rate of growth of yield (G) is here measured by the logistic constant of the S-shaped potential growth curve. Tree crops that take a long time to mature have a low G value, while fast maturing crops have a higher value.

The third crop characteristic examined is the risk involved. This includes biological variations in yield, variations in the proportion of the crop reaching market in salable condition, and variation in market price. This crop variability (V) is approximated by the variance of revenue actually received by growers, adjusted about a production trend to take account of varying inputs. Perishable crops like tomatoes have higher V-values than less sensitive ones like forest trees.

Values for the explanatory variables P and V came from field data collected in 1974–75 on Atiu. They cover ten project crops available to growers in the previous decade. Estimates for G were derived from experimental data on the potential performance of similar crops under controlled conditions.[2] The dependent variable, grower participation, is represented by the annual household income (Y) received from each crop. These data were derived from the detailed planting and marketing records maintained on the island, and were available for all of the 200 households for the period under study.[3]

It is now possible to test the hypothesis that grower participation in a crop depends, among other things, on the structural crop design—specifically its profitability—growth rate, and variability as measured above. For estimation, a roughly linear explanatory relationship is assumed:

$$Y = \beta_0 + \beta_1 P + \beta_2 G + \beta_3 V. \tag{1}$$

It already has been claimed from observation that Atiuans like quick returns but dislike risk; that is,

$$\beta_1, \beta_2 > 0; \beta_3 < 0.$$

But what is more at issue is how important a typical grower considers each of these crop design traits to be relative to the other ones.

The coefficients of equation (1) were estimated for the range of crops available to growers over the period 1965 to 1974. The data were grouped into four subperiods in order to allow sufficient observations during the earlier years when there were fewer crop possibilities available. These subperiods are not long enough to allow structural distortions to take place. (Figures for 1968 are omitted because a hurricane early that year severely disrupted production.)

The regression results are presented in table 1. They offer a consistent picture: as predicted, growers seem to appreciate profitable crops, they like fast maturing ones (with one nonsignificant exception), and they try to avoid risky ones. The statistical fits are reasonable, although given the quality of the data and the number of observations, too much confidence should not be placed on this.

Optimal Crop Design

The most interesting part of these results for us is the relative magnitude of each coefficient, for this is an indication of the importance of each production trait in determining participation. However, these coefficients are measured in different units and are not directly comparable. Furthermore, just how difficult it will be for breeders to affect equivalent changes in each of these production parameters is not known (although, of course, every time breeders aim for a particular trait, they are making an implicit analysis of the relative opportunity costs of neglecting other heritable traits).

Take the case of an orange breeder seeking to develop an improved strain of trees for his community. What should he or she breed for? Assuming coefficients roughly of the order of magnitude of those estimated in the regression for 1974, it can be shown what the approximate range of relative breeding costs should be for a breeder to give priority to improvements in either profitability or growth rate or variance. This assumes that changes in any of these traits can be achieved independently of the others, and that improvements in a trait have the same probability of being passed on between generations.

It can now be seen (table 2) that if a breeder were to achieve a fixed percentage improvement in each trait in turn, he would elicit different relative in-

[2] There clearly are other things that determine grower interest in crops apart from points of technical design. Examples are the stock of knowledge possessed by a grower about a crop, the attitude of fellow growers toward it, and the role of the administration in cushioning its introduction. In this study, as in Perrin and Winkelmann's, these were all found to play an important role in acceptance.

[3] It was also possible to test an alternative measure of grower participation, namely the average household labor devoted to a crop, for one year only. The source of this data was an extensive labor use survey carried out by the author. Regression results were similar.

tractors and implements, and an assurance of potentially high yields.

How did Atiuan growers respond? Exhorted by government and some local leaders, most were keen to join (164 plots were planted in six years), and they worked hard at clearing, planting, watering, and weeding. But after a few seasons, growers began to tire of waiting for the oranges to mature. They found the maintenance especially irksome because it had to be done regularly and privately, clashing with traditional work patterns. And having grown their old oranges satisfactorily without fertilizing, spraying, or pruning, they were not convinced that these practices were worthwhile, and neglected them.

The trees proved botanically ill-suited to the Atiuan environment: sea winds and salt air in exposed places damaged delicate foliage. Some plots suffered from soil deficiencies, while droughts stunted growth and hurricanes broke boughs. Yields were marked by extremes of biennial bearing (alternate good and bad years). Oranges suffered from white moth infestations, sooty mold, and scaly bark diseases, against which they had no natural resistance.

Support services were quite inadequate. A locally trained agricultural officer could offer only limited technical advice. Machinery, fertilizer, and sprays were available irregularly, and often unavailable when most needed. Shipping, too, was unpredictable and usually inadequate.

As a result, by the time the trees should have reached maturity they were stunted and diseased. Yields over the next twenty years averaged only 40% of expected output; with low produce prices and heavy emigration from the island about 80% of plots fell heavily into debt, their owners having lost interest in them.

This decline was hastened by the administration introducing a whole series of other short- and long-term cash crops over the next twenty years. These included forest trees, tomatoes, peanuts, coffee, pineapples, and other vegetables. For the most part these were also "improved" varieties of crops that had been grown previously or harvested from the wild. A variety of technical and marketing innovations accompanied them (see Bollard 1979a).

Unfortunately, not much had been learned from the Citrus Replanting Scheme. Most of these new crops were also poorly suited and did not perform well. Atiuan growers were characteristically choosy about which ones they wanted to grow. For all its ineptitude in crop introduction, the local administration did keep detailed records of individual grower participation in each crop. These records now are used to draw conclusions about what sort of crops would have been most desirable (as indicated by grower response) in the first place.

It appears that the profitability of a new crop was an important consideration for Atiuan growers; though in common with most Polynesians, extra income did not act as a strong inducement after certain household needs had been provided for. On the other hand extra work, especially regular monotonous jobs that threatened to cut into important social activities, could be distasteful. Like most low income farmers, Atiuans displayed positive risk premiums and sought insurance against uncertainty. Further, they gave evidence of low rates of time preference by selecting faster maturing crops. Growers also seemed to avoid crops they knew little about and were attracted by the presence of other growers in a bandwagon effect.

This is all important information for the crop breeder. Yet it is much too general to help him decide between different research paths. In fact it does not distinguish the Atiuan farmer from most other third world growers. So it is necessary to test the importance of each of these technical crop characteristics in a more precise way. This is done by estimating to what extent each of a number of crop parameters can explain the pattern of grower participation.

The production possibilities of the crops are now specified so as to highlight in a simplified way those technical points of design that growers look at and respond to. This is done by developing a nonstationary production function that specifies profitability, variability, and rate of growth as a series of estimable parameters. Each of these parameters is, of course, a highly aggregated measure subsuming many other minor technical characteristics. This production function is more fully described elsewhere (Bollard 1979b).

The function is designed to explain the performance of slow growing crops (reducing in the short term to include annual crops as a limiting case), where the only significant input is household labor in its various roles. On Atiu, crops are grown by extended household groups with unpaid family labor constituting the only significant costs. The specification is based on the principle that the current and future performance of a crop depends on its current inputs, its natural age, and how well it has been looked after in the past.

The first crop characteristic considered is its profitability. Included in this are many of the farmer's early questions, such as: What will the harvest yield be? How much money will that be worth? And, how much work will it require? For the steady state, a common exponential relationship of returns and labor is assumed.[1] Then profitability (P) is measured by the marginal revenue product of labor in the steady state adjusted for the current level of production. For fast maturing annual crops, this reduces to the simple marginal revenue product. For other agricultural systems the presence of other factor costs may require more involved measures.

A second characteristic of tree crops is that as they grow older, production will increase indepen-

[1] The specific form used is the Mitscherlich function, because it provides useful subparameters, like the fixed labor required to commence production and the asymptotic maximum potential yield.

Grower Preference for Crops and Implications for Plant Breeders

Alan E. Bollard

In an article in this *Journal*, Perrin and Winkelmann summarize the patterns of adoption of new wheat and maize varieties in developing countries. Their general conclusion is that agricultural technology is more site-specific than has been believed. Their warning to the plant breeder is that, in areas not already dominated by new varieties, it is unlikely that any single new variety could repeat the early successes.

This leaves scientists in crop research institutions in something of a quandary. The era of massive improvements in yields is past. In any case, they are well aware that crops bred purely for their high yields are not completely satisfactory and may even be dangerous for their vulnerable low income small farmer clients. (See, for example, Flynn.)

It is clear that efficient plant design requires a knowledge of the prevailing natural growing environment and available technical infrastructure, as well as an appreciation of the social and cultural character of the people involved. But it is not always clear precisely which plant characteristics scientists should be breeding for, nor how they should weight relative breeding priorities when there is a trade-off, other than by what Sanders and Lynam call the subjective method of "critical inference."

One approach is that followed by Ladd and Gibson in a recent article. They investigate breeding priorities for hog improvement in the United States. By estimating potential increases in profit to be had, they can recommend between breeding for each of three heritable traits. However, their objectives are much more limited: these traits are all yield-increasing ones, and so their deterministic approach ignores all the complications of predicting the behavior of growers faced with risk, choice over time, and other culture-bound decisions.

This note takes the site-specific approach recommended by Perrin and Winkelmann. It describes a study made of a small homogenous community in the Pacific, and reactions there to the introduction of a variety of new cash crops including tree crops. Although both people and crops are quite different to the cases of Perrin and Winkelmann, several of the findings about patterns of crop adoption are similar. Appropriate research priorities for breeders are then investigated.

The format is as follows: section two uses the experiences of growers with new crops to estimate the extent to which different technical crops have affected decisions to participate in projects in the past. The third section investigates how far this information may be used to indicate those crop traits that could be expected to draw the most enthusiastic response from these particular growers. It is not clear, even in this small homogenous community, just what the optimal crop design is; but it can be shown that current designs are suboptimal, and that they may be improved.

New Crops for Atiu

Atiu is a small coral atoll in the Cook Islands in the South Pacific. The population of 1,380 lives in adjoining villages and are mixed subsistence farmers and cash croppers. Until the mid-twentieth century Atiuans earned small amounts of cash, mainly by picking the fruit of the native orange trees. These straggling self-sown trees bore regular yields of poor quality fruit without any cultivation. Picking was done by the small boys who climbed the trees and threw down the tough oranges. This system corresponded well to the communal work habits and the traditions of food gathering rather than modern agricultural cultivation.

In the 1940s the orange trees became exposed to new diseases and began to die out. The New Zealand government decided that improved orange varieties should be introduced through an aid project. The question was what the best type of tree would be. The criteria decided on were typical of agricultural projects of the time. The trees must be high-yielding, with top grade fruit. To minimize labor, low varieties were to be planted symmetrically in large, mechanizable, cleared plots, each to be privately managed by an individual nuclear family. They were to make full use of new Western citricultural techniques such as heavy fertilizing, pruning for light, and machine spraying against pests and diseases.

In 1951, two new varieties of "improved" trees on lemon rootstocks were offered to Atiuan growers with suitable lands. With the seedlings came advice on cultivation, credit (to be repaid out of later proceeds) to purchase materials, use of

Note: Based on the distribution of reporting members in the 1976 *AJAE Handbook-Directory* and adjusted for nonreporting by the ratio of the estimated number of individuals in age group *i* in 1975, to the number of reporting members in age group *i* in 1976 *Handbook-Directory*.

government or private industry each year. This leaves 61 new Ph.D.s to cover annual replacement needs of universities. Deducting the 50 per year required to cover retirements and death leaves 11 new Ph.D.s per year to cover resignations (shifts to administrative positions as well as changes of profession), positions created through upgraded educational requirements, and entirely new positions. The projected replacement needs for the early 1980s will absorb all of the new Ph.D.s destined for university employment under the Fuller scenario.

Table 5 contains the estimated age distribution in 1975 by employer.[4] Academic institutions continue to be the major employer and will have the greatest replacement needs. The overall distribution by type of employer is similar to Fuller's results. Sixty-four percent of the total are employed by colleges and universities.

The areas of specialization of most interest will continue to be production/farm management and marketing (table 6). These areas of specialization will be consistently high in demand. Natural and community resources will have higher replacement needs in the later 1980s. Other areas such as policy and economic development will experience increasing replacement needs but not to the extent of production and marketing.

Several factors have the potential for increasing the supply of Ph.D.s in the United States or reducing the replacement needs in the near future. More intense recruiting of graduate students would increase supply. Increased employment opportunities as well as budgetary restraints may induce more U.S. Ph.D.s, currently employed abroad, to return to the United States. A third factor is the recent change in mandatory retirement laws. Postponing retirement beyond age 65 may be sufficient to alleviate any shortfall. If all retirements occurred at age 70, replacement needs for the period 1981–85 would be 44% of the requirements with retirement at age 65. For the period 1986–90, replacement needs would be 75% of the estimated figure if retirement is delayed five years.

The actual replacement needs likely will be somewhat less than projected with retirement at age 65 and more than implied with retirement at age 70.

[*Received August 1979; revision accepted January 1980.*]

[4] Tables 5 and 6 are generally consistent with the projected age distribution, except for rounding discrepancies. An anomaly occurred in the youngest age group. Ph.D. candidates projecting 1976 completion dates resulted in a larger than forecast number of individuals in this age group.

Table 4. Estimated Ph.D. Age Distribution, 1975, with Projected Declines

	Age								
Year	61–65	56–60	51–55	46–50	41–45	36–40	31–35	26–30	Total
1975	163	221	383	358	490	461	495	131	2,702
1980	198	358	344	478	454	490	130		2,452
1985	318	322	458	443	483	129			2,153
1990	289	428	425	471	127				1,740

Each age group in each year's age distribution, A_{ij}, was multiplied by the ratio of the sum of U.S. recipients plus one-fourth of the foreign recipients to reporting recipients in the appropriate *Handbook-Directory*. The age distribution of reporting recipients was assumed to be representative of the distribution for all recipients entering the U.S. market.

A review of data on foreign recipients of Ph.D.s in four different years indicated that 44% maintained membership in the AAEA in 1975. Of the 44%, approximately one-half (22% of the total) remained in the United States. It was assumed that 25% of the foreign recipients entered the U.S. labor market. Life expectancy adjustments for these distributions were from 1971 to 1975. Data for degree recipients in the years 1972 thorugh 1975 were obtained from the 1976 handbook. Bibliographic data in the 1976 handbook were obtained in 1975. No life expectancy adjustments were made in the age distributions for these latter years.

Combining the adjusted age distribution from the 1966 handbook and the adjusted age distributions for degree recipients in the years 1967 through 1975 yields the overall age distribution from which the effects of retirement and death are projected. Using a retirement age of 65 and the life expectancy tables, the overall age distribution is projected to the years 1985 and 1990.

The distribution of major specialty by age of reporting Ph.D.s in the 1976 *Handbook-Directory* was combined with the age distribution estimated here to project needs by major specialty. It was assumed that the distribution of reporting members in each age group across major specialties is representative of the population. Within each age group reporting in 1976, the number of individuals indicating a major specialty was adjusted by the ratio of the estimated age group in 1975 to the reporting age group in the 1976 *Handbook-Directory*. The distribution of Ph.D.s by employer according to age was obtained in an analogous manner.

Results and Implications

Table 4 contains the estimated age distribution for all Ph.D. agricultural economists in the United States in 1975. The distributions for 1980, 1985, and 1990 show the anticipated effects of retirement and deaths prior to retirement. It is estimated that 50 new Ph.D.s are needed per year during 1976–80 for replacement. Replacement needs in the first half of the 1980s will average 60 new Ph.D.s and in the second half will average 83 new Ph.D.s per year. The declining number of degrees granted and the increasing proportion of foreign recipients has resulted in a much smaller number of Ph.D.s entering the U.S. market each year. Assuming 25% of the foreign recipients remain in the United States, the average number of new Ph.D.s entering the U.S. market during 1975–77 was 96. Fuller's 1970 survey (excluding foreign positions) has implications for the current market and future trends. Of the 160 recipients entering the 1970 labor market, 64% found employment at universities or colleges (including Extension) and 28% were employed by the federal government. The remaining 8% were employed by private industry and foundations or institutes. If these figures are representative of the current market, 35 new Ph.D.s are being employed by

Note: Based on the distribution of reporting members in the 1976 *AJAE Handbook-Directory* and adjusted for nonreporting by the ratio of the estimated number of individuals in age group *i* in 1975, to the number of reporting members in age group *i* in 1976 *AJAE Handbook-Directory*.

Table 1. Number of Agricultural Economists at Agricultural Experiment Stations and Other Cooperating State Institutions

	1965	1975
Ph.D.	793	1,249
Master	569	428
Bachelor	138	80
Total	1,500	1,757

Comparison of the number of degrees granted over time with the number of Ph.D.s listed in the three most recent *AJAE Handbook-Directories* indicated the 1966 handbook likely included a higher percentage of Ph.D.s in the United States. Regular membership in the AAEA during the period 1959–66 increased by almost 50% (Kearl). This growth was substantially more than the total number of Ph.D.s granted during the same period and listed in the 1966 handbook—1,098 new regular members versus 593 new Ph.D.s. The total number of Ph.D.s listed in the 1966 handbook is also greater than the total number of degrees granted during the years 1951 through 1966. In addition, the growth in reporting membership by Ph.D.s is substantially less than degrees granted during the years 1967 through 1975. There were 1,515 degrees conferred during this time period (see table 2). The number of reporting Ph.D.s increased by 540 between 1966 and 1975 (see table 3).

Nonreporting Ph.D.s cause a downward bias in the 1966 distribution.[2] The magnitude of this bias was reduced by adjusting the distribution upward. The adjustment factor, N_o, was determined by the ratio of all U.S. degree recipients for the years 1951–66, inclusive, to U.S. degree holders listed in the 1966 handbook. U.S. degree recipients are defined as those individuals whose first degree was awarded by an institution in the U.S. The list of U.S. degree recipients was obtained from the May issues of the *Journal* for the years 1951–66, inclusive.

The estimated distribution for 1966, adjusted for nonreporting, was brought forward to 1975 using a life expectancy adjustment factor, L_{1966j}. This factor explicitly accounts for preretirement deaths.

The yearly listing of Ph.D. recipients in *AJAE* provided the data base for the period 1967 through 1975.[3] Year of birth data were obtained for each class of recipients. The resulting yearly age distributions, A_i, were adjusted to allow for nonreporters and foreign recipients entering the U.S. labor market.

Source: *AJAE Handbook-Directory* 1966, 1972, and 1976.

[2] Because interest here is in the U.S. market, two additional sources of bias exist: (*a*) foreign degrees employed outside U.S.; and (*b*) U.S. degrees employed outside U.S. A systematic sample was taken of the 1966 handbook resulting in 144 observations (10%). The first bias represented 1.2% of the sample, and the second bias was 8.3%.

[3] Comparison of the total number of degree recipients published in the May issue of this *Journal* for the years 1959–74, inclusive, with the *Earned Degrees* series (U.S. Office of Education) for the academic years 1959–60 through 1974–75 indicates that underreporting in the May issues is not serious. The *Earned Degrees* series indicates 2,324 Ph.D. degrees granted. The total number of recipients listed for the calendar years 1959–74 in the *AJAE* was 2,212, and for the calendar years 1960–75, the number of degree recipients listed was 2,273.

Projected Replacement Needs for Agricultural Economists

Ralph T. Schotzko

Demand for Ph.D. agricultural economists, in general, comes from academia, government, and private industry. Within each market, employment opportunities result from attrition and newly created positions. New positions may result either from the decision to increase the number of professionals or through upgrading educational requirements of positions vacated through attrition. Attrition includes resignations, retirement, and premature death. This paper presents a projection of replacement needs in the profession as a result of retirement and premature death. No attempt is made to document resignations resulting from administrative appointments or changes in profession.

The potential for new positions in academic institutions, and possibly government, is declining and may be negative. Forecasts of declining college enrollments (Helmberger) portend an academic market that may be reduced to replacement hiring only. Budgetary constraints also may inhibit both funding of new positions and filling of vacant positions.

The potential for upgrading any sizable number of positions is much less now than ten or fifteen years ago. A count of agricultural economists in *Professional Workers in State Agricultural Experiment Stations and Other Cooperating State Institutions* for 1965 and 1975 is provided in table 1.[1] Over that ten-year period, the number of individuals in departments of agricultural economics increased 17% and the number of Ph.D.s increased 58%.

A significant number of agricultural economists are employed at non-land-grant institutions. Employment opportunities at these institutions may be more severely constrained by budgetary and enrollment problems than land-grant universities.

Some growth in the total number of academic positions held by Ph.D.s may occur through movement into administrative positions. Potential mobility of agricultural economists in this direction has not been documented.

Documentation of employment of Ph.D. agricultural economists in the private sector is limited. Of the Ph.D.s listed in the 1976 *American Journal of Agricultural Economics Handbook-Directory* (Redman), 16% were not employed by either academic institutions or government. Melichar's analysis of data in the 1966 *National Register of Scientific and Technical Personnel* indicated this group represented 14% of all agricultural economists. Fuller's 1970 survey also shows a slight shift in beginning employment toward private industry.

While the private sector may be hiring an increasing percentage of agricultural economists, academic institutions continue to be the major employer. The primary reason for employment opportunities at academic institutions likely will be attrition.

Procedures

Using age 65 as the retirement age and life expectancy tables to account for early deaths, two of the three leakages associated with attrition can be estimated. An age distribution for Ph.D. degree holders in 1975 is estimated. This distribution is then used to estimate replacement needs. Data for the distribution were based on the three most recent AAEA handbook-directories and May issues of the *AJAE* for the period 1951–76.

The estimated number of people in the jth age group in 1975, Y_j, was obtained according to the following expression.

$$Y_j \equiv N_0 L_{1966j} X_j + \sum_{i=1967}^{1971} N_i L_{ij} A_{ij} + \sum_{i=1972}^{1975} N_i A_{ij},$$

where N_0 is nonreporting adjustment factor for degree recipients prior to 1967 ($N_0 = 1.37$); L_{ij}, life expectancy adjustment factor from year i to 1975 for the jth age group (HEW); X_j, number of Ph.D. degree holders in the jth age group as listed in the 1966 *Handbook of the American Farm Economics Association;* A_{ij}, number of reporting degree recipients in year i in the jth age group as listed in the appropriate *AJAE Handbook-Directory;* N_i, non-reporting adjustment factor determined by $\dfrac{US_i + 0.25\,F_i}{A_i}$; US_i, U.S. recipients in year i; F_i, foreign recipients of U.S. degrees in year i; and A_i, number of reporting degree recipients in year i.

Ralph T. Schotzko is an extension economist with the Cooperative Extension Service, Washington State University.

Leroy Blakeslee, Donald West, and Raymond Folwell reviewed an earlier version of this paper. Their suggestions and comments are greatly appreciated.

These data were collected while the author was an assistant professor of agricultural economics at Rutgers University.

[1] Individuals listed in these directories include college staff, station staff, extension staff, and the staffs of cooperating government agencies.

allegiances, has seen a substantial dropout rate. The FB and FU, with their selective incentives, have seen opposite trends. Yet it is apparent that the views of both writers must be qualified to include the magnitude of farm operation, and, at least for Wisconsin, the role of history as suggested by regional variations.

[Received June 1979; revision accepted November 1979.]

plained in a regression analysis, nearly two-thirds of this (.10) is explained by a single variable: gross farm income.

If the magnitude of farm operation is important in determining whether one is currently a member of an organization, might it also be important in determining whether a farmer stays in or leaves a particular organization?

This appears to be the case for the NFO, where the variables together account for nearly half of the variance (.441). While the overall pattern of those who remain in the NFO emphasizes magnitude, a third of the variance is explained by their agreement with NFO policies (.17), as opposed to those who quit. This is in contrast to FB and FU, where there are no observed differences between remaining and former members on the organization's policies.

The magnitude variables together explain .14 of the variance between current and former FB members. The statistically important variables included in the description of remaining Farm Bureau members are virtually all directly related to magnitude of the farm operation.

The explanation of those who remain Farmers Union members follows a pattern similar to FB members who remain with .18 of the variance explained. The variables are essentially the same, with most directly tapping the magnitude dimension.

Regional Analysis

Also important in the decision to join a particular organization is the location of the farmer. Marked differences in organizational membership by region can be seen from the data reported in table 6 (see also Cell and Johnson). It would appear, from talking with current and former officials of these organizations, that history has had a strong impact on these regional variations. The Farmers Union entered Wisconsin in the northwestern third of the state from its strong Minnesota base. Consequently, it has been much stronger in the northwestern regions of the state. The Farm Bureau, in contrast, entered Wisconsin from the South, fueled by the very strong Illinois Bureau. It has not penetrated the northern or central regions of the state heavily, apparently preferring to concentrate on the larger farmers in the southern part of the state. In its efforts to capture a controlling share of the market, the NFO also has tried to concentrate on larger farmers, thus tending to cover the same areas as the FB. Region plays little role in determining who leaves these farm organizations, at least for the FB and FU. However, for the NFO, quitters have been much more likely in the central, north-central, and northwest regions, all among the least productive farming areas. (Those regions where NFO joiners were more likely to stay were among the most productive: east-central, south-central, and west-central.)

Conclusion

These data suggest that the magnitude of the farm operation is an important factor in the decision to join a farm organization. However, the decision regarding which organization to join is somewhat more complex. Because farm organizations have been differentially active in different parts of the state, region plays an important intervening role. While ideological commitment plays some role in the original decision to join and remains important in the maintenance of NFO membership, it appears to be of little consequence for the FU and FB. For the FU and FB, the most important factor in sustaining membership over time has been their continued ability to deliver selective incentives to members. This ability to sustain membership is more likely to apply to farmers who maintain large-scale operations.

Thus, with the exception of the original decision to join, these data provide little support for the views of Wilson on the importance of ideological commitment. They do, however, suggest that Olson may be on the right track. The NFO, with its apparent lack of selective incentives and higher political

Table 6. Farm Organization Membership and Region

Membership in Farm Organizations	Region									No. of Members in Sample

members indicated that they are not getting any specific benefits from the FB. Only 25% saw disagreement with FB policies as having some level of importance in their decision to leave. Forty-seven percent of former FU members considered the lack of specific benefits important in their leaving, while only 20% felt their disagreement with FU policies had any importance. The reasons for NFO members leaving were basically reversed: 70% saw their disagreement with NFO policies as having some level of importance, whereas only 50% found the lack of specific benefits as significant.

Thus, the composite picture of these findings suggests that for the FB and FU, the role of specific benefits, most of which are types of Olson's selective incentives, plays the most important part in farmers remaining members, as well as deciding to leave the organizations. This is in contrast to the NFO where agreement with policies appears to be more important than specific benefits in the decision to join, stay, or leave. For all three organizations, the agreement with policies and programs and the desire to help promote them were more important in the original decision to join than were economic factors. Thus, while Wilson's emphasis of political and policy questions may have some merit in the original decision to join, it would appear that once a person becomes a member, selective incentives, especially of an economic nature, become paramount to him.

Magnitude of Farm Operation

In addition to the impact of selective incentives on farm organization membership, these data reveal that the magnitude of farm operation is strongly related to farm organization membership.

Strong relationships exist between a number of variables that measure the size of the farm operation and whether or not one is currently a member, or a past member, of a farm organization. Most of these variables, such as income statistics, acreage size, number of dairy cows, and absence of work off the farm, appear to be merely different ways of tapping the same dimension: magnitude of farm operation. Although only .17 of the variance is ex-

[a] Single asterisk means significant at .05 level; ** is significant at .01 level; *** is significant at >.0000.

These services included various forms of insurance as well as more general forms of advice on planting, harvesting, and marketing. Seventy percent of the FB members obtained at least one form of insurance from the FB insurance companies and nearly 50% of the FU members did so from FU insurance companies, but only 5% of the NFO members obtained insurance from the FB or FU companies.[5] NFO members were most likely (43%) to obtain marketing advice from the NFO. The NFO provides little in the way of other services. Of those who are not members of any organization, only 8% obtained services from any farm organizations. However, FB members were three times as likely to use the FB-related FARMCO/FS coop as FU or NFO members or those not members of any organizations. FU members were twice as likely to use FU-related CENEX coop as FB or NFO members or those not members of any organization. Higher patronage refunds usually go to those who are members. Especially for farmers with high business volume, this refund differential can make a substantial monetary difference. Similar relationships between farm organization membership and independent coop patronage were not apparent with coops such as Midland, milk marketing, and livestock sale barns. This suggests that joint farm organization membership and coop patronage is economic rather than ideological.

Those who had left the organizations were asked to rank the importance of reasons for leaving. The most important reason, indicated by 57% of the former Farm Bureau members, is that they "were not getting any specific benefits from the FB." When combined with the specific selective benefit item of obtaining insurance more cheaply elsewhere, a total of 80% of the former Farm Bureau

[5] In certain limited circumstances, the farm organizations will provide services to nonmembers. For example, the Farm Bureau will sell life, crop-hail and fire-wind insurance to nonmembers, but one must be a member to obtain auto, health, or comprehensive farm insurance. The Farmers Union will sell all forms of insurance to members and nonmembers alike. Most farmers, whether members or not, patronize one or more coops.

In short, although a scale has been developed which is believed to represent reliably the views of the state Farm Bureau, there is little indication that the members of the Farm Bureau, either present or past are more or less likely to adhere to those views than non-FB members. Further credence is lent to this position by the fact that with the exception of three items indicating Farm Bureau members' desire to reduce government influence in agriculture, there are no significant tau_c correlations on the specific items with FB members. Indeed, the item (5), on free markets most central to the Farm Bureau's basic position on free market competition, has the lowest correlation of all the items—.001. Thus, the rationale for membership in the Farm Bureau will have to be found elsewhere.

In table 3, similar results can be seen for past and current members of the Farmers Union. Again there are no significant differences between whether one is or has never been an FU member of between current and former members of the FU, although the mean for former members is slightly higher. Conversely, farmers who are not currently members of any farm organization have a lower mean than any other group, suggesting that, if anything, their views may be closer to the FU position of government intervention and greater control of the market than FU members, past or present. Also, with the exception of two items which are barely significant (at the .05 level), there is virtually no correlation between FU positions and the attitudes of FU members toward these policies.

Conversely, the data in table 4 show that former and, especially, current members of the National Farmers Organization are more likely to hold attitudes in line with the NFO's policies than nonmembers of the NFO, whether or not they are or have been members of other organizations. Particularly noteworthy is the significant difference in means between those who have never been members of the NFO and those who were or are now members (2.51 vs. 2.00). Not surprisingly, virtually all of the index items have significant correlations with current NFO members. In short, it would appear that unlike the FB or FU, members of the NFO are more likely to agree with the positions of the NFO than nonmembers.

The Farmer Alienation Index in table 5 indicates that farmers who are not currently members of farm organizations are more likely to be alienated in terms of agricultural policy options and life style than are members. Conversely, members of the FB and NFO and, to a lesser extent, FU members, are less likely to be alienated. This supports Wilson's position.

Selective Incentives

In follow-up interviews farmers were asked what services they obtained from farm organizations.

Table 3. Farmers Union Index of Support for Government Intervention (Support Control of Market)

and FU has increased since a similar survey in 1966 (Johnson and Warner); the NFO has experienced a considerable decline in membership (table 1). Two-thirds of farmers who have ever been NFO members have quit the NFO, while only about a third of those who have ever been members of the FB and FU have quit. On the question of the ability to sustain membership, Olson appears to be correct.

Agricultural Policies and Farm Operators' Opinions

The data in table 2, the Index of Free Market Support, show no significant differences in means of paired relationships determining whether one has been or is a member of the Farm Bureau, or whether or not a farmer is a member of any farm organization.[4] The mean is significantly different only when comparing those who are or have been FB members with those who have never been members of the FB. This difference undoubtedly is due to the fact that NFO members with clear views which often oppose FB policies are included here, along with FU members and others who are not current members of other groups or have never been members of the FB.

[4] A .05 level, 2-tailed test. This is the minimum significance level used for all tests of mean differences in tables 2–5.

more with Democratic Party policies, and the FB with Republican Party policies (p. 33). In any case, he argues that farmers in the United States do have a choice. Thus, in the spirit of Hirshman's notions of exit, voice, and loyalty, farmers in the United States will seek the group most suited to their political benefits, rather than develop rancorous politics within the organization (p. 42). In contrast to Britain, the lack of political debate among members in U.S. farm organizations should not be seen as an absence of interest in farm policies and politics but rather as a function of homogeneity of attitudinal beliefs on agricultural policies.[2]

If Wilson is correct, the data should show that the attitudes of members of any given farm organization should correspond closely to the policies of the state organization. This would be in contrast to farmers who are not members of that organization.

Data from a recent survey of Wisconsin farmers conducted by the Department of Rural Sociology at the University of Wisconsin sheds some light on this debate over motivation for membership. Four dimensions are examined: attitudes toward agricultural policies, the impact of selective incentives, the magnitude of the farm operation, and regional location. The first two dimensions provide a direct test of Olson's and Wilson's perspectives. The latter two dimensions provide additional levels of explanation of farm organization membership. Specifically, these data show that the larger the farm operation, the more likely it is that a farmer will join an organization. Location is important in Wisconsin because it points to the importance of historical factors in determining which organization farmers are more likely to join.

Methodology

The data presented here were gathered as part of a questionnaire mailed to 1,000 Wisconsin farm operators in January-March 1978, and through follow-up field interviews conducted in March–April 1979. The reported data refer to the 1977 calendar year. The sample was selected randomly from lists of farmers furnished by local township tax assessors. About 62% of those sampled returned usable questionnaires.[3] Follow-up interviews were conducted with about 200 of those who completed the questionnaires. All data are from the questionnaire except for items on the use of farm organization services, coop patronage, and decisions to join or leave the farm organizations, which are from the interview.

To measure correspondence of farmers' attitudes with farm organizations' agricultural policies, farmers were asked to rank their level of agreement, on a scale of one to five, with statements relating to farm life and agricultural policy. Most of these items were designed to tap the views of one or more of the state farm organizations on agricultural policy. These views were determined via consultation with observers in the University, an analysis of the organizations' literature, and discussion with representatives of the organizations.

In addition to the conceptual division of the items described above, the items were examined statistically via an intercorrelation matrix to determine which were more likely to be empirically interrelated. These two methods were combined to produce three scales, each of which is believed to be a reasonable approximation of policies of the FB, FU, and NFO. Means were calculated for each of four groups: (*a*) the current members of a given organization (FB, FU, or NFO), (*b*) former members of the organization, (*c*) farmers who have never been members of that organization, and (*d*) those who are not currently members of any farm organization. This latter category overlaps with parts of groups 2 and 3, but it is useful in distinguishing the effects of a current lack of any organizational affiliation.

In addition to these three scales of policy items, another grouping appeared. This group reflected a negative reaction to most of the policy options offered by the farm organizations, as well as a general dissatisfaction with community life and a feeling of powerlessness. To distinguish this from traditional alienation indexes, it is called a Farmer Alienation Index. An extension of Wilson's argument would suggest that the 62% of the sample who are not currently members of any organization are those who generally are more alienated, and thus do not find palatable any of the farm organization alternatives.

Scale means were calculated for five groups: farmers not currently members of any organization, members of each of the three organizations, and a composite mean for all three member groups. These means were tested for reliability with the SPSS Alpha Reliability program (Nie, pp. 58–102). In all cases, the reliability was significantly above the accepted minimum of .4 (.55 or more).

Regional analysis was conducted on the basis of regions used by the Department of Agriculture for crop-reporting purposes. Essentially, the intention was to divide Wisconsin's counties into nine regions, which emphasizes similarities within regions, especially in terms of soil and climatic conditions.

Findings

There is a substantial difference between organizations in their abilities to sustain membership. The percentage of farmers who are members in the FB

[2] Wilson does note political differences between national leadership and state organization, especially with the NFO and the FB (pp. 40–41). However, because we are testing his theories only in terms of Wisconsin, whose primary agricultural interest is dairying, this issue need not concern us here.

[3] Through telephone interviews, limited information was gathered on 38% of the nonrespondents. Little difference between this group and the group who completed questionnaires (616) is apparent.

Selective Incentives versus Ideological Commitment: The Motivation for Membership in Wisconsin Farm Organizations

Charles P. Cell

A common explanation for farmers' problems is the claim of poor organization (Morrison). In a 1965 survey of Wisconsin farm operators, Johnson and Warner determined that only 38% of farm operators were then members of major farm organizations. Twenty-two percent had been members previously, and 40% had never joined. The research reported here indicates that the overall percentages remain virtually unchanged a decade later. It appears, however, that the National Farmers Organization (NFO) has lost membership, while the Farm Bureau (FB) and Farmers Union (FU) have gained members relative to the total number of farmers in Wisconsin. Why do some farmers join, others quit, and still many others never join any of these organizations?

A debate has developed recently regarding the motivation for membership in farm organizations. This debate stems from the work of Olson. Although Olson is concerned with broad issues of how various sizes and types of groups function, the focus here is on his analysis of how large-scale or "latent" groups, without coercive abilities, function and gain commitment from their members. This is the focus because the farm organizations considered here all fit within this category.

Olson argues that large-scale organizations working toward the acquisition of resources that will benefit the entire constituency (i.e., all farmers) will not sustain membership. The incentive to belong is weak because all potential constituents including nonmembers will benefit if the organization is successful. However, if they offer "selective incentives," such as low-cost insurance plans and greater patronage refunds which benefit only members, then the organization is more likely to sustain its membership over time. Although this perspective may not explain the initial reasons for joining an organization (Cell), it does attempt to predict which farm organizations will sustain membership in the long run, and why.

Thus, Olson contends that the political policies and lobbying programs of the FB and FU are not significant factors in drawing support from farmers. However, he argues that selective economic benefits (e.g., low-cost insurance, milk testing, and higher patronage refunds from related coops) gained by joining should account for membership in these organizations. This, he believes, is in contrast to the NFO, which does not have selective incentives. The central goal of the NFO is to improve market conditions by gaining a commanding control of production through collective bargaining agreements. Olson believes that these benefits, should the NFO be successful, would not be selective, but rather all farmers would benefit.[1]

If Olson is correct, the data should show little difference of opinion between members and nonmembers of the State Farm Bureau and the Farmers Union on political and policy issues. NFO members would be expected to have a higher level of commitment to NFO policies. These data also should reflect the fact that the NFO has been less able to sustain its membership and that selective incentives are an important motivation for sustaining membership in the Farm Bureau and Farmers Union, as opposed to the NFO.

Wilson attacks Olson's position. "Olson's theory seems to explain neither the differences in the proportion of potential farmers recruited by pressure groups nor the number of such organizations which compete for his favours" (p. 33). If selective incentives are so important, Wilson asks why twice the number of British farmers join Britain's only farm organization than do American farmers who have multiple choices and selective incentives? This is particularly incongruous Wilson argues when one remembers that Britain's welfare state presumably makes the need for such benefits of selective incentives even less likely.

In contrast to Olson, Wilson sees farm organizations fundamentally as pressure groups (p. 44). This, he notes, is particularly true in the United States with the FU and NFO usually identified

---

The funding for this project was provided by the Wisconsin Agricultural Experiment Station.

The author wishes to thank the members of the Rural Sociology Core Area Seminar for their helpful comments. He is grateful to Pat Mooney for his dogged persistence in making the computer turn out the statistics in this paper, and is especially appreciative of the patient counsel and inciteful criticism of Doris Slesinger.

[1] There is some basis for arguing that when a farmer signs a collective bargaining agreement with the NFO he is getting a selective incentive. If the market price of the product is less than the contract price at the time the product is sold, the farmer benefits. Unfortunately for the NFO, it also can work the other way.

[a] Null hypotheses are as follows for the model $Y_t = \alpha + \beta_1 X_t + \beta_2 X_{t-1} + \beta_3 X_{t+1}$:

Column No. 1 $\alpha = \beta_1 = \beta_2 = \beta_3 = 0$;
Column No. 2 $\beta_2 = 0$;
Column No. 3 $\beta_3 = 0$;
Column No. 4 $\beta_2 = \beta_3 = 0$.

[b] SW indicates spring wheat, WW indicates winter wheat.

(1, 5)	1.69	4.06	6.61	16.3
(2, 5)	1.85	3.78	5.79	13.3

positive feedback was found for Oklahoma. These later results suggest that the allocation of allotments to states may have been endogenous and responsive to recent trends in plantings in the states. For the U.S. aggregate data, a negative relation was found between current allotment and lagged acreage, perhaps reflecting counter-cyclical effects of the allotment.

Although these results should not be interpreted as definitive, they do suggest that the temporal ordering of the relation between allotments and acreage is not homogenous across states and involves, in several states and possibly at the U.S. aggregate level, lags in response of acreage planted to the allotment, and vice-versa.

Instantaneous causality between X and Y would require, in addition to (4),

$$\theta^{\circ}_{t-j} = 0 \quad \forall \quad j = 1, \ldots, \infty \tag{6}$$

Finally, if the restrictions in equation (2) as well as those in (4) are rejected, then evidence exists which is consistent with the hypothesis of feedback between X and Y.

To summarize, the two regressions (1) and (5) present a basis for a two-step procedure of hypothesis testing concerning the temporal ordering of the relation between X and Y. In the above discussion, we began with equation (1) and proceeded conditionally to test parameter restrictions on equation (5). However, the choice of this starting point was arbitrary. By an analogous procedure, the process of inquiry could begin with equation (5).

Before proceeding we must consider the usefulness and necessary alterations of the proposed methodology in a context which is not bivariate. Certainly, if there existed a third variable Z, its relation with Y must be specified under the null hypothesis. If both Z and X are hypothesized to cause Y, then Z should be incorporated in (1). Alternatively, if Z is hypothesized to determine simultaneously X and Y, equation (1) would be a misspecification. Instead, the hypothesis of Z's exogeneity with respect to X or Y should each be investigated with appropriate variations of (1). Thus, in a multivariate system such as a national or international commodity market, the test of exogeneity can not be done with a bivariate model such as (1), but instead must be conducted in the context of a fully specified market model, see Geweke (1978).

In the present paper, the question of interest is the exogeneity of wheat acreage allotments in the determination of wheat acreage planted. Past studies have maintained the hypothesis that acreage planted is determined by a number of market, climatological, and policy factors. For example, we might postulate that at an aggregate level, supply of acreage could be written as a function of relative expected output prices, input prices, indexes of fixed factors or other technological constraints, and the wheat acreage allotment. However, under the null hypothesis that wheat acreage planted is determined by an exogenous wheat allotment, the above bivariate test procedure may be employed. Such a hypothesis would be consistent with simultaneity of allotments and planned acreage so long as actual acreage planted deviated from the plan. Specifically, the exogeneity of wheat acreage allotments to wheat acreage planted was investigated during the quota program (1950, 1954–64) at the state (for thirteen major wheat states) and national levels of aggregation. We focus on the quota program years because during these years allotments were designed specifically as constraints on acreage planted. Although there were years during which other programs were operative (e.g., marketing certificate programs, 1965–70; or the set-aside programs, 1971–73) no a priori basis was apparent for the justification of the hypothesis that parameters were stable across different government programs. Furthermore, Morzuch, Weaver, and Helmberger; and Weaver and Krainik present evidence which supports the hypothesis that parameters changed across government programs. Thus, we choose to employ a small sample (1954–64) rather than a larger, perhaps heterogenous one which might involve inappropriate parameter restrictions.[1] Specifically, models which are consistent with equations (1) and (5) are estimated with a single one-period lead and a single one-period lag.[2] That is, if we let acreage planted be Y and the allotment be X, and if we follow equation (1), then acreage planted is the dependent variable, and measures of the acreage allotment are the independent variables. Alternatively, when the allotment is the dependent variable, measures of acreage planted are independent variables as noted in equation (3). As discussed above, the temporal ordering of the relation between acreage planted and the allotment is investigated by testing the validity of appropriate leads or lags.

Table 1 reports F-statistics in columns labelled 1 for the empirical versions of equations (1) and (5), which include one lead and one lag. In addition, F-statistics are presented for tests of restrictions discussed above, which allow inference concerning the temporal ordering of the relation between acreage planted and the allotment. Specifically, columns marked 2 indicate the F-statistic associated with the hypothesis that the lag coefficient is zero, while columns marked 3 report tests of a zero restriction on the lead. Columns marked 4 report the F-statistic for a joint test of the restriction that both the lead and the lag are zero.

As results in table 1 indicate, no general conclusion can be drawn concerning the exogeneity of allotments. We see that in North and South Dakota the relation appears to have been instantaneous, while in Montana and Colorado no relation appears to have existed. For the remaining states we find a one-period lag in the relation. Specifically, for Kansas, Illinois, Indiana, and U.S. aggregate data, we find evidence which supports the hypothesis that allotments were exogenous and had a one-period lagged effect on acreage. For Ohio and Washington evidence strongly supports the hypothesis that acreage planted was exogenous to allotments, having a positive, one-period lagged effect. Similar, though weaker, evidence is found for Nebraska, Texas, and the United States. Strong evidence of

[1] Geweke (1977) reports results of application of the methodology to small samples, which lead him to the tentative conclusion that the exogeneity results appear robust.

[2] We have followed Geweke's 1977 suggestion that an appropriate criterion for selection of the length of lag is the convergence of the residual to a white noise process. In all cases, inclusion of one lead and one lag was sufficient to accomplish this.

A Test of the Temporal Exogeneity of Allotments and Acreage Planted

The importance of the classification of variables as either endogenous or exogenous was noted above. We will adopt Granger's definitions of causality which underlie what Sims has called exogeneity. Specifically, Granger has emphasized that the effect of a change in an exogenous variable on an endogenous variable must take time. (This differs from the orientation taken in earlier literature on simultaneity and instantaneous causality which largely ignored the importance of time in causation; see, e.g., Strotz and Wold, Basman, Simon, and Orcutt.) That is, at a theoretical level exogeneity is only meaningful if time passes while cause takes effect. For example, the statement X causes Y makes sense only if we mean X_t causes $Y_{t+\delta}$ where δ is a positive, though possibly infinitely small, increment.

To proceed, it is useful to establish the set of possible relations between X and Y which may exist at a theoretical level as well as those which may be identified at an empirical level. As illustrated in figure 1, we have three possible hypotheses concerning relations between X and Y: (*a*) X_t is exogenous to $Y_{t+\delta}$ (indicated by single lined arrows); (*b*) Y_t is exogenous to $X_{t+\delta}$ (indicated by double lined arrows); or (*c*) X_t is exogenous to $Y_{t+\delta}$, and $Y_{t+\delta}$ is exogenous to $X_{t+\delta+1}$; or Y_t is exogenous to $X_{t+\delta}$, and $X_{t+\delta}$ is exogenous to $Y_{t+\delta+1}$. The latter possibility is labeled feedback and would be represented by a path of causation which alternates between single and double lined arrows. In addition to one of these relations between X and Y, the possibility that no relation exists represents a fourth hypothesis which must be considered. Consistent with this possibility would be the simultaneous occurrence of X_t and Y_t, both determined by a common vector $\mathbf{Z}_{t-\delta}$.

Unfortunately, stepping from a theoretical concept to an empirical setting requires measurement of X and Y over discrete intervals. In such a case, it is possible that X_t is exogenous to $Y_{t+\delta}$; however, if the time series X and Y can be observed only discretely at intervals of an equal length which exceeds δ, then the effect of X on Y would appear to be instantaneous. Likewise, if Y_t is exogenous to $X_{t+\delta}$; however, the observation interval exceeds δ, then the effect of Y on X would appear to be instantaneous. In either case of instantaneous causality, no inference can be made concerning the direction of causation in the absence of observations taken at equal intervals of length less than δ. However, we may conclude that in an empirical context the concept of instantaneous causality between X and Y would be consistent with the Granger notion of the temporal ordering of cause and effect.

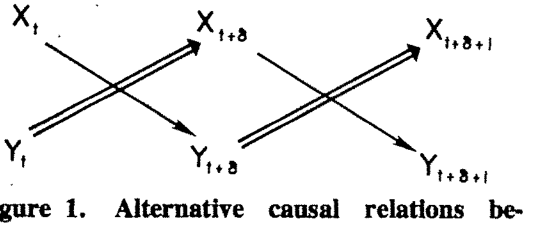

Figure 1. Alternative causal relations between X and Y

As Granger has shown, these definitions provide the basis for a convenient empirical test of a hypothesis of exogeneity. We will review briefly these techniques and their usefulness for investigating the exogeneity of allotments to acreage planted, the hypothesis maintained by past acreage supply studies.

To begin, consider the case where the relation between X and Y is bivariate; i.e., simultaneous determination by other factors, $\mathbf{Z}$ is ruled out. Suppose that we pose as a null hypothesis that in such a bivariate system, X_t is exogenous to $Y_{t+\delta}$. It follows that at any time t, Y cannot be determined by X and also determine X. The empirical analog of this implication (Y is not exogenous to X) of the null hypothesis is that the partial correlation between any future X and current Y will be zero. Translating this into a regression context, the null hypothesis implies that the coefficients of any future $X_{t+\delta}$ included in a regression of Y_t on $(X_t, X_{t+\delta})$ would be zero. Stating this explicitly, we may employ the following equation:

$$(1)\qquad Y_t = \phi(F)X_t + \theta(B)X_t + \gamma X_t + \epsilon_t,$$

where $\phi(F) = \sum_{j=1}^{\infty} \phi_{t+j}F^j$; $\theta(B) = \sum_{j=1}^{\infty} \theta_{t-j}B^j$; F, B are forward and backward shift operators, respectively; and $\epsilon_t \sim N(0,\sigma^2)$. Under the null hypothesis, X causes Y, or (as argued above), equivalently, Y does not cause X,

$$(2)\qquad \phi_{t+j} = 0 \quad \forall \quad j = 1, \ldots, \infty.$$

In addition, the null hypothesis X causes Y instantaneously would require

$$(3)\qquad \theta_{t-j} = 0 \quad \forall \quad j = 1, \ldots, \infty.$$

The alternative hypothesis to X is exogenous to Y is a composite of two possibilities: (*a*) Y is exogenous to X, or (*b*) no relation between X and Y exists. To discriminate between these possibilities, we may proceed conditionally upon the rejection of the restrictions in (2) and test as a null hypothesis the statement that Y_t is exogenous to $X_{t+\delta}$ versus the alternative that Y_t is not exogenous to $X_{t+\delta}$. However, the only inference consistent with the rejection of the restrictions in (2) and this latter alternative is that no relation exists between X and Y. By an argument similar to that presented above, the hypothesis Y causes X, or, equivalently, X does not cause Y implies

$$(4)\qquad \phi^{\circ}_{t+j} = 0 \quad \forall \quad j = 0, \ldots, \infty$$

in the regression:

$$(5)\qquad X_t = \phi^{\circ}(F)Y_t + \theta^{\circ}(B)Y_t + \beta^{\circ}Y_t + \epsilon^{\circ}_t.$$

The Causal Linkage of Control Policy and Its Targets: The Case of Wheat

Robert D. Weaver

Measurement of the impact of a policy instrument (I) on a target variable (X) which is the object of control traditionally has relied upon the hypothesis that I is exogenous to X. Given this hypothesis, a reduced form equation relating X to I is specified and estimated. However, this specification ignores the fact that the level at which the instrument I is set and the desired level of the variable X are both chosen by the policy maker in an attempt to optimize some criteria. Thus, just as inputs, outputs, and, typically, profits are determined endogenously by the firm, the instrument I and the target level for X are chosen simultaneously by the policy makers. In other words, policy instruments, like prices, may be endogenous at the market level, determined by exogenous factors considered by policy makers, although "taken by" or exogenous to individual producers.

Despite the intuitive appeal of this proposition, economists only recently have acknowledged its implication for the measurement of impact multipliers employed in policy design (Lindbeck, Feige and Pearce, Sims). If I is endogenous and determined simultaneously with X, direct estimation by ordinary least squares (OLS) of an equation relating X to I would result in inconsistent estimates (Theil). Unbiased estimates of the impact multipliers can only be achieved through a linkage of the estimation procedure to the theoretical specification of the system in which the instruments and targets are related. In the firm's case, as in the policy maker's, this sytem is the necessary condition for optimal choice of instruments, given the objectives of and the constraints on its choices.

At an empirical level, the validity of the hypothesis is more complicated. Clearly, if the chosen target level of X is not achieved or observed, then although planned X and the level of I may be simultaneous, actual X and I may not be. However, even in such a case the endogeneity of I implies that feedback between I and X may exist as past levels of X influence the choice of current I. Thus, at an empirical level we may conclude that alternatives exist to the hypothesis that I is exogenous to X as maintained in past literature (Lucas; Rausser and Stonehouse). Despite its importance for model specification, the validity of hypotheses concerning endogeneity or exogeneity of variables is difficult to assess. This paper presents and considers the usefulness of a methodology developed in recent literature for assessing the validity of hypotheses concerning the exogeneity of variables such as I to others, such as X. The design of effective and least-cost policies for the control of acreage planted to crops has relied on policy impact multipliers estimated under the maintained hypothesis that policy instruments are exogenous to acreage allocations, see e.g., Garst and Miller, or Houck et al. As a case for application, the present paper considers the exogeneity of wheat acreage allotments to wheat acreage planted at the state and national levels of aggregation during the quota program years 1954–64.

Robert D. Weaver is an assistant professor of agricultural economics, Pennsylvania State University.

The Relation between Policy and Its Targets: The Case of Wheat Acreage

One of the most crucial specification decisions which must be made if the relationship among a group of variables is to be quantified is the classification of those variables as either exogenous or endogenous. Past studies of the determinants of acreage allocation and the effects of control policies have maintained the hypotheses that acreage is endogenous and subject to the control of the farmer, and prices (or moments of their subjective distribution) as well as policy instruments are exogenous determinants of acreage. While this classification may be justified by market structure evidence when acreage is measured at the farm level, at aggregate levels its validity is subject to uncertainty. At some level of aggregation, prices or policy may be endogenous to the mechanism which determines them although they may be exogenous to the farmer. Although the validity of a particular specification concerning the exogeneity of prices is an important empirical question, the present paper will focus on the exogeneity of the acreage allotment with respect to acreage planted to wheat.

While it would be difficult to dispute the statement that acreage control instruments such as the allotment are exogenous at the farm level, acreage supply studies most often estimate the relation using aggregate data. For example, national aggregate data is employed by Houck et al., Garst and Miller, and Gardner. Although less typical, state or regional studies have been completed, e.g., Just, Harrison and Heady, Weaver and Krainik, and Morzuch, Weaver, and Helmberger. As has already been noted above, if at any of these levels of aggregation the policy instruments and acreage are simultaneous, then the parameters reported by these studies would be inconsistent estimates.

modity Markets, ed. F. G. Adams and S. A. Klein, pp. 161–88. Lexington, Mass.: Lexington Books, 1978.

Turnovsky, Stephen. "The Distribution of Welfare Gains from Price Stabilization: A Survey of Some Theoretical Issues." *Stabilizing World Commodity Markets*, ed. F. G. Adams and S. A. Klein, pp. 119–48. Lexington, Mass.: Lexington Books, 1978.

goals of increased price stabilization are deemed to be worth the increased program costs of stabilization in a rich country such as the United States; the rate of growth in the export demand for grain, as well as its stability; the policy position with respect to price stabilization of such third parties as livestock producers and grain dealers and millers; and the commercial trade relations of the United States with such superpowers as the Soviet Union and the People's Republic of China. In the process of arriving at a decision with respect to a new and possibly strengthened grain stabilization policy, the U.S. Congress may be expected to gather information, data, and analyses in connection with the above developments, and perhaps many others. This it may be expected to do through the hearing process in which it takes testimony from all parties with an interest in stabilization policy, including the administration in power.

If a team of welfare economists should be invited to present testimony, or if they should offer to present testimony, with respect to grain stabilization policy that is based solely on the logic of consumer and producer surplus, they and their testimony in all likelihood would be destroyed in the hearing process; their destruction would occur as congressmen, unsympathetic to their conclusions and with the aid of legal counsel, inquired into the substance—the empirical content—of their testimony. The discrediting of their testimony might well lead down the following path of questions. "My dear Professor Y, would you please tell the committee how I might measure my consumer surplus for Wheaties, or for all food if you prefer?" "My dear Professor Y, would you please compare the consumer surplus of Mr. A for Wheaties with the consumer surplus of Mr. B for Wheaties?" And finally, "My dear Professor Y, would you please tell the committee which federal agency in this town can provide it with an estimate of the consumer surplus of the nation for the product, Wheaties, or bread, or all food?"

Answers by the economic team to the effect that their analysis was not intended to provide that kind of empirical information would be to no avail. The congressmen would insist upon receiving solid, substantive answers to what they perceived to be reasonable questions. And in holding to this position they would not be entirely wrong. If they are to make policy decisions, in this case a decision with respect to a stabilization policy for the grains, on the basis of testimony presented to them, they must, in turn, be able to use the information provided in testimony to defend their policy decisions on the political hustings. Politicians engaged in the policy decision process demand and get solid, substantive information and analyses which they can use with their constituents; and they are wary, exceedingly wary, of logical niceties, no matter how elegantly presented, which have little or no meaning to their constituents.

In Conclusion

It may be the case that welfare analyses of commodity stabilization schemes have some value in the way of exercising the brain cells of economists. But chess also exercises the brain cells. And chess has the clear advantage of being exactly what it purports to be, namely, a game. Thus, I find it easy to recommend that each economist, who heretofore has busied himself with welfare analyses of commodity stabilization schemes, substitute the playing of chess for his or her welfare analysis activity. If these practitioners of welfare analyses are the skilled problem solvers that neoclassical apologists would have us believe, they should be world class chess players in no time at all, and the clear-cut victories won in tournament play should lift them to utility planes never dreamed of in the mundane field of economics. Meanwhile the rest of us would be spared the time-consuming chore, the cost, of reading each new welfare analysis of a commodity stabilization scheme for fear that we might miss some new piece of usable knowledge if we did not. And finally, this vigorous pursuit of chess as a substitute for welfare analyses of commodity stabilization schemes should provide the same contribution to the making of decisions with respect to national commodity stabilization policy that the former welfare analyses did, namely, a zero amount.

consequences for them, and producers fear a big downswing in farm product prices which can ruin them financially.

Starvation and Stabilization Policy

A less developed country, 20% to 40% of its population living in abject poverty, that has experienced a shortfall in grain production (the basic foodstuff of its people), causing grain prices to rise sharply, has no need for a theoretical welfare study (in which the position and slope of the demand curve for grains are unknown, outside the customary range of prices, and hence the magnitude of the consumer surplus is unknowable) for guidance as to the best way to deal with the situation. Every man and woman in such a country knows from past experience what an important shortfall in grain production and a sharp rise in the price of grains means; it means that through the income effect of such a price rise, large numbers of the poor will be forced into a state of starvation, unless the shortfall is in some way offset. If the government of such a nation is a responsible government, it will be seeking ways before the advent of a production shortfall, in the midst of such a shortfall, and following it to obtain supplies of grain to offset the production shortage and thereby stabilize food prices to its people. To this end the government will require information, data, and empirical analysis with respect to the magnitudes of potential or actual production shortfalls, the numbers and locations of the persons involved, storage costs, methods of distribution, methods of financing, and outside sources of supply. But it does not require a theoretical analysis based on dubious assumptions, devoid of empirical content with regard to the possible costs and benefits to its people of a grain stabilization program, when it knows what the costs to its people of a "no-program" course of action are, and when it can obtain empirical estimates of the costs of operating such a program.

The Policy Process in the United States

The activist consumer in the United States dutifully votes for his or her governmental officers, writes to his or her congressman, votes at his or her union meeting or League of Women Voters meeting, and attends rallies on nuclear power and the high cost of living. Such a consumer may have a hazy concept of demand from some far-off course in the "Principles of Economics," but he or she will have little or no idea of how much of commodity *X* he or she will purchase if the price of commodity *X* increases by 50%, and all else remains constant, and he or she will be totally ignorant of the concept of consumer surplus and the wonderful benefits that are accruing to him or her from buying commodity *X* at the current price rather than at a price 50% higher. And God only knows what the nonactivist consumer is thinking about; it certainly will not be about his or her consumer surplus. But the activist consumer will know and the nonactivist will dimly perceive that a significant increase in grain prices will result almost immediately in an increase in the price of bread and cereal products, in an increase in the near future in dairy and poultry prices, and in an increase in the not-too-distant future in red meat prices. And even the dumbest of consumers will recognize that these increases in food product prices will, other things holding constant, result in a somewhat reduced material level of living for them. Thus, ignoring for the moment the program costs of grain price stabilization, consumers can be expected to favor a stabilization program for the grains which operates to place a ceiling over upward movements in grain prices but which does little or nothing to halt their decline.

In a comparable fashion, the individual grain producer will be well informed regarding his current cost situation, and will have a pretty good idea regarding his individual supply curve for grain over a limited range of prices. But he will be at a loss to say how much grain he would try to produce if the price of grain increased by 50%, all else holding constant, and he will be unaware of the cost and supply structures of grain producers outside his local area. Finally, he will never have heard of the concept of producer surplus. Thus, the slope and position of the supply curve for grains, outside the customary range of prices, will be a mystery to him, as it also is to economists, and the concept of producer surplus will have no meaning at all for him. But the individual grain producer will know exactly how his gross and net returns will be affected by a 10% or 20% or 30% increase, or decrease, in the price of grain, all else holding constant. And if he is an activist type he will be telling his farm organization leaders to work for, and he will be writing his congressman to elicit his support for, a program which places a floor under grain prices at or near his perceived average costs of production, and which allows grain prices to rise freely in the market above that support level.

In a society such as that in the United States in the 1970s, where the political power of consumers is emerging and grain producers continue to hang on to their power, it is reasonable to expect some form of price stabilization to take shape for the grains with both a floor and a ceiling. The current price support program for the grains and the farmer-held grain reserve are in fact a manifestation of that shared political power. Whether a grain reserve program with a greater capacity to stabilize grain prices on the upside, as well as the downside, will come into being in the 1980s is a moot question. The answer to that question will depend upon a series of developments: whether the conflicting price stabilization goals of consumers and grain producers can be further reconciled; whether the

Notes

Some Nonconformist Thoughts on Welfare Economics and Commodity Stabilization Policy

Willard W. Cochrane

The theoretical literature based upon the welfare concepts of consumer and producer surplus dealing with economic instability and commodity stabilization is wide, deep, and growing. This work will not be reviewed in this brief note, first, because it is well known to economists concerned with commodity stabilization and, second, because it recently has been surveyed by others (Burnstein; Turnovsky; Sarris and Taylor; Smith; Burmeister). As is equally known, this body of literature does not provide a conclusive argument either for or against deliberate commodity stabilization by national governments or international organizations. But it is not the purpose of this note to try to strengthen the theoretical arguments based upon welfare concepts either for or against commodity stabilization by government. It is the purpose of this note to argue that welfare analysis based upon the concepts of consumer and producer surplus has not in the past made, and will not in the future make, any recognizable contribution to the making of decisions by the United States, other developed countries, the less developed nations, or the international agencies either to initiate commodity stabilization programs or to reject them. This is true for a variety of reasons, some of which are discussed below.

Conceptual Issues

The demand curve is a powerful tool of economic analysis. It enables us to describe the quantities of a product that will be purchased at varying prices and to state how the price of a product will vary with changes in its supply. And we can derive from it such useful concepts as marginal revenue and total revenue. From it also is derived the concept of consumer surplus. I find this concept to be both slippery and of limited use, and controversy has swirled around the concept of consumer surplus since it was rediscovered and popularized among economists, at least, by Alfred Marshall around 1890 (Marshall, pp. 125–30; Currie, Murphy, and Schmitz). This is the case, first because it is not completely clear in what sense a consumer reaps an economic surplus from purchasing a given product at its current price. I, for example, cannot believe that I am the recipient of an economic surplus, if I cannot conceive of the conditions under which I would be required to purchase single units of a given product at succeedingly higher prices along my unknown demand curve for that product. The concept of consumer surplus is, for me, an illusion created by an alternative purchasing procedure which is nonoperational.

Second, consumer surplus may properly measure the change in utility to a consumer, or a group of consumers, for a change in the price of safety pins because the values involved are so small that the income effect of the price change to the consumers is negligible; hence, changes in the marginal utility of money to those consumers is negligible. But consumer surplus will not properly measure the change in utility to consumers, particularly poor consumers, for a significant change in the price of food because the income effect of such a price change becomes large relative to the incomes of those consumers; hence, the price change induces a significant change in the marginal utility of money for those consumers.

Third, it may well be the case that consumers generally would agree with Waugh that price instability is to be preferred to price stability where they know with certainty that price will fluctuate in a regular pattern such that their total expenditure for the product is reduced in a future time period over what it would be with perfect price stability. But such a formulation of the problem of product price instability might well be relegated to a footnote, as Samuelson has suggested, for the entire concept of consumer surplus. The instability problem that concerns consumers mightily is the unpredictable possibility of an increase in the price of food of such a magnitude and of such a duration that their real income position would be seriously and adversely affected.

Fourth, when the concept of producer surplus is added to the concept of consumer surplus in an analysis of product price instability, the analysis tends to become a geometric puzzle in which little boxes of uncertain content are pushed around under the assumption of regularized, predictable price fluctuations and the certainty of government compensation. This kind of puzzle-solving seems to have an appeal for some economists (Samuelson, Little), but it has little or no relevance for the uncertain world in which consumers fear the unpredictable prospect of a large upward thrust in food prices which can have devastating real income

Summary and Conclusions

This study has outlined the complexities of natural resource production under uncertainty. Formally, the estimation of timber stock levels and the rate of experimentation are two parts of a joint problem that, along with the determination of optimal production rates, require simultaneous solution. The LQG control model is employed as an approximately optimal solution to this problem. The LQG is seen to complement deterministic natural resource models. This complementarity allows for the inclusion of stochastic factors to analyze the varying impacts of uncertainty on policy decisions. Stochastic simulations over the planning horizon can be utilized to reveal not only the likely impact of disturbances omitted in the deterministic model, but how to minimize the cost of unexpected events. Of course, the specification of quadratic preferences implies risk aversion, which is certainly not an implausible stance for a manager of publicly owned resources.

While the strengths of LQG analysis are considerable for natural resource models, some weaknesses remain. For example, uncertainty is not modeled explicitly in the objective function, but the impact of preference uncertainty can be approximately measured by varying the objective function parameters. Varying these parameters also can be used for preposterior analysis to help policy makers define their preferences more distinctly as discussed by Rausser and Freebairn. The solution to the LQG in (8)–(10) requires that $\delta \mathbf{u}_t$ and $\delta \mathbf{x}_t$ can take on any real value, a substantial difficulty for natural resource models. Further methodological research is needed to cope with feasibility constraints in a less approximate way that is still manageable computationally.

The LQG is not the only approximation that could be used for resource management under uncertainty. The method of Taylor and Talpaz using first-order certainty equivalence is a possibility but would require iterative optimization. In problems with numerous controls, such as ours, this approach and others requiring iterative methods are not practical. Additionally, it is important that the approximating method used should incorporate an observer and state estimation capability that can be readily utilized.

The application of the LQG model to the harvest scheduling problem of a national forest illustrates why policy makers are justified in not adhering strictly to plans generated by deterministic models. The simulations demonstrate the impact of uncertainty on production levels and give the relative costs of various sources of uncertainty. Thus the scheduling of production and the allocation of research funds or, indeed, the allocation of capital between information collection and production, can be approached more rationally. Since the problems of research and production are being jointly solved for most empirical problems, it is not unreasonable that plans and policies from deterministic models are not more widely applied.

(or cardinal) costs of uncertainty can invest in improved passive information to reduce these costs. It can be seen easily from table 3 that for this problem, the costs of uncertainty exceed the costs of target deviation influenced by direct policy actions.

Table 3 decomposes the costs for $S1$ on a period-by-period basis for the first five periods. For the initial period, the future cost of stock evolution uncertainty, $\Sigma tr.\mathbf{H}_{t+1}\Omega_t$, is 65% of the expected total costs. The importance of this source of uncertainty relative to the costs of imprecise timber volume estimation in the successive time periods, $\Sigma tr.\mathbf{A}'_t\mathbf{H}_{t+1}\mathbf{B}_t\mathbf{G}_t\mathbf{P}_{t|t}$ and $tr.\mathbf{H}_t\mathbf{P}_{t|t}$, is evident in table 3. The total cost of future additive uncertainty about the dynamics exceeds the cost of future stock estimation uncertainty in every period as shown by comparing the fourth column in table 3 with the fifth column. Thus, for preferences that emphasize the maintenance of targeted harvest levels, more is gained by lowering the additive uncertainty in the dynamic growth equations, Ω_t, than observation uncertainty. Furthermore, lessening uncertainty about the dynamics also serves to lessen the covariance of the state vector estimate due to the recursive nature of the Kalman estimator. In effect, the precision of state variable predictions based on prior sample data is increased so that *ceteris paribus*, the precision of all future state vector estimates is increased.

When nonstumpage loss values are included in the preferences, the largest percentage share of uncertainty costs shifts to the imprecision of current stock level estimates. In the initial period, the cost of current uncertainty in the estimate of the stock levels, $tr.\mathbf{H}_0\mathbf{P}_{0|0}$, is 59% of the expected total costs as indicated in table 3. This result follows naturally when nonstumpage benefits are derived from the current stocks. It can be further observed in table 3 that the cost of dynamics' uncertainty, $\Sigma tr.\mathbf{H}_{t+1}\Omega_t$, is greater than the cost of future stock estimates, $\Sigma tr.\mathbf{A}'_t\mathbf{B}_t\mathbf{H}_{t+1}\mathbf{G}_t\mathbf{P}_{t|t}$, so that once again the cost of future dynamics' uncertainty is greater than the cost of estimating future stock levels. The implication is that the future growth estimation uncertainty, Ω_t, is of greater cost than future observer uncertainty, θ_t.

Given the large proportion of costs accounted for by current uncertainty in the state estimate for $S4$, it would be prudent to attempt lessening of the current stock estimate's variance. In the LQG problem, the initial state covariance, $P_{0|0}$, is a prespecified parameter, a realistic assumption because the sampling of forest stocks cannot be undertaken at a moment's notice. Thus the decision makers should reexamine existing data and estimation methods to see if the current stock levels could be estimated with greater precision.

A strong case can be made that the growth dynamics error should be lessened relative to observer imprecision, irrespective of which of the preferences in $S1$–$S5$ is selected to determine management actions. However, the rate of return to expenditures on uncertainty reducing research must also be considered in determining the most efficient allocation of resources for passive information acquisition.

Table 2. Mean Norms for the Control Vectors for Five Periods for the Five Different Preferences

Preference Period	S1	S2	S3	S4	S5
1	.082	2.398	3.786	8.037	11.351
	(.007)	(.280)	(.442)	(.936)	(1.314)
2	.177	3.229	4.911	9.182	11.690
	(.014)	(.336)	(.492)	(.810)	(1.009)
3	.413	2.533	3.648	5.839	7.288
	(.032)	(.215)	(.302)	(.463)	(.579)
4	.598	2.864	3.904	5.562	7.317
	(.036)	(.196)	(.259)	(.408)	(.457)
5	1.107	2.946	3.653	4.467	5.332
	(.077)	(.214)	(.268)	(.390)	(.445)

Note: The norms are in millions of cubic feet and the standard error of each mean is given in parentheses below each sample mean.

effort being exerted. It can be readily observed that in comparison with all of the norms for $S1$, the other preference structures result in much more control action. Thus it is clear that the preference structure results in actions that strongly favor taking nearly all the scheduled harvests in each period and letting stocks vary from their targets. When $\mathbf{Q}_t$ is increased parametrically, the control trajectories first change substantially even for seemingly small values of $\mathbf{Q}_t$. In periods one through five the mean norms for $S2$ are at least two-and-a-half times as large as those in $S1$. For preference weightings $S3$, $S4$, and $S5$ the corresponding norms are larger than those in $S2$, but the rate of increase decreases rapidly as a function of the increases in $\mathbf{Q}_t$. It is clear that as the nonzero elements of $\mathbf{Q}_t$ increase, the harvest levels are increasingly set to insure that the targeted stocks and their associated benefits will be available for future periods. Observe that the marginal change in the control norms is relatively small once the nonzero elements of $\mathbf{Q}_t$ are greater than one.

The basic patterns of the simulated trajectories over varying preference weights $S1$–$S5$ can be summarized as follows: due to the uncertainty in the model represented by the additive error terms $\mathbf{e}_t$ and $\mathbf{v}_t$, either control deviations or stock deviations must be tolerated. For this particular model and for most forestry models, the greatest sensitivity of controls is when the nonstumpage benefits of the timber stocks per period are substantially less than the benefits generated by the harvest of a unit of timber in a given period. Timber growth is slight over a ten-year period for most stands, so that removal of part of a timber resource has substantial implications for numerous future decades. Thus uncertainty about the management preferences is most crucial for the level of control actions when the nonstumpage benefits of the timber stock per period are quite modest relative to the stock's harvest value.

Cost of Additive Errors to Dynamics and Stock Observation Systems

The simulated results from the prior sections emphasize the importance of knowing which preference structure is to be implemented. In this section, the cost of uncertainty about the physical system is considered from two directions. First, which of the sources of uncertainty about the physical resources tend to be most costly for a given preference weighting and, second, how the relative costs of uncertainty vary across the set of preferences represented in $S1$–$S5$.

In analyzing the costs of uncertainty, the decomposition of the expected cost as given in (11) is utilized extensively. The impacts of uncertainty in $S1$–$S5$ can be dichotomized conveniently. The costs of a given source of uncertainty under the various preferences in $S2$–$S5$ are approximately proportional to the loss value of nonstumpage benefits. Thus, the analysis of the costs of uncertainty can be limited to a comparison of the costs between the stumpage-oriented objective function, $S1$, and the objective function $S4$, which has equal loss values for both stumpage and stock deviations.

Because the preferences $S1$–$S5$ use an arbitrary loss unit and the costs are invariant under a linear transformation, only ordinal and percentage comparisons can be made. Nevertheless, these results are useful to the resource manager concerned with allocating an operating budget between competing needs. What is of primary importance for optimal resource management is that the relative costs of uncertainty are known. Because the control actions are optimal, the costs of direct policy action in column two of table 3 cannot be reduced. However, a manager who knows the ordinal

stochastic simulations is a measure of the relative responsiveness of the controls under the preferences $S1$–$S5$. An alternative measure of responsiveness would be the mean absolute deviation of the controls from their target values.

watershed management, wildlife conservation) as summarized in Clawson, the set of objective functions is structured to represent this diversity. Each deviation from a scheduled harvest is given a weight of unity and the weights for each deviation from a target volume for five different preference sets are shown in table 1. The terminal volume deviation cost is simply the sum of squared volume deviations in each class for all of the simulations. The costs in each period are discounted at 7% per year.[3]

Control Model Solution Procedure

The optimal filter estimates, covariances, and optimal controls are calculated using a program written by the authors. The solution procedures for the linear Kalman filter are closely analogous to the LQG control solution, so only the latter will be outlined.

Careful perusal of equations (10), (9), (8), and (5) shows the basis of the analytic solution procedure. In equation (10), the transversality condition defines the terminal costate matrix, $\mathbf{H}_T$ as equal to $\mathbf{Q}_T$. This allows solution of last-period gain matrix, $\mathbf{G}_{T-1}$ from equation (9). Substitution of $\mathbf{G}_{T-1}$ into equation (10) enables the costate matrix $\mathbf{H}_{T-1}$ in the $T-1$th period to be calculated. Thus the costate and gain matrices for each time period are solved in a backwards recursive manner and stored in the computer memory. Using equation (8), $\delta\mathbf{x}_{0|0}$ and $\mathbf{G}_0$, the optimal initial control $\delta\mathbf{u}_0$ is calculated and implemented. At the beginning of the next period $\delta\mathbf{x}_{1|1}$ is estimated using the Kalman filter and the whole process is repeated.

Table 1. Values of the Undiscounted, Nonzero Elements of the Objective Function Weighting Matrices

Preference Set	$\mathbf{R}_t$	$\mathbf{Q}_t$
*S*1	1.0	0.0
*S*2	1.0	0.1
*S*3	1.0	0.2
*S*4	1.0	1.0
*S*5	1.0	4.0

In the runs analyzed in this study, a random number generator is used to simulate $\mathbf{e}_t$ and $\mathbf{v}_t$, the random error terms. The dominant sources of computing costs lie in the storage of the $\mathbf{G}_t$ and $\mathbf{H}_t$ matrices in each time period and the inversion of the matrix $[\mathbf{R}_t + \mathbf{B}'_t\mathbf{H}_{t+1}\mathbf{B}_t]$, which has the dimensions of the vector of control variables. Using this approach, optimal unconstrained controls for systems exceeding twenty state variables and twenty controls can be solved at moderate cost.

Analysis of Simulations

The results of stochastic simulations are analyzed in this section to demonstrate the usefulness of the LQG model for policy evaluation under uncertainty. The effects of differing objective function weights in response to estimated deviations and the impact and costs of various sources of uncertainty are analyzed.

The Effect of Changing Preferences on Control Response

Due to the quadratic form of the objective function, certain characteristics of the controls are predictable. As discussed in Athans, the relative weight of $\mathbf{Q}_t$ to $\mathbf{R}_t$ indicates how responsive the controls are to estimated deviations in the state vector. Referring to the definition of the control matrix $\mathbf{G}_t$ in (9), it is apparent that with $\mathbf{R}_t$ fixed, control response increases with increases in the size of the elements of the $\mathbf{Q}_t$. However, the rate of increase in control response generally will decrease with further increases in the $\mathbf{Q}_t$. The important question from a management point of view is for what values of $\mathbf{Q}_t$ will small variations in the objective function weights have the greatest impact on the control levels?

The answer to this question is revealed in table 2, which gives the means of the norms of the control vectors over thirty stochastic simulations for each of the five objective function specifications.[4] The norm (Euclidean length) of a vector is used as a measure of the control effort.[5] The larger a norm is, the more control

[3] A potentially disturbing aspect of the quadratic preferences is that the $\mathbf{x}^*_t$ and $\mathbf{u}^*_t$ define bliss points. However, greater timber densities do not necessarily have positive marginal benefits for nonstumpage flows. Thus the bliss point characteristics of quadratic preferences are not a substantial detriment in this application.

[4] Despite the construction of $\mathbf{B}_t$ designed to avoid infeasible controls, about 6% of the controls were infeasible. These were set to the nearest feasible value, similar to the method in Kim, Goreaux, and Kendrick.

[5] Chow states that $\mathbf{G}'_i\mathbf{G}_i > \mathbf{G}'_j\mathbf{G}_j$ by a positive semidefinite matrix where i and j denote different G's in (9) indicates more policy response to a given, estimated deviation in the state vector. Hence, comparing the mean norm of the control vector over

cate how research efforts might be allocated between increasing knowledge of production and growth processes or sampling of resource stocks. In the LQG formulation, the optimal observation intensity problem is not explicitly solved. As discussed in Rausser and Howitt, computation of the optimal sampling intensity usually must be computed numerically for even algebraically simple problems.

Description of Empirical Model

This section briefly describes harvest scheduling on the Stanislaus National Forest and then transforms the problem into a linear-quadratic-Gaussian model. Our discussion is descriptive because the details of parameter estimation are lengthy and given fully in Dixon and Howitt. The model used to derive the target trajectory of state and control variables is discussed first, and then the quadratic preferences and linearized dynamics are described.

The Underlying Problem

The current harvest-scheduling policy for national forests as given in the National Forest Management Act of 1976 (Public Law 94-588) is to ". . . limit the sale of timber from each national forest to a quantity equal to or less than a quantity which can be removed from such forest annually in perpetuity on a sustained-yield basis . . ." (Sec. 11). The Act further provides that the Secretary of Agriculture may allow departures from the projected long-term average sale quantity to meet overall multiple-use objectives. The de facto harvest-scheduling policy utilized by the United States Forest Service, as discussed in Zivnuska, basically is maximizing the first decade harvest subject to the constraint of even-flow and nondeclining yield.

The target trajectory used in this study is derived from a linear programming model developed by Navon called the Timber Resources Allocation Method (Timber RAM) which is used by the Forest Service on the Stanislaus. Only seven classes of the mixed conifer timber type, which is 49% of the area in the forest suitable for timber production, are modeled for the first ten decades of the thirty-eight-decade deterministic trajectory to limit computing costs.

The Linearized Growth and Observation Models

The dynamics of timber growth in the Stanislaus are based on stand age and the level of basal area per acre. Basal area is the area of any given acre occupied by standing timber where the area occupied by a tree is measured at a height of four and one-half feet. Timber volume is computed as a function of basal area and age in each period where each period is a decade. The components of $\delta \mathbf{x}_t$ are the levels of volume and basal area for the various age classes. The A_t, which are time varying, give the linear approximations of volume and basal area evolution.

The control matrices, $\mathbf{B}_t$, measure the impact of thinnings and regeneration harvests, the only control actions considered in Timber RAM for the timber stocks. To avoid numerous infeasible control levels, the $\mathbf{B}_t$ are constructed so that only the controls with positive target levels are allowed to vary in the computed solutions.[1] In the observation system on the Stanislaus, precision on basal area observations is set initially with the standard error equal to 5% of the target level of basal area being observed. The level of observation precision is always a managerial input to an LQG model. The precision can be varied to determine approximately the most efficient level of observation precision. The remaining variances and covariances in the LQG model are derived from the regression results used to estimate the growth dynamics.[2]

Specification of the Quadratic Objective Function

The Multiple Use Sustained Yield Act does not define a financial criterion for National Forest management; therefore, we specify a set of alternative objective function weights for analysis. Because the current debate on national forest utilization is largely between the intensity of stumpage (the term stumpage is used here to refer to the volume of harvest) versus nonstumpage uses (recreation,

[1] This construction also avoids the problem of scheduling many relatively small harvests in many of the classes in each time period.

[2] The levels of the variances and covariances of the additive error terms, $\mathbf{e}_t$ and $\mathbf{v}_t$, are a function of the levels of the timber stocks and, hence, the controls. Thus, the separation principle for state vector estimation no longer holds. An exact solution to this problem would require impractical numerical methods. Hence, we assume that the separation principle holds and the covariances are fixed.

To solve the more general problems not fitting the specification above, the tracking approach of LQG method can be employed. The tracking approach utilizes a three-step procedure to design and solve an approximate model of the underlying problem. In the first step the objective function (preferences), resource dynamics, and observation process of the underlying problem are specified in their most accurate algebraic (usually nonlinear) form, but are assumed to be deterministic. This deterministic problem is optimized and the resulting trajectory of state and control variables then constitutes the target trajectory. The optimizing philosophy is to keep the actual evolution of the system "close" to these targets.

At step two, the resource dynamics and observer are linearized about the target values of the state and control variables via Taylor's Theorem. A quadratic objective function is specified to measure the loss of deviating from the target values. Minimizing the expected loss from deviations subject to the linearized resource dynamics and observer constitutes a linear-quadratic control problem when additive Gaussian error terms are appended to the linearized dynamics and observer. The third step is the real time control of the evolving system. Samples are taken to estimate the current level of the state variables, and then the control actions for the current period are computed as a function of the estimated states. This estimation-control cycle is repeated in every period.

It is immediately apparent that the tracking model complements deterministic control models of resource production because their solution provides the target levels needed in step one of the LQG method. Derivation of the solution to linear-quadratic-Gaussian control models is given in Aoki, so it is reviewed tersely. Assuming that a set of target values $\mathbf{x}^*_t$, $\mathbf{u}^*_t$, and $\mathbf{y}^*_t$ are available from a deterministic model, the LQG is stated in terms of control, state, and observation deviations, where

$$\delta\mathbf{x}_t = (\mathbf{x}^*_t - \mathbf{x}_t) \qquad \delta\mathbf{u}_t = (\mathbf{u}^*_t - \mathbf{u}_t) \qquad \delta\mathbf{y}_t = (\mathbf{y}^*_t - \mathbf{y}_t).$$

The resource dynamics and observer relationships are linearized around $\mathbf{x}^*_t$ and $\mathbf{u}^*_t$, as

$$(5) \qquad \delta\mathbf{x}_{t+1} = \mathbf{A}_t\delta\mathbf{x}_t + \mathbf{B}_t\delta\mathbf{u}_t + \mathbf{e}_t,$$

$$(6) \qquad \delta\mathbf{y}_t = \mathbf{C}_t\delta\mathbf{x}_t + \mathbf{v}_t,$$

where $\delta\mathbf{x}_t$ is nx1, $\mathbf{A}_t$ nxn, $\delta\mathbf{u}_t$ mx1, $\mathbf{B}_t$ nxm, $\delta\mathbf{y}_t$ rx1, and $\mathbf{C}_t$ is rxn. Finally, $\mathbf{e}_t$ and $\mathbf{v}_t$ are nx1 vectors of Gaussian errors with serially uncorrelated covariances, Ω_t and θ_t, respectively; and $E(\mathbf{v}_i\mathbf{e}_j) = 0$ for all i, j. The objective of minimizing the expected cost of deviations is written as

$$(7) \qquad E(J_0) = E\sum_{t=0}^{T-1}(\delta\mathbf{x}'_t\mathbf{Q}_t\delta\mathbf{x}_t + \delta\mathbf{u}'_t\mathbf{R}_t\delta\mathbf{u}_t) + \delta\mathbf{x}_T\mathbf{Q}_T\delta\mathbf{x}_T.$$

Under this LQG specification, the joint problems of optimal control derivation and state estimation are solved independently (Joseph and Tou). Defining the conditional estimate of $\delta\mathbf{x}_i$, given all the samples and controls through j as $\delta\mathbf{x}_{i|j}$, the optimal controls are

$$(8) \qquad \delta\mathbf{u}_t = \mathbf{G}_t\delta\mathbf{x}_{t|t} \quad t = 0, \ldots, T-1, \text{ where}$$

$$(9) \qquad \mathbf{G}_t = -[\mathbf{R}_t + \mathbf{B}'_t\mathbf{H}_{t+1}\mathbf{B}_t]^{-1}\mathbf{B}'_t\mathbf{H}_{t+1}\mathbf{A}_t \quad t = 0, \ldots, T-1, \text{ and}$$

$$(10) \qquad \mathbf{H}_t = \mathbf{Q}_t + \mathbf{A}'_t\mathbf{H}_{t+1}\mathbf{A}_t + \mathbf{A}'_t\mathbf{H}_{t+1}\mathbf{B}_t\mathbf{G}_t, \quad t = 0, \ldots, T-1,$$

with $\mathbf{H}_T = \mathbf{Q}_T$. Estimates of $\delta\mathbf{x}_t$, $\delta\mathbf{x}_{t|t}$, which are optimal with respect to minimizing costs in (7), are generated by the Kalman filter. The covariance of $\delta\mathbf{x}_{i|j}$ is $\mathbf{P}_{i|j}$, and the recursive equations that generate the estimate and its covariance are given by Athans.

The expected loss for any period t is:

$$(11) \qquad E(J_t) = \delta\mathbf{x}'_{t|t}\mathbf{H}_t\delta\mathbf{x}_{t|t} + tr.\mathbf{H}_t\mathbf{P}_{t|t} + \sum_{i=t}^{T-1} tr.\mathbf{H}_{i+1}\Omega_i + \sum_{i=t}^{T-1} tr.\mathbf{A}'_i\mathbf{H}_{i+1}\mathbf{B}_i\mathbf{G}_i\mathbf{P}_{i|i}.$$

Only the first term in (11) is a function of the estimated deviations, a similar expression as would be obtained from a deterministic model. The last three terms of (11) are the costs of various sources of uncertainty. The second and fourth terms represent the cost of current and future uncertainty from not being able to observe the resource stock perfectly. The third term yields the present cost of future uncertainty about resource evolution through time. This uncertainty arises from the inherent uncertainty in (2) and the approximation error induced by linearization.

The three uncertainty cost terms provide the policy maker with the decision relevant value of better information. These costs indi-

strate some of the advantages of its use for decision making and problem analysis over strictly deterministic methods. Limiting aspects of the LQG approach also are discussed.

In the first section, the changes in the management problem induced by relaxing the certainty assumption of deterministic models are considered. This discussion motivates the use of approximate stochastic models. The second section discusses the theory and empirical application of the LQG technique. In the concluding sections, the LQG approach is applied to harvest scheduling on a national forest. The first of these sections briefly describes the resource model and management objectives, and in the final section the results and policy relevant aspects of 150 stochastic simulations are analyzed.

Natural Resource Production under Certainty and Uncertainty

To frame a generalized, deterministic, resource production problem, it is assumed that the owner's objective function can be written as

$$(1) \qquad \text{Max} \sum_{t=0}^{T-1} B_t(\mathbf{x}_t,\mathbf{u}_t) + B_T(\mathbf{x}_T),$$

where $\mathbf{x}_t$ is a vector of state variables representing resource and capital stock levels and T denotes the terminal period. The control vector, $\mathbf{u}_t$, gives the rates of production and investment; time discounting is assumed implicit in the form of B_t. The resource dynamics are modeled as

$$(2) \qquad \mathbf{x}_{t+1} = f_t(\mathbf{x}_t,\mathbf{u}_t),\ \mathbf{x}_0 = \mathbf{x}(0).$$

It is assumed that the state and control vectors are confined to a prespecified feasibility region L:

$$(3) \qquad \mathbf{x}_t,\mathbf{u}_t \in L.$$

As shown in Burt and Cummings, the necessary conditions that maximize (1) subject to (2) and (3) yield the familiar rule that current production should be increased until the marginal benefit of current production equals the marginal cost of future profits foregone by producing today, i.e., user costs.

It is assumed in (1)–(3) that all of the stock levels, $\mathbf{x}_t$, are observed perfectly in each time period. This assumption is a major weakness in problems of resource production when the stock of available resource, or its effective productive capacity, is uncertain. The stock of usable timber within any given geographical region is uncertain until harvested. This same problem is present in various ways in fish, water, mineral, and environmental resources. It follows that the uncertainty about levels of productive resource stocks is central to resource management plans. To represent the reality of inexact knowledge of resource stocks, we posit an observer or measurement relationship

$$(4) \qquad \mathbf{y}_t = g_t(\mathbf{x}_t),$$

where the vector $\mathbf{y}_t$ is a signal or observation generated as a function of the state vector and a random component.

Two additional sources of uncertainty complicate the empirical problem of resource management. The value of goods and services derived from resource stocks is usually uncertain and the physical evolution of resource stocks subject to control actions is not precisely known. The problem of valuing resource worth or prices is particularly vexing for publicly owned resources that are to be managed to maximize vaguely defined social welfare.

In coping with these three sources of uncertainty, the manager must determine production rates and rates of information acquisition. Information gathering can take the form of purchase of information, active learning, and setting of the observation or sampling precision. Even for very simplified problems, the optimal solution requires simultaneous determination of production and information gathering. Such solutions usually are numerically burdensome. For almost any empirical problem, theoretical elegance and exact specification must be exchanged for a workable model.

LQG Methodology

The LQG control method, as summarized and analyzed in Athans, solves two different stochastic control problem specifications known as basic trajectory and tracking, respectively. If (*a*) the resource dynamics (2) and observer (4) are linear with additive, Gaussian (normally) distributed errors, (*b*) the objective function is quadratic and known, and (*c*) the state and control variables can take on any real value, the optimal controls can be derived analytically.

Resource Production under Uncertainty: A Stochastic Control Approach to Timber Harvest Scheduling

Bruce L. Dixon and Richard E. Howitt

Most empirical natural resource management problems are intertemporal optimization problems under uncertainty. The Linear-Quadratic-Gaussian (LQG) method derives an approximate stochastic solution to such problems. The error in modeling resource dynamics and error in observing resource stocks are incorporated explicitly into the LQG problem solution. The LQG is outlined briefly and applied to the harvest-scheduling problem on the Stanislaus National Forest. The importance of knowing management preferences precisely is shown by stochastic simulations. In particular, harvest levels and the cost of a given source of uncertainty are shown to be quite sensitive to the objective function specification.

Key words: resource management, stochastic optimal control, timber harvest scheduling.

The problem of efficient production from natural resources is conventionally approached by constructing a deterministic model of management objectives and resource dynamics from which the optimal intertemporal production schedule is derived. The literature abounds with theoretical resource models, but few have been applied and used for public policy. Given the current interest and concern with optimal resource use, why are the deterministic models not embraced by policy makers? One answer that this paper advances is that due to its specification, the deterministic resource model essentially ignores two of the critical areas of public resource policy: response to parameter uncertainty and investment in information to lessen uncertainty. Because investment in information can be justified only on the basis of improved future decision making, the information problem can be viewed as the dual to the primal problem of determining the intertemporal production rates under uncertainty.

Experiments often are conducted separately from the actual production process, and then the resulting information can be incorporated into the production problem. An example of this is the use of experimental plots to generate knowledge to be applied to managing an entire resource stock, in this case a forest. Additionally, it may be possible to purchase information. For either of these methods of essentially passive information accumulation the decision maker must determine the cost of the current and future levels of uncertainty. As discussed by Rausser, the theoretically optimal solution to the control-parameter estimation problem includes the use of active learning strategies. However, the computational burden of active learning solutions can be excessive even for modestly sized problems and the performance of an approximate active learning solution does not necessarily surpass that of passive strategies (Norman).

Recent advances in optimal control methods have yielded solution procedures that allow for incorporation of significant stochastic components of the resource management problem. In this paper one of these methods, the Linear-Quadratic Gaussian (LQG) control model, is used for the problem of harvest scheduling on a national forest. Our purpose is to state the stochastic resource production problem for the LQG specification and demon-

East Yolo	2.66	2.19	1.57	1.12	0.78	0.51

of values, depending on several factors: (*a*) the physical parameters of the individual basins; (*b*) the costs associated with pumping a unit of groundwater; and (*c*) the economic demands for current use (both for agriculture and urban use).

Finally, the tax rate declines over time under constant energy costs, a result to be expected since over time the stock values (user costs) decline. This reduces the disparity between the restricted pumping situation and the socially optimal allocation, and the tax rate correspondingly declines.

From an analytical viewpoint the two methods of dealing with commonality of water use offer very different lines of attack. Quota setting in effect imposes a tighter constraint on the resource than does taxation. Quota setting transfers the decision making from the private user to a central agency. Taxation allows greater flexibility because the decision on pumpage is left to the individual user. The tax simply becomes another component of the pumper's cost function and is taken into consideration when deciding how much water should be used in any time period. Baumol demonstrates that where an externality (technical) exists that taxes upon the generator of the externality are all that is required to produce an efficient allocation. Baumol argues that even if the level of taxation needs to be adjusted in a tâtonnement process to achieve the desired result, it is still the best way to correct the divergence between social and private cost.

Concluding Remarks

This paper has proposed a control model framework for determining the optimal spatial and temporal allocation of water in a complex hydrologic and economic setting. The advantage of this framework over past work done in the area of water resource allocation is the ability of the model to handle a large degree of disaggregation and to provide valuable economic and hydrologic information about the physical system with respect to its common pool nature. Thus, this paper demonstrates the usefulness of a framework that can take the interaction of several groundwater basins into consideration as the socially optimum allocations are determined. Two broad policy implications can be drawn from the results.

First, the areal size of a water resource-planning unit must be chosen with care. The results presented in this paper illustrate quite dramatically that the six basins making up the Yolo County aquifer react differently to alternative economic and hydrologic parameters. In terms of policy, this means that designation of groundwater planning units should be based on economic and hydrologic parameters and not on political or geographical boundaries. The degree of hydrologic interdependence between different basins in the same aquifer, or between aquifers, is the key factor in determining any planning unit. These interdependencies are directly related to the common pool problem associated with groundwater use. If the interdependencies are not accounted for in the allocation decision, there will be a large reduction in the social value of the groundwater resource.

The second policy implication relates to the economic impacts associated with policy alternatives for moving current groundwater allocations to a more socially preferred set. Although taxation and pro-rata allocations have been suggested a number of times in the literature as institutional instruments to achieve a more socially optimal allocation of resources, the current framework has shown the change in social value of the resource that can be expected upon their implementation. The results indicate that both instruments will increase the social value of the groundwater re-

Table 6. Yearly and Total Present Value of the Water Resource under Socially Efficient and Private Decision Allocations (1977–2005, $0.045/Kwh.)

[a] Represents total value of the water resource over the entire planning horizon.

cial optimum and the private optimum value of the water resource, much larger than the difference between the social optimum and the quota solution described above. These differences, however, are not directly comparable because they measure different things. The difference between the quota and the socially optimum value represents the returns foregone if the amount of groundwater usage is limited to a long-run mean recharge quota. The unrestricted pumping value is a measure of the external cost imposed on all water users by the failure of individual pumpers to take into account the total social costs of individual pumping. The total difference between the social optimum and the private solution is $52,918,000 over the thirty-year-planning horizon. In comparing the unrestricted solution to the quota policy solution, it must be concluded that neither policy is efficient. However, the quota policy appears better to approximate the social optimum than does the unrestricted pumping policy. Thus, a policy to control groundwater use appears to be justified if the transaction costs are less than the costs of the externalities. Thus, even though it has been shown that the long-run recharge quota is not a "good" policy for reaching the true social value of the water resource, it can be used to control allocations so that the negative externalities are taken into consideration.

It appears, therefore, that a good case can be made for limiting the water pumped from the aquifer, unless there are opportunities for economically efficient transfers among basins on the surface through a market transfer process. If so, continued overdrafting would be justified only if the value of the transferred water at the margin were higher than the sum of the user costs, pumping costs, and transfer costs.

Pumping tax policy. An alternative policy for managing a groundwater basin that suffers from the problem of commonality of use is to levy a tax on pumping. This is a widely proposed solution to correct a divergence between private and social costs (Pigou). In this case the marginal private cost is simply the marginal cost of pumping to individual users. The marginal social cost includes as well the loss of productivity to individual users because of competitive pumping. The dominant problem with Pigovian solutions is the selection of the correct tax (Baumol). Milliman demonstrates that if the marginal value of a unit of water pumped is equated to the marginal social cost of pumping the water that a social optimum has been reached.

The necessary condition for the empirical model to allocate water optimally requires that the net marginal value of a unit of water used be equated to the transformed user cost. Because the marginal private pumping costs already have been subtracted from the marginal values, the transformed user cost actually measures the difference between the marginal social and marginal private cost of pumping a unit of water. As such, it represents the optimal marginal tax rate that is required to force private and social costs to converge.

Table 7 contains the optimal tax under a 4.5¢ energy cost scenario. The results listed in the table indicate that the optimal tax structure is not a fixed levy over the entire planning horizon, but is rather a declining set of tax rates. The table results raise other issues. First, all tax rates are positive. At first glance this may appear somewhat surprising given that three of the six basins indicate rising water tables after the 4.5¢ energy cost has been reached. Even with rising water tables, however, if an individual pumper did not extract a unit of water, the water table would rise somewhat higher than if the unit of water were extracted. This extraction thus increases the pumping costs of the other individuals using the aquifer.

In addition, the tax rates show a wide range

surface water would move toward a more socially efficient allocation. For example, if agricultural producers were allowed to bid for available water supplies, assured full property rights and perfect competition, they would bid the price up to the level of the marginal value of water utilized in production. Because the control model is based on exactly this type of allocation procedure, it is expected that surface allocation resulting from the "water market" arrangement would approximate the socially optimum allocation indicated by the control model.

The pro-rata groundwater policy. The prorata method is one that attacks the common pool problem by adjudicating annual groundwater quotas to overlying landowners. The quota most often recommended is established by restricting pumpage to the long-run mean recharge rate. This suggests that no mining of the resource should be permitted on the average.

Table 5 provides a comparison of the total value of the groundwater resource for the entire Yolo County aquifer under socially optimum conditions (no restrictions on temporal allocations of the resource in any basin) as opposed to a quota system, where the quota is limited to the mean recharge rate. This comparison is made under two energy cost scenarios and the results under both energy cost runs indicate that using a quota diminishes the potential social benefits to be derived from the resource. The 4.5¢ energy cost scenario shows a much wider divergence from the optimal social value, however, than does the 6.5¢ energy cost scenario. The percentage loss of social value under the 4.5¢ energy scenario ranges from 11% to 6% over the planning horizon, while for the 6.5¢ energy scenario the range is only 4.4% to 1.1%. As energy costs increase and the optimal amount of water to be used in any single period declines, the quota system comes closer to approximating the social value of the resource on a basin-wide basis.

From the above it is obvious that quotas will be least inefficient where the amount of water mining in the optimal allocation is small in relation to recharge. However, quotas always will be suboptimal if any economic mining of the resource is optimal, and their inefficiency will increase as transaction costs are taken into consideration. These costs would be in the form of administrating and policing the quota policy. The quota values listed in table 5 include none of these costs, and thus must be viewed as upper bounds and the differences are biased downwards. It should be noted here that this situation is not unique for quota policies. Any policy which controls the use of a common property resource in a more socially preferred manner probably would require a new institutional structure and therefore would require new transaction costs.

Laissez-faire groundwater policy. The inclusion of transaction costs in the calculus of considering policy changes creates the possibility that the status quo may offer the "best" that can be done in terms of maximizing the social value of the water resource. Table 6 compares the value of the groundwater of Yolo County under a purely private decision-making situation where each pumper decides independently how much water to take from the aquifer and the socially efficient situation where the negative externalities associated with private actions are taken into consideration. The user cost or stock value is assigned a zero value to represent the private allocation situation.

There is a large difference between the so-

[a] Represents total value of the water resource over the entire planning horizon.

groundwater basin in Yolo County as an aggregate unit would miss the sizeable variation in optimal utilization of the groundwater in the various basins composing the aquifer. These data show that the choice of a planning unit for determining optimal water allocations is very important. If the unit chosen is too large, and a single utilization rate were used throughout, groundwater mighe be seriously under- or over-utilized. Even more subdivision of the aquifer studied might have revealed even more variation in optimal utilization rates, but further analysis was infeasible.

Effects of rising energy costs. Energy costs can have an important influence on whether the model indicates a groundwater basin with an increasing or decreasing water table. For example, Upper Cache-Putah basin would be mined under a 2.6¢ energy cost assumption but would have a rising water table initially under the 8¢ energy cost assumption (fig. 1). The remaining basins move in the same direction as indicated in table 4 at alternative energy cost assumptions. In those basins where groundwater use exceeds recharge under a 4.5¢ energy cost, the effect of higher energy costs is to slow down the rate of mining.

Table 4 illustrates the impact increasing energy costs have on temporal water allocation, using the Cache Creek basin as an example. Surface water allocations depend upon the net marginal value of water in a single basin relative to the net marginal values in other competing basins. For Cache Creek, the allocations are reasonably constant over time. Groundwater pumpage at any time period decreases as expected as energy costs increase, because the net marginal value of water is lower and the stock value is higher.

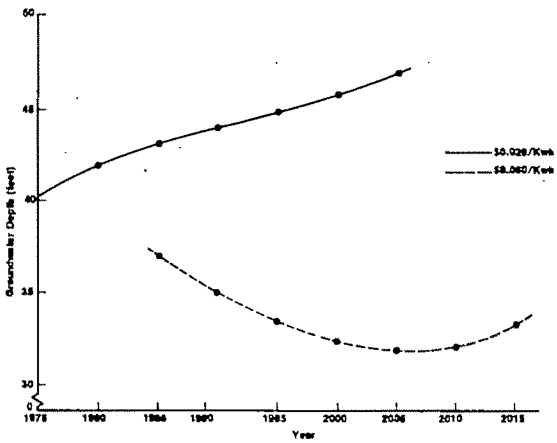

Figure 1. Impact of constant energy cost on Upper Cache-Putah Basin groundwater depth ($0.026/kwh. and $0.080/kwh., 1975–2015)

Policies to Reduce Misallocation of Groundwater

In this section two policies are analyzed empirically that could be utilized to achieve a more socially preferred allocation of groundwater. The focus here is on groundwater because of the lack of any definitive empirical studies which evaluate the impact of various policies on the social value of groundwater. This is not meant to infer that surface water allocation is unimportant. Quite to the contrary, surface water sources supply almost one-half the county's agricultural water demands.

The control model provided the socially efficient allocations of the surface water resource. If contractual arrangements were made on a "market value" rather than a "first come-first serve" arrangement, then

Table 4. Increasing Energy Cost Impacts on Temporal Surface and Groundwater Allocations, 1975–2015—Cache Creek Basin (acre-feet)

in net marginal values and also in user costs in the six basins indicate potentials for economic intra and interbasin transfers of groundwater.

Table 2 contains the optimal spatial and temporal allocation of groundwater and surface water suggested by the model under a 4.5¢ electrical power cost scenario. Several observations can be made about these results. The amount of groundwater used for agricultural production generally increases over time. Several economic factors determine the temporal allocation of water in the model. Factors which limit the quantity allocated to a specific period are (*a*) increased pumping costs for the remainder of the planning horizon for those basins having declining water tables and (*b*) lower marginal values from additional quantities of water used in that time period. The factors tending to increase the quantity used per period are (*a*) time preference reflected by the discount rate and (*b*) high net marginal values on low rates of water usage. The wide range of agricultural groundwater pumpages (0.0 to 141,690 acre-feet in 1980) illustrates quite dramatically the variability in optimal groundwater allocations that can exist in a single aquifer when both the economic and physical parameters in each basin are considered in the decision-making process.

Table 2 also contains urban groundwater allocations which are based on "need" projections. The projections are based on urban water requirement studies done by several engineering consulting firms, and by using an urban water projection model developed by Savage and Helweg for estimating the impact of population and areal growth patterns for water use rates for the City of Davis. The projections were used as constraints on urban allocations because early control model runs, based on the hypothetical urban demand functions estimated for this study, allocated certain amounts to the urban areas in excess of existing or projected distribution system capacity.

The amount of groundwater needed by urban users moves from 6.8% of the total amount of groundwater used in all basins in 1977 to 8.6% of the total by 2,005. This represents a small proportion of the total amount of groundwater used in any period. Thus, the impacts on groundwater stocks by urban usage is rather insignificant for any basin as a whole. This suggests that concern that urban growth will affect adversely agricultural pumpage and pumping cost is largely unfounded.

The surface water allocations shown in table 2 can be explained by the surface water cost used in this model: namely, those that existed in 1977 were selected due to the difficulty in predicting the future price-setting actions of the various agencies allocating surface water. Because surface water costs are substantially less than groundwater pumping costs, surface water allocations depend on the relative net marginal values of this water between the various basins and on the capacity of the distribution system. Surface water allocations are limited in every power cost scenario by constraints associated with either reservoir water distribution capacity or the amount of surface water that can be obtained from the Sacramento River-Colusa Drain complex. The surface water allocations listed in table 2 are thus constrained allocations.

Table 3 contains the groundwater depths and surface water stocks associated with the optimal allocations contained in table 2. Note that in three of the six basins the water table decreases over time, while in the remaining three it increases. This set of figures indicates quite strikingly that treating the whole

marginal values, stock user costs, and transformed user costs associated with the groundwater allocations listed in table 2. Surface water stock values are not included in table 1 because the surface water distribution system constraint limits the amount of surface water which can be used in any period to less than would have been allocated in the unconstrained solution. This restriction increased the net marginal value of the surface water in any time period to a level greater than the existing reservoir user cost in that time period.

The stock user cost for all basins except Plainfield Ridge can be interpreted as the present value of the loss in social surplus if one more acre-foot were allocated for use in the specific time period. For example, if one more acre-foot of water were used from the Lower Cache-Putah basin than is socially optimal, the value of the stock would diminish by $149.58. The user cost figures given for Plainfield Ridge are not an accurate estimate of the true user cost because the lower bound constraint on the depth of the water table was reached. This constraint assumes that the volume of stored water associated with a depth greater than 420 feet is zero. Even though somewhat arbitrary, the lack of data on groundwater storage beneath 420 feet made the constraint necessary.

The transformed user costs are the present value of the stock in terms of current use. The transformation was made by the model to allocate water optimally between time periods. Note that the transformed user costs and net marginal values are approximately equal in each time period for each basin except Plainfield Ridge. Differences are due to rounding errors associated with use of the algorithm. It should be noted that these transformed user costs are a measure of the external costs that are imposed on other pumpers under the common property situation where private decision making on the part of individual users of the groundwater basins is based solely on private rather than the social cost of pumping a unit of water. Except for Plainfield Ridge, the extreme values of transformed user cost is $10.62 for Lower Cache-Putah and $2.66 for East Yolo. This indicates that different basins even in the same aquifer can exhibit different external costs. The magnitude of these costs can serve as at least one measure of whether or not governmental intervention into the allocative process is warranted. The differences

Table 2. Optimal Temporal Groundwater and Surface Water Allocations (1977–2005, $0.045/Kwh.)

(3) $y_t - y^*_t \leq 0,$

(4) $u_t - u^*_t \leq 0,$ and

(5) $y_t \geq 0 \quad u_t \geq 0.$

The welfare function [equation (1)] is an explicit economic measure of welfare. It is composed of two parts. Producer and consumer surplus measures the economic value of the flow component of the water resource base. The consumer surplus is associated with the urban sector demand functions, while the producer surplus represents economic rent available to the agricultural sector.[2] The second part is a social surplus for the stock portion of the water resource base. It measures the returns to the stock that could be gained from monopoly control. The social surplus increases as stocks increase and pumping costs decrease, *ceteris paribus*; and, alternatively, the social surplus decreases as stocks diminish and pumping costs increase. Note that these components are inversely related. The consumer and producer surplus components relate to flows and increase at a diminishing rate with increasing water use; however, as water use increases stocks diminish and the rents associated with this component decrease at an increasing rate. Thus, the model maximizes the value of the water resource base by equating the net marginal value of the flow to the opportunity cost or marginal value of the stock in that period.[3]

The welfare function is subject to two sets of constraints. The first set [equation (2)] is the equations of motion or first-order difference equations describing the physical system. This is a reduced-form system, which in this study is a linear approximation to a complex physical system. A, B, and C are specified as time invariant matrices and $\mathbf{d}$ is a vector of constants. The second set of constraints [equations (3), (4), and (5)] respresents the physical, institutional, and nonnegativity conditions on the stocks and flows of water. These constraints are not applied to every scenario posed by the model but rather act as individual scenario conditions so that resulting allocation patterns and effects on social welfare can be observed.

The Results

One reason for using an optimal control model was that it allowed direct calculation and interpretation of the user costs associated with temporal allocations. Table 1 presents the net

[2] This measure has been used by Samuelson and later Takayama and Judge to measure social welfare. Mishan discusses the assumptions of this approach to social welfare measurement.

[3] The net marginal value is defined as the marginal value of water net of water cost. A more detailed description of the empirical model and the analytical necessary conditions for achieving an optimal solution is contained in Noel.

Table 1. Stock User Costs, Net Marginal Values, and Transformed User Costs (1977–2005, $0.045/kwh.)

		Value (dollars/acre-foot)

water resource system. They provided a theoretical framework in which a demand function for water is an integral part of an aquifer model. Gisser and Mercado (1972, 1973) also integrate the demand function for water into a hydrologic model.

The model proposed in this paper is a linear quadratic control model (LQCM) and is composed of two basic parts, (*a*) an economic component and (*b*) a hydrologic component. The economic component contains a derived demand model, a stock opportunity cost model, and an urban demand model. The derived demands are obtained from a linear programming model. The use of linear programming to develop demand functions for agricultural water is rationalized in Moore and Hedges and Gisser. The stock opportunity cost model is a set of marginal pumping cost functions which are estimated so that the stock value of the resource can be derived. Finally, urban demand functions were estimated by an indirect method so that the LQCM can allocate water efficiently between the two sectors.

The hydrologic component of the LQCM is comprised of a set of equations of motion for the surface water reservoirs and groundwater basins. The former are estimated from data obtained from a surface water hydrology model, while the latter are a set of simultaneous equations estimated from data obtained from a finite element groundwater model. These equations indicate the changes that will occur in groundwater depths, given various pumping and recharge rates and also account for subsurface flow between basins.

The LQCM maximizes the value of economic components subject to the constraints implied by the hydrologic component. This particular model extends previous work in several ways. First, there is a direct interaction in the LQCM between a complex multibasin aquifer-surface water system and the demands for water. Second, the LQCM is solved by an algorithm based on Pontryagin et al. maximum principle, which provides an advantage over other work using dynamic programming, which limits the number of state and control variables. Finally, the use of the LQCM allows direct calculation of the user cost of groundwater. Both Kelso and Renshaw discuss the importance of including stock values in determining optimal water allocation. By using the LQCM, it is possible to maximize the value of both the stock and current value components of the water resource simultaneously, thereby allowing the calculation of the socially optimal spatial and temporal allocation.

Application of the Conceptual Framework

The geographical setting, Yolo County, located in the southwest corner of the Sacramento Valley, was selected for several reasons. It provides an example of a region in which conjunctive use of groundwater and surface water has evolved without any particular centralized planning (California Department of Water Resources). Several water agencies have areas of jurisdiction within the county and most if not all of each agency's planning is independent of the others with decisions being made to maximize private rather than overall social value of the water.

The county has a highly variable supply of surface water from Clear Lake, Indian Valley Reservoir, and the Sacramento River-Colusa Drain complex, used almost exclusively for irrigation. Groundwater supplies a more costly but more dependable source of water to both agricultural and urban users. The aquifer was partitioned into six basins for modeling purposes and follows the work done by hydrologists Scott and Scalmanini. The partitioning permitted the model to allocate water spatially and took account of unequal pumping lifts throughout the aquifer. There was also the problem of unequal specific yields throughout the aquifer, and the division of the aquifer into several basins permitted specification of storage capacities reflecting yields. The division of the aquifer required that the subsurface inflows and outflows between the six basins be accounted for in the model. Burt (1974) developed an approximately optimal decision rule where the subsurface flow between two basins in the same aquifer is explicitly contained in the model. For the model reported here, the subsurface flow is calculated by the groundwater model. Thus, the coefficients of the groundwater stock variables contain the effects of the subsurface flow term.

The LQCM used for determining allocations of water resources in Yolo County can be represented as follows:

$$\text{(1)}\quad \text{Max}\quad W = RR'u_t - \tfrac{1}{2}u_t'Ru_t - KK'y_t + y_t'Ky_t,$$

subject to

Optimal Regional Conjunctive Water Management

Jay E. Noel, B. Delworth Gardner, and Charles V. Moore

An optimal control model is used to determine the socially optimal spatial and temporal allocation of groundwater and surface water among agricultural and urban uses. The control model is described briefly and its advantages over other dynamic models are enumerated. Optimal rates of groundwater pumpage over the planning horizon were highly sensitive to increasing energy costs. Groundwater basins are shown to react differently to alternative economic and hydrological parameters. In a dynamic setting, a policy of pump taxes was shown empirically to be superior to pro-rata quotas and uncontrolled pumpage.

Key words: control model, groundwater, energy cost, pro-rata allocation, Pigovian taxation.

The severe drought in the western United States in 1976–78 brought the problems of allocating extremely limited water resources to the attention of agriculturalists and urbanites alike. Greatly reduced surface water supplies exacerbated the already critical pressure on remaining groundwater stocks in the same areas.

The chronic overdraft of many western states groundwater basins can be attributed directly to their common pool nature. The lack of explicit property rights to groundwater stocks results in individual users of the resource evaluating only their own private pumping costs in their decision framework and implicitly assigning a zero opportunity cost to the stock portion of the resource. Thus, the private decision does not take into account any user cost and results in a divergence in the private and the social optimal rate of pumping.[1]

The objective of this paper is to describe briefly an optimal control model which can be used to determine the socially optimal spatial and temporal allocation of groundwater and surface water among agricultural and urban uses. The control model is then applied to a representative region of California under several sets of energy costs. Two policies, pro-rata allocation and taxation, are evaluated empirically as alternatives for accounting for externalities due to the common pool problem.

The Conceptual Framework

Several authors have investigated the conjunctive use of groundwater and surface water using various techniques. Buras developed a dynamic programming algorithm to solve the problem of conjunctive use of reservoirs and aquifers. His operating policy, however, considered the physical system as a single unit and thus ignored differences in hydrology that occur in a complex groundwater system. Burt (1964, 1966, 1967a, b) utilized a mathematical programming approach to develop a demand function for irrigation water used in a dynamic programming formulation of the aquifer management problem. Bredehoeft and Young used a simulation model to estimate the solution of problems involving the development of a stream-aquifer system in an economic model of irrigation. Bear and Levin studied optimal utilization of an aquifer as one element of a

[1] Scott defines user cost of a natural resource as "the present value of future profit foregone by a decision to produce a unit of output today." Although this definition is used in the context of a profit-maximizing firm, it also applies to the water resource problem and refers to the existence value of the stock.

various formats which may be used for iterative bidding, it seems that formats which directly observe *WTP* are most effective. There are reasons to expect that WTP^C formats usually would be most effective of all because they assume correspondence between the subject's initial welfare level and his reference welfare level, without relying on the notion of compensation payments.

The results of our hypothesis tests suggest that, in contexts where compensation is not customarily paid to those who experience decrements in natural and environmental amenities, iterative bidding formats for the direct observation of WTA^C do not appear to collect reliable value data. In such contexts, it remains possible to estimate WTA^C by collecting data in the form of *WTP* (preferably, WTP^C) and using the theoretical relationships developed by Randall and Stoll to derive WTA^C.

[a] The hypothesis test was $H_0:\mu_1 = \mu_2$; $H_1:\mu_1 \neq \mu_2$. If the calculated $|t^*|$ was greater than the critical value $t_{n_1+n_2-2},\ 1-\frac{\alpha}{2}$, H_0 was rejected. Thus, by failing to reject H_0, we infer that the two means are not significantly different at the chosen level of confidence.

served WTP^E was not significantly different from derived WTP^C. However, observed WTA^C was significantly different from, and up to an order of magnitude greater than, derived WTA^C. In addition, 54% of the subjects confronted with formats to obtain observed WTA^C refused to accept any finite amount of compensation, and were eliminated from the analysis to test H_2.

set) are of similar empirical magnitude. As Willig and Randall and Stoll demonstrate, *WTP* and *WTA* are of similar magnitude when the "income effect" is small and the total value of the good represents only a small proportion of the total budget. Where these conditions do not hold, one can expect larger differences between *WTP* and *WTA*.

Conclusions

We have derived the theoretical relationships between various measures of value and shown that, in any particular situation, the proper measure of value can be identified on the basis of theoretical considerations. Of particular importance, to implement the benefit-cost criterion (i.e., the potential Pareto-improvement) estimates of *WTA* for decrements in goods, services, and amenities are required.

While the total value model places no restrictions on the methods by which data may be collected, the iterative bidding method of contingent valuation has been found to be an effective data collection mechanism. Of the

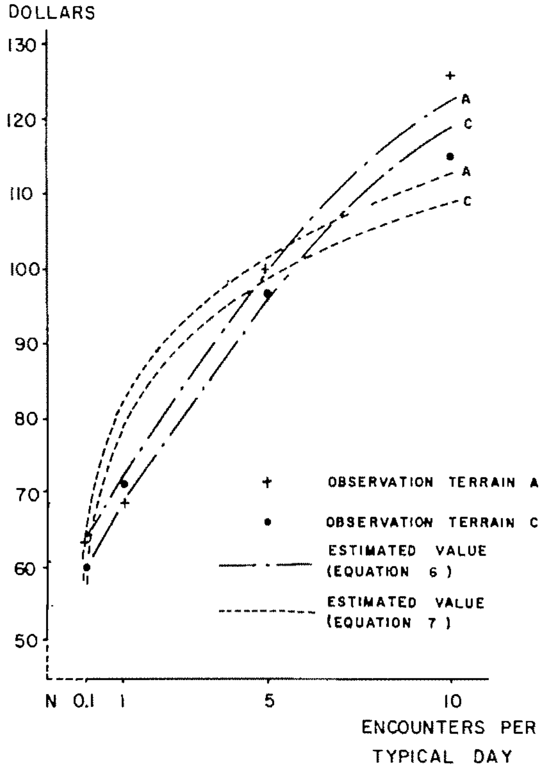

Figure 4. Mean (per hunter) annual value of the right to hunt elk, Laramie, Wyoming, 1977–78, as influenced by hunting environment and frequency of encounter with elk

An additional equation (9), which differed from (8) only in that the dependent variable was *Indbid* (i.e., individual bid for each *Encl Environ* combination) was also estimated. For equation (9), the R^2 was only .09 and the coefficient for ln(*Income*) was insignificant. The procedure of using mean bids for income groups as the dependent variable [equation (8)] results in a substantial reduction in mean square error, MSE [.224 for equation (8), as opposed to 1.80 for equation (9)], at the expense of increased magnitudes of the principle diagonal elements of the inverse transpose matrix (table 1).

Comparison of results obtained with WTP^C, WTP^E and WTA^C formats. The results of valuation exercises for the same good using WTP^C, WTP^E, and WTA^C formats may be different for two reasons: (*a*) as a result of "income effects," the different measures of consumer's surplus are empirically different, and (*b*) subjects may react differently to different contingent market formats. Subjects may take offense at WTP^E formats, which face the subject with an inferior reference level of welfare. Subjects who are not accustomed to being offered compensation for losses in natural and environmental amenities may find WTA^C formats incredible and unrealistic, or they could interpret WTA^C formats as providing an opportunity for making strong statements about a set of rights which seems fairer than the rights which actually exist ("If the choice were mine, I would not let them decimate elk populations for anything!"). Because WTP^C formats are based on correspondence between the subject's initial and reference welfare levels without relying on the notion of compensation payments, there seems little reason to expect WTP^C formats to encounter the resistance and difficulties which may confront WTP^E and WTA^C formats.

The bounds on the difference between *WTA* and *WTP* (Randall and Stoll) permit the precise calculation of the differences in results which may be attributed to income effects. Once these differences are accounted for, any remaining differences in results must be attributable to differential efficacy of WTP^C, WTP^E, and WTA^C formats as data collection devices.

From the raw data set used to estimate equations (6)–(9), estimates of WTP^C for increments in elk populations such that frequency of encounter would increase from 0.1 to 1, 1 to 5, and 5 to 10, and WTA^C for decrements across the same ranges, were derived, using the formula, $WTA - WTP = \frac{\zeta M^2}{Y}$. In order to test the following two hypotheses:

H_1: observed WTP^E = derived WTP^C, and
H_2: observed WTA^C = derived WTA^C,

observations of WTP^E and WTA^C for decrements across these three ranges were obtained using subsamples and iterative bidding formats which were different from those which provided the data used to estimate derived WTP^C and WTA^C.

The results of the tests of H_1 and H_2 are presented in tables 2 and 3, respectively.[5] Ob-

retrospect, that the iterative bidding procedure was a "waste of time" and "hard to take seriously"; and *Acc* 2 is probability . . . thought, in retrospect, that his own response to the iterative bidding procedure was "a poor guide for game management policy." The coefficient for each of these additional variables had the expected sign. *Acc* 1 and *Acc* 2 enable identification of the proportion, in each income category, of individuals whose acceptance of the contingent valuation procedure was poor.

[5] Examination of tables 2 and 3 indicates that derived WTP^C and derived WTA^C (both of which were derived from the same data

[b] Thirty-two combinations of 4 levels of *ENC*, 2 *ENVIRON*s, and 4 income groups.
[c] Five bids (4 levels of *ENC* at typical *ENVIRON*, plus 1 level of *ENC* at atypical *ENVIRON*) for 58 respondents.

Enc/Environ combination, and *Income* is mean income ($/year) for each income category.

In estimating equation (8), the sample was divided into these four income categories:

Income Category	Income Range ($/year)	Number of Observations	Mean Income ($/year)
1	Income ≤ 10,000	12	5,592
2	10,001 ≤ Income ≤ 18,000	17	14,500
3	18,001 ≤ Income ≤ 26,000	15	21,433
4	26,001 ≤ Income	14	41,508

Because the number of observations in each category is similar, this procedure should not introduce serious heteroskedasticity problems. Coefficients for ln(*Enc*) and ln(*Income*) were highly significant, while the coefficient for *Environ* was again insignificant (table 1). Note that, when an equation such as (8) is estimated, the coefficient for ln(*Income*) is an estimate of ζ. The adjusted R^2 was 0.4. Again, the F-statistic for the entire equation was significant at the .01 level. When the model of equation (8) was re-estimated with four additional variables (sex of subject, subject did/did not kill an elk last season, and two variables indicating the respondent's degree of acceptance of the contingent valuation procedure) a marked increase in R^2 was noted, while the coefficient for *Enc* and *Income* changed only slightly, in each case becoming a little larger and more significant statistically.[4]

[4] The estimated equation was

$$\begin{aligned}\ln(Bid) &= \underset{}{1.563} + \underset{(.026)}{.197}\ln(Enc) + \underset{(.096)}{.369}\ln(Income) + \underset{(.296)}{.727}\,Kill\\ &\quad - \underset{(.654)}{1.017}\,Sex - \underset{(.349)}{.697}\,Acc\ 1 - \underset{(.383)}{3.096}\,Acc\ 2,\\ &\qquad R^2 = .83,\ N = 32,\ F = 27.10\end{aligned}$$

where *Kill* is probability that a randomly selected member of the income category killed an elk in the previous hunting season; *Sex* is probability . . . is a female; *Acc* 1 is probability . . . thought, in

population levels to the various sources of utility which the individual derives from the elk hunting experience.

The raw value data were collected using the iterative bidding technique (Randall, Ives, Eastman; Brookshire, Ives, Schulze; Randall et al.). Each iterative bidding format established a contingent market (a scenario which includes a complete description of the good to be "traded," the institutional structure within which "trade" takes place, and the subject's assumed initial situation and reference level of welfare), posited a starting level of total value, and conducted an iterative bidding process until the subject's actual total value (i.e., maximum *WTP*, or minimum *WTA*) was identified. Formats were designed to obtain estimates of WTP^C for increments in the quality of wildlife-related amenities, WTP^E to avoid decrements, and WTA^C to permit decrements.

Each survey schedule included two iterative bidding formats, a record of the subject's hunting activity, various questions designed to elicit information on the subject's attitudes relevant to hunting, and a confidential "feedback" section in which the subject could express his reaction to the interview and the contingent valuation exercise.

Analysis and Results

Previous studies (e.g., Brookshire, Ives, Schulze) have identified several sources of potential bias in value data collected with iterative bidding methods. Thus, preliminary analysis of the data collected in this case study included statistical tests for bias. The hypotheses that final value data were influenced by the initial bids posited to respondents, or by the particular interviewer who collected the data, were rejected at the .05 level of significance. The hypothesis that final bids (i.e., estimates of TV) were influenced by the choice of bidding vehicle (a component of the bidding scenario) was rejected at the 0.1 level of significance. Nevertheless, it was observed that refusal to bid, with *WTP* formats, occurred in six of fifty cases with a "utility bill" vehicle, but in none of fifty-eight cases with a "hunting license fee" vehicle. Negative comments in the "feedback" section occurred more frequently with the "utility bill" vehicle.[3]

[3] "Utility bill" vehicles were used because the sponsor expressed an interest in attempting to estimate directly preferences with respect to the trade-off between energy production and wildlife habitat in certain western states.

Although three terrains were included in the research design, no hunter in the sample typically hunted in terrain B. Thus, since the survey format collected a complete set of information for each subject's "typical" terrain and encounter frequency but only a subset of the possible information for "atypical" terrains, the data set for terrain B was incomplete. Therefore, further analyses consider frequency of encounter 0.1, 1, 5, and 10, and terrain A and C.

Using WTP^E data provided by fifty-eight subjects working with the "hunting license fee" bidding vehicle, the mean bid curve (or, mean total value curve) corresponding to curve 5′ in figure 3 was estimated, using two functional forms:

$$(6)\quad Meanbid = \beta_0 + \beta_1\, Enc + \beta_2\, Enc^2 + \beta_3\, Environ + \epsilon, \text{ and}$$

$$(7)\quad \ln(Meanbid) = \beta_0 + \beta_1 \ln(Enc) + \beta_2\, Environ + \epsilon,$$

where *Meanbid* is the mean of fifty-eight respondents' total value bids for each of the eight *Enc/Environ* combinations, in dollars per year; *Enc* is the frequency of encounters with elk on a typical day of hunting (0.1, 1, 5, 10), and *Environ* is a qualitative variable taking the value 1 for terrain C and the value 0 for terrain A.

The results of estimation are shown in table 1 and figure 4. Coefficients for *Enc* and ln(*Enc*) [equations (6) and (7)] and Enc^2 [equation (6)] were statistically significant at the .01 and .10 levels, respectively, while the coefficients for *Environ* were insignificant. The *F*-statistics led to rejection of the hypothesis that all parameters are equal to zero at the .01 level of significance. To determine the aggregate sample bid for each *Enc/Environ* combination, *Meanbid* may be multiplied by the sample size (i.e., 58). To estimate the aggregate bid for the population, *Meanbid* may be multiplied by the population size.

The "income effect". The price flexibility of income for the good, ζ, was identified as the key variable permitting rigorous calculation of the empirical value of *WTA* from *WTP* data or vice-versa (i.e., permitting correction for the "income effect"). To calculate ζ for elk-hunting amenities, equation (8) was estimated,

$$(8)\quad \ln(Bid) = \beta_0 + \beta_1 \ln(Enc) + \beta_2 \ln(Income) + \beta_3\, Environ + \epsilon,$$

where *Bid* is the mean of the total value bids of respondents in each income category for each

pation in elk hunting; Q', participation with frequency of encounter, Q'; and Q'', participation with frequency of encounter, Q''.[1] It is conceivable that the hunter could find himself in any one of three initial situations: N, Y^0; Q', Y^0; or Q'', Y^0. Given these three initial situations, a family of three total value curves may be defined (fig. 3):

$$(5')\quad U(N,Y^0) = U(Q',Y^{-b}) = u(Q'',Y^{-c}),$$

$$(5'')\quad U(Q',Y^0) = U(N,Y^{+a}) = U(Q'',Y^{-a}),$$

$$(5''')\quad U(Q'',Y^0) = U(Q',Y^{+b}) = U(N,Y^{+c}),$$

where $N < Q' < Q''$ and $Y^{-c} < Y^{-b} < Y^{-a} < Y^0 < Y^{+a} < Y^{+b} < Y^{+c}$. Consider the income axis: $Y^0 - Y^{-a}$, $Y^0 - Y^{-b}$, and $Y^0 - Y^{-c}$ are measures of *WTP*, while $Y^{+a} - Y^0$, $Y^{+b} - Y^0$, and $Y^{+c} - Y^0$ are measures of *WTA*.

This family of total value curves permits estimation of the annual value of elk-hunting amenities using data provided in a wide variety of forms. For example, curve (5′) may be fitted, using data on *WTP* for an elk-hunting license when the hunter expects frequency of encounter Q' and Q''. Curve (5″) permits the analysis of data indicating WTP^C for an increment in frequency of encounter from Q' to Q'', and WTA^C of a hunter currently enjoying participation with frequency of encounter Q' to accept nonparticipation. Curve (5‴) permits analysis of data for WTA^C of a hunter currently enjoying participation with frequency of encounter Q'' for a reduction in elk populations such as that his frequency would become Q', and WTA^C to accept nonparticipation in hunting. Empirical estimates of Hicksian equivalent value measures also may be used to derive this family of curves. Equivalent measures simply assume that the reference level of welfare (or presumed right) is different from the initial situation. For example, $Y^0 - Y^{-c}$ is equal to the WTP^E of a hunter currently enjoying Q'', Y^0 to avoid nonparticipation in hunting.

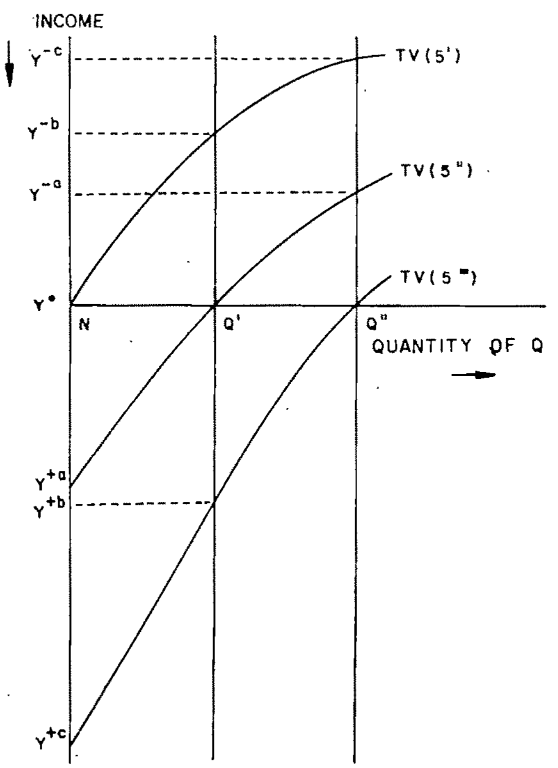

Figure 3. Total value curves for wildlife-related amenities, Q

Data Collection

In 1977 and 1978, an extensive pilot study was conducted in the vicinity of Laramie, Wyoming, for the purposes of (*a*) testing the general value model in application and (*b*) field testing a variety of contingent valuation methods for collecting value data for a considerable variety of wildlife-related amenities. The two purposes are logically distinguishable. That is, the general valuation model provides a conceptual framework for organization of empirical data obtained using any acceptable technique. The terms, *WTP* and *WTA*, do not per se imply data collection via contingent valuation. As a part of this study, 108 licensed elk hunters were interviewed.[2]

The "good" to be valued was the right to hunt elk, for one annual season, at various levels of hunting amenities. The amenities related to elk hunting were quantified in two dimensions: the terrain in which elk hunting takes place (A. foothills; B. plains; C. mountains); and the population of elk in the hunt area, which was indicated by the frequency of encounter with elk (0.1, 1, 5, or 10 elk encountered per day of hunting). These dimensions are sufficient to permit variation in the contributions of hunting environment and elk

[1] Compare our approach with that of Cocheba and Langford. They distinguished between an exclusive good aspect (game taken) and a collective good aspect (missed shots) of the hunting experience. We emphasize the collective good aspect, which we quantify in terms of "frequency of encounter" with elk.

[2] The pilot study was supported by the U.S. Fish and Wildlife Service (under Grant 14-16-0009-002), the Kentucky Agricultural Experiment Station and the Resource and Environmental Economics Laboratory of the University of Wyoming.

pensating and equivalent variation measures of the welfare impact of price changes.

In benefit-cost analysis, however, the immediate concern is the evaluation of the welfare impact of changes in the levels of goods, services, or amenities provided, rather than changes in price levels. In such cases, it is convenient to work with the terms *WTP* and *WTA* (thus rendering the absolute value terminology unnecessary). A general rule can be stated: $WTP \leq M \leq WTA$ (Randall and Stoll). Returning to the specific situation of the example used in figure 2,

$$(4) \quad WTP^E = WTP^C \leq WTA^C = WTA^E.$$

Two questions remain: (*a*) under what conditions are *WTP* and *WTA* equal, and (*b*) when $WTP < WTA$, can bounds on the difference be defined rigorously? The findings of Randall and Stoll, building on the work of Willig, may be summarized.

(*a*) For goods which are perfectly divisible and exchanged at zero transactions costs in infinitely large markets, *WTP* and *WTA* are equal and are equal to the price multiplied by the quantity change. In figure 1, the total value curve may be replaced with the price line. When the good whose quantity is subject to change has the characteristics of currency, and the proposed change is thus conceptually equivalent to a lump sum tax, *WTA* to permit the tax is equal to *WTP* to avoid the tax, and both are equal to the tax itself. The general total value model thus generates the primary result of partial equilibrium microeconomics (i.e., price equals unit value at the margin), as a special and limiting case. Market price is the appropriate measure of unit value lost or gained, when the good under consideration is perfectly divisible and may be exchanged at zero transactions costs in infinitely large markets.

(*b*) For goods which are indivisible or lumpy and can be held only in quantities Q^- and Q^0 (fig. 2), *WTP* is less than *WTA* (except when the income effect is zero). The difference between *WTA* and *WTP* may be approximated by $WTA - WTP = \dfrac{\zeta M^2}{Y}$, where

$\zeta = \dfrac{\partial P(Q,Y)}{\partial Y} \dfrac{Y}{P(Q,Y)}$, i.e., the price flexibility of income for the good, Q. This approximate bound on the difference between *WTA* and *WTP* is valid when ζ is constant and $\zeta M/2Y$ is relatively small (say, equal to or less than .05). Randall and Stoll also provide more rigorous bounds, which are appropriate when ζ is not constant and when $\zeta M/2Y$ is relatively large.

For divisible goods traded in costly markets (i.e., those where transactions costs are positive) the difference between *WTA* and *WTP* will be greater than zero, but no greater than the bounds discussed immediately above. The result of case (*a*) is predicated upon costless post-change adjustments in holdings, while that of case (*b*) is predicated upon the impossibility of post-change adjustments. Prohibitive transactions costs and indivisibility are both sufficient to preclude such adjustments. Thus, the difference between *WTP* and *WTA* in the positive transactions costs situation will never exceed the difference found in the case of indivisibility.

Annual User Values for Wildlife-Related Amenities

Consider a hunter who obtains utility from the right to hunt elk. This right is customarily granted by state agencies, in exchange for a license fee, and subject to restrictions upon hunting season, the number and type of elk taken and, often, on the region in which hunting takes place. The hunter derives utility from the environment in which he hunts; the exercise of hunting skills; the encounter with elk; and, perhaps, the taking of an elk. Frequency of encounter and probability of taking an elk vary with elk population. Enjoyment of the environment and the opportunity to exercise hunting skills may vary with the location of the hunt and, in addition, the hunter may perceive these things to be related to elk populations.

The elk is a fugitive resource which, while living, is unowned, and which may be converted to an exclusive good only at the successful completion of the hunt. Enjoyment of the environment, the opportunity to develop and display hunting skills, and the encounter with elk are all collective goods which are nonrival in consumption until the hunter population becomes so large that congestion reduces the utility of individual hunters.

The General Value Model for Elk-Hunting Amenities

Consider three levels of provision of the amenity, the annual right to hunt elk: N, nonpartici-

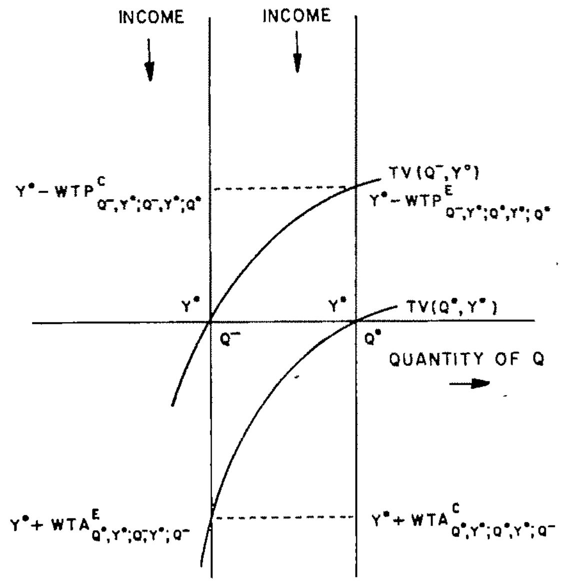

Figure 2. The relationships between *WTP* and *WTA*, and Hicksian compensating and equivalent measures of consumer's surplus

denoted $WTP^E_{Q^-,Y^0;Q^0,Y^0;Q^0}$. The superscript indicates that it is a Hicksian equivalent measure of value. The first subscript pair indicates that the reference level of welfare (or, if you will, the individual's presumed right) is taken to be Q^-, Y^0. The second subscript pair indicates that the individual's initial state is Q^0, Y^0. The third subscript indicates that, after the individual has paid, he will be permitted to enjoy the Q^0 level of amenities; if he pays exactly his *WTP*, his final income will be $Y^0 - WTP^E$.

Notice that the initial welfare level is different from the reference welfare level. That is the distinguishing feature of Hicksian equivalent measures. Compensating measures, on the other hand, assume that the initial situation is the reference welfare level. WTP^E cannot be found using a total value curve passing through the individual's initial state. It can only be found using another total value curve, which passes through the individual's reference level of welfare (fig. 2).

At this point, it occurs to us that the pair of total value curves shown in figure 2 may also be used to estimate the value to the same individual of a different project: a project which would increase the level of provision of wildlife-related amenities from an initial level Q^- to a "with project" level Q^0. For evaluating this project, the individual's initial situation is Q^-, Y^0. His willingness to pay for the increment in wildlife-related amenities the project would provide is $WTP^C_{Q^-,Y^0;Q^-,Y^0;Q^0}$. It is a compensating measure, since the reference level of welfare is the same as the individual's initial welfare level. A *WTA* measure can also be defined: $WTA^E_{Q^0,Y^0;Q^-,Y^0;Q^-}$. This is the individual's willingness to accept compensation in lieu of a promised increment in wildlife-related amenities from Q^- to Q^0. It is an equivalent measure, since the reference level of welfare is not the same as the individual's initial welfare level. It cannot be estimated from the total value curve passing through the individual's initial welfare level, Q^-, Y^0, but must be estimated from a new total value curve passing through the individual's reference welfare level, Q^0, Y^0.

The foregoing example makes a number of points. The Hicksian compensating measures of value of alternative levels of provision of a good, service, or amenity can be determined from a single total value curve, while equivalent measures of value must be estimated using a series of different total value curves, one passing through each of the possible levels of provision under consideration. When comparing two alternative levels of provision of a good (as in fig. 2), there are four relevant Hicksian value measures: WTP^C to obtain the preferred level; WTP^E to avoid the less preferred level; WTA^C to accept the less preferred level; and WTA^E to forego a promised increment to the preferred level. There is a compensating and equivalent version of *WTP*, as there is of *WTA*. Figure 2 suggests that, when comparing any pair of alternative levels of provision of a good, service, or amenity, WTP^C is equal in value to WTP^E, while WTA^C is equal in value to WTA^E.

The Relative Magnitudes of the Compensating and Equivalent Measures of Consumer's Surplus

The concept of consumer's surplus is most commonly used, as in Currie, Murphy, and Schmitz, to analyze the welfare impacts of price changes. It generally is concluded that (in absolute value terms) for price increases, $EV \leq M \leq CV$ and, for price decreases, $CV \leq M \leq EV$ (where *CV* is compensating variation, *EV* is equivalent variation, and *M* is Marshallian consumer's surplus). Willig rigorously derived empirically operational bounds on the magnitude of the differences between com-

often can be rigorously derived from estimates of other more readily available value measures.

Hicks showed that there are four measures of consumer's surplus, none of which is conceptually identical to the Marshallian measure. These are equivalent surplus, equivalent variation, compensating surplus, and compensating variation. The surpluses differ from the variations in that the latter are calculated after the consumer has made optimizing adjustments in his consumption set, while the former do not permit such adjustments. In general, the variations should be used when such optimizing adjustments are possible. However, benefit-cost analysts often encounter situations where optimizing adjustments are prohibited: once project or program specifications have been determined, the individual must take these as given. Thus there will be circumstances in which the Hicksian surpluses are appropriate.

The difference between the Hicksian compensating and equivalent measures of consumer's surplus is considerably more significant. The equivalent measure is defined as the amount of compensation, paid or received, which would bring the consumer to his subsequent welfare level if the change did not take place. The compensating measure is defined as the amount of compensation, paid or received, which would keep the consumer at his initial welfare level if the change did take place.

The Hicksian compensating and equivalent measures of consumer's surplus are both measures of the welfare impacts of changes, but they differ with respect to the reference level of welfare. The compensating measure, by using the initial welfare level as the reference level, measures the welfare impact of changes as if the individual had a right to his initial level of welfare (that is, as if he had the choice of keeping what he has or voluntarily trading for changes). The equivalent measure, by using the subsequent welfare level as the reference level, treats the individual as if he had only a right to his subsequent level of welfare (that is, as if he must accept his subsequent situation, or seek to trade his way back to his initial situation). Clearly, Hicksian compensating measures are consistent with the potential Pareto-improvement criterion, while Hicksian equivalent measures are not.

To clarify the relationship between Hicksian compensating and equivalent measures of value, *WTA* and *WTP*, and the total value curve introduced in figure 1, consider the following example. The benefit-cost analyst is evaluating a proposed project which would, among other things, divert a specified area of wildlife habitat to some alternative use, effectively destroying its usefulness as habitat. The benefit-cost analyst needs to know, among other things, the value of the losses which would be suffered by an individual who currently enjoys the wildlife amenities provided by that habitat. In the "without project" situation, the individual has the utility level $U(Q^0, Y^0)$. To keep the example simple, assume that this individual gains no benefits from the project. Thus his "with project" utility level would be $U(Q^-, Y^0)$. The level of Q, either the "without project" level Q^0 or the "with project" level Q^-, is predetermined so that optimizing adjustments are impossible.

What is the welfare impact of the proposed change on this individual? One could determine his *WTA* to accept the proposed change. Let us call this $WTA^C_{Q^0,Y^0;Q^0,Y^0;Q^-}$. The superscript C indicates that this is a Hicksian compensating measure of value, the first subscript pair, Q^0, Y^0, indicates that the individual's reference level of welfare (or his presumed right) is Q^0, Y^0. The second subscript pair indicates that Q^0, Y^0 is also his initial welfare level. The third subscript, Q^-, indicates the level of provision of wildlife-related services the individual would enjoy after he has accepted the compensation and the change in habitat-related services; if it turned out that he were compensated with an amount exactly equal to his *WTA*, his after compensation income would equal $Y^0 + WTA^C$. This measure of *WTA* for a reduction in the quantity of wildlife-related amenities from Q^0 to Q^-, which we shall denote by the abbreviated notation WTA^C, was derived from a total value curve passing through the individual's initial state at Q^0, Y^0 (fig. 2).

However, there is another value measure sometimes used to estimate the individual wildlife amenity user's loss: the amount of money he would be willing to pay to avoid a reduction in the provision of wildlife amenities. What kind of value measure is *WTP* to avoid a less preferred situation? It assumes the individual must accept the less preferred situation, or pay to avoid it. Thus, the reference level of welfare is not the initial situation, but the proposed (or subsequent, in Hicksian terminology) welfare level. So, this second measure of the individual's welfare loss can be

$$(1) \qquad U = U(Q,Y).$$

The individual is thus at the origin (figure 1), which defines his level of welfare in the "without project" situation. Examine the axes. To the right of the origin, the level of provision of Q to the individual increases; to the left of the origin, it decreases. From the origin, a movement up the income axis indicates a decrease in income, while a movement down the vertical axis indicates an increase in income. The total value (TV) curve, or bid curve (Bradford), is of positive slope, given that the service is a commodity and the individual is not satiated in the range under consideration. For decreases in Q, the TV curve lies in the southwest quadrant; for increases in Q, it lies in the northeast quadrant. If it is possible to define the quantity of the service in unidimensional, cardinal terms, the assumption of diminishing rates of commodity substitution is sufficient to ensure the curvature shown. Alternatively, if "quantity" is multidimensional, or if it cannot be defined accurately in cardinal terms, no a priori assumption can be made concerning the curvature of the TV curve (Bradford).

The TV curve is an indifference curve, passing through the individual's initial state. That is,

$$(2) \quad U(Q,Y) = U(Q^-, Y^+) = U(Q^+, Y^-).$$

Starting at the origin, $Y^0 - Y^-$ is the individual's willingness to pay (WTP) to obtain an increment in the level of provision of the service from Q^0 to Q^+. Willingness to accept (WTA), i.e., $Y^+ - Y^0$, is the amount of money

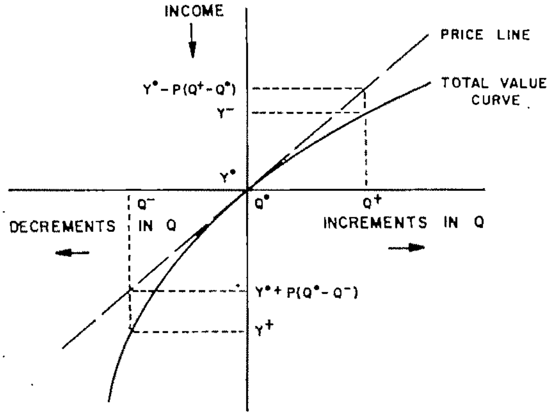

Figure 1. The total value curve for increments and decrements in the level of provision of a service, Q, for an individual who initially enjoys the level Q^0 and the income Y^0

which would induce the individual to accept voluntarily a decrease in the level of provision of the service from Q^0 to Q^-. Thus, WTP is the total value to the individual of an increment from Q^0 to Q^+; WTA is the total value to the individual of a decrement from Q^0 to Q^-. Restating equation (2),

$$(3) \quad U(Q^0, Y^0) = U(Q^-, Y^0 + WTA) = U(Q^+, Y^0 - WTP).$$

WTA and WTP bear the following relationship to the traditional market indicators of value. If $Q^+ - Q^0$ is a one-unit increment in Q, WTP is equal to the buyer's best offer for that increment. If $Q^0 - Q^-$ is a one-unit decrement, WTA is equal to the seller's reservation price for that decrement. If a market existed in which the individual could purchase the increment $Q^+ - Q^0$ for some amount less than his WTP, he would proceed with the purchase and enjoy a gain in trade. Likewise, if a market existed in which he could sell the decrement $Q^0 - Q^-$ for some amount more than WTA, he would proceed with the sale and again enjoy a gain from the transaction. If an increment would cost the individual more than his WTP, and a decrement would net the individual less than his WTA, he would eschew all trade in Q and remain at his initial situation.

WTP, *WTA*, and Consumer's Surplus

Following Mishan (1971, 1976), we argue that consumer's surplus is the appropriate measure of value in benefit-cost analysis; that consumer's surplus is correctly defined by the Hicksian measures, rather than the Marshallian measure; and that, unless a project or program is proposed primarily for the purpose of redistribution, the potential Pareto-improvement is the proper criterion for benefit-cost analysis and, therefore, Hicksian compensating measures are the proper measures of value. However, depending on the applied benefit-cost problem at hand, available value data may be in the form of market prices, Marshallian consumer's surplus, Hicksian compensating measures of consumer's surplus, WTP, or WTA. Our purposes in this section are to develop the relationships between these measures; to show that, in any particular benefit-cost situation, the proper measure of value can be identified on the basis of theoretical considerations; and to show that empirical estimates of the theoretically correct measure of value

Valuing Increments and Decrements in Natural Resource Service Flows

David S. Brookshire, Alan Randall, and John R. Stoll

A general model for valuation of changes in natural resource service flows, entirely consistent with Hicksian concepts of consumer surplus, is developed. It is a total value model, applicable to all classes of goods: divisible and indivisible in production, divisible and indivisible in consumption, exclusive and nonexclusive. The standard result of partial equilibrium microeconomics—price is equal to value at the margin—may be derived as a special case from this model. An empirical application involving the valuation of changes in the provision of wildlife-related amenities is presented.

Key words: consumer's surplus, natural resources, valuation, wildlife.

In the course of his work, the benefit-cost analyst frequently encounters situations in which a proposed program or project would divert natural resources from their current use to some, quite different, alternative. In keeping with the "with and without" principle, he must determine "without project" benefits, which are equal to the net present value of the stream of services that would be provided by the natural resource in its current use over the life of the proposed project. For example, projects are often proposed which would drain wetlands, fill coastal marshlands for housing or resort developments, dam free-flowing streams, inundate canyons, or divert wildlife habitat for agricultural, forestry, or mineral extraction purposes. These few examples suggest that the flow of goods, services, and amenities which must be valued to determine "without project" benefits is often complex. The natural resource often provides flows of goods, services, and amenities quite diverse in physical terms. In economic terms, too, the diversity of goods, services, and amenities produced may be awesome. There may be goods that are divisible, lumpy, or indivisible in production; divisible, congestible, or nonrival in consumption; and exclusive or nonexclusive. "With project" benefits are more likely to involve marginal increments in the supply of undifferentiated goods—e.g., agricultural commodities, electricity, and slack-water recreation—but may also include complex goods.

We propose a general conceptual model for the valuation of natural resource service flows. The model focuses on total value and, at the outset, would seem to represent a radical departure from the partial equilibrium, marginal microeconomics commonly applied in benefit-cost analysis. However, the model generates, as a special and limiting case, the traditional results of marginal analysis; and, in so doing, defines the appropriate role for marginal analysis in the benefit-cost framework.

The Total Value of Changes in the Level of Provision of a Service

Consider an individual who currently enjoys some specified level, Q, a service. In addition, he enjoys a given quantity of the Hicksian "all other goods" numeraire, Y, which for convenience is called income. Thus, his level of utility is always dependent upon his income and the quantity of the particular service upon which we focus, i.e.,

concave region. If time and grade are ignored, rations within a concave region would not be optimal. In general, for *ad libitum* feeding, as the energy concentration of the rations increases, the time required to achieve a given weight level declines. Thus, depending on the relative prices of roughage, concentrate, and time, either a high concentrate ration which contains a minimal amount of roughage to prevent rumen dysfunction, or a ration high in roughage, such as full corn silage, would be optimal.[3]

Roughage is bulky and relatively more difficult to transport, store, and feed than grains. Thus, producers who purchase feedstuffs might be expected to feed high concentrate rations. On the other hand, a corn producer who has silage production and storage facilities may feed a full corn silage ration. A full corn silage ration would yield more pounds of beef per acre. However, corn silage reduces soil cover, removes more nutrients, and increases the potential for erosion losses relative to corn grain.

Additional research is needed in several areas. For example, the NE_g of the soilage study (ignoring the full soilage ration) ranged from 0.84 to 1.23 Mcal./kg. and for the corn silage study from 0.99 to 1.24 Mcal./kg.[4] Experiments extending over a wider range of energy concentration could provide more information on the turning points between concave or linear and convex regions. Because of the nature of the function, six rations may be insufficient to detect accurately turning points. Work also is needed to determine the impact of nonnutrient additives and implants across rations. Finally, the impact of restricting intake should be explored.

We cannot conclude that a concave or linear region exists in the roughage-concentrate isoquant for all types of roughage and concentrates. Also, it is not entirely certain why the derived isoquants have the shape shown. These and other issues remain to be settled.

[*Received March 1979; revision accepted November 1979.*]

[3] Carcass quality grades and yield grades were not statistically significantly different among the corn silage rations. Steers from all pens consistently graded low choice to high good across years and rations. Thus, the output can be assumed to be homogenous across rations for the corn silage experiment.

[4] Many producers feed rations that exceed the energy concentration of those fed in either experiment. For example, an 85% corn grain-15% corn silage ration has an estimated NE_g = 1.41 Mcal./kg.

rived from equation (4.1) are graphed in figure 4. They are concave over a wide range of rations. They are not progressively tipped away from the corn silage axis. Thus, for this particular study, in which the range of rations in terms of energy concentration is relatively small, and the range of gain considered is also relatively small, tipping is not evident. Of course, tipping would be easier to detect if both the range of gain and the range of energy concentration were increased.

Corn Silage (Restricted Intake) Estimates

The directly estimated 160-kilogram-restricted intake gain isoquant is reported as equation (3.2) in table 3. It is graphed in figure 5. This estimated isoquant also has a nonconvex range.

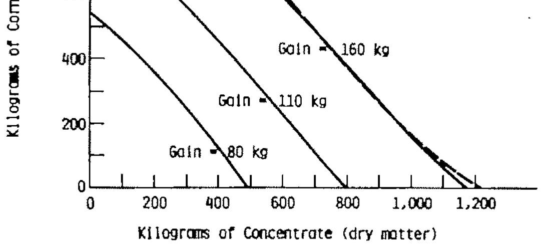

Figure 5. Corn silage restricted intake isoquants—direct estimate and production function estimates

The second degree polynomial production function estimate, equation (4.3), resulted in a lower MSE than the third and fourth degree functional forms. As with equation (4.1), the estimated regression coefficients on θd^2 and $\theta^2 d^2$ are not statistically significantly different from zero at the 0.10 level of probability. However, the other coefficients are significant at this level. Three isoquants derived from equation (4.3) are graphed in figure 5. They are also concave over a wide range of rations.

Equations (3.2) and (4.3) both exhibit sigmoid isoquants. Unlike Brokken's sigmoid isoquants, the corn silage isoquants show a convex range in the high concentrate region. The ration which is devoid of hay or silage is probably not a good ration for physiological reasons.

Even though the restricted intake scenario might be expected to increase the time on feed and, thus, the energy required for maintenance and, thus, the total feed required, the restricted intake isoquants lie below the corresponding *ad libitum* isoquants across all rations. This suggests that if time is ignored, *ad libitum* feeding is inefficient.[2]

Implications and Conclusions

The isoquants and production functions estimated from the data of the two experiments suggest that we cannot reject the hypothesis that the overall beef gain roughage-concentrate isoquant may have a linear or

[2] Because the marginal product of feed is zero beyond stomach capacity, Dillon (p. 99) has suggested that *ad libitum* feeding may not be optimal.

$$(8)\quad A = a_0 + a_1B + a_2B^2 + DO + D1B,$$

where $DO = b_0 - a_0 + A_0 - a_1B_0 + a_2B_0^2$ and $D1 = -2a_2B_0$.

A similar procedure can be followed to adjust for trial 3 differences. The regression equation used to estimate the quadratic gain isoquants for the three trials pooled is

$$(9)\quad \hat{A} = a_0 + a_1B + a_2B^2 + a_3D1 + a_4D1B + a_5D2 + a_6D2B,$$

where A and B are interpolated quantities of concentrate and corn silage required for the specified weight gain, $D1 = 1$ for trial 2, 0 otherwise, and $D2 = 1$ for trial 3, 0 otherwise (Dahm, Heady, Sonka).

For production functions estimated in polar coordinates, dummy "distance" variables can be used to account for differences among trials. Because rations, in terms of proportions of corn silage and concentrate in the feed, were fixed for all trials, the measure of "angles" does not vary among trials. The following example illustrates the type of dummy variables used and the form of a second degree function:

$$(10)\quad W = (a_0 + a_1\theta + a_2\theta^2)d + (a_3 + a_4\theta + a_5\theta^2)d^2 + (a_6D1 + a_7D2)d + U,$$

where $D1 = 1$ for trial 2, 0 otherwise, and $D2 = 1$ for trial 3, 0 otherwise. The variable θ is not used without interaction with d since this would imply a variable intercept term.

Corn Silage (*Ad Libitum* Intake) Estimates

The dummy variable techniques were used to adjust starting weights to 320 kilograms. Cubic, quadratic, and linear functional forms were fit. The cubic functional form reported in table 3 resulted in the lowest MSE. It reflects a gain of 160 kilograms from a starting weight of 320 kilograms.

Perhaps as a result of the limited number of observations, most of the estimated coefficients of equation (3.1) are not statistically significant. It is graphed in figure 4. The isoquant is concave with a convex tail near the concentrate axis.

Production function estimates were obtained in polar coordinates. Polynomial functions of the second, third, and fourth degree in angle θ were estimated. The fourth degree function did not reduce MSE. The second and third degree functions are reported in table 4. All estimated coefficients of equation (4.1), except for those on θd^2 and $\theta^2 d^2$, are significant at the 0.10 level of probability. However, only the coefficients on d, d^2, and the dummies are significant at the 0.10 level for equation (4.2). The 80-kg., 120-kg., and 160-kg. isoquants de-

[a] The IV procedure was used to obtain estimates of B, B^2, and B^3 which are independent of concentrate consumption (B is corn silage consumption).
[b] Numbers in parentheses are t-values (absolute value).

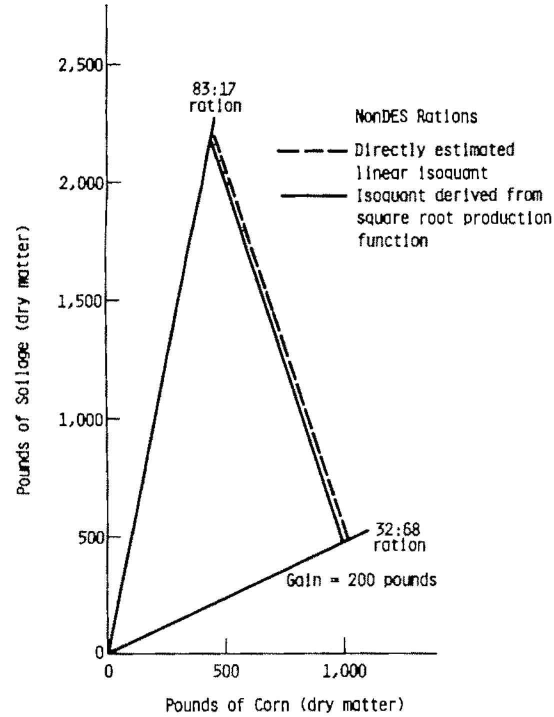

Figure 3. Soilage without DES isoquant—direct estimate versus production function estimate

tive. Also, the two isoquants are more divergent for the higher roughage rations. Perhaps, the impact of DES varies across rations. Because the data were collected on two different farms, soilage quality and weather could not be fixed across farms. Thus, the difference in the estimates may be due to factors other than the DES.

The soilage experiment was limited in time to the length of the growing season. Hence, not all of the steers, especially those receiving the full soilage ration, had equal opportunity to gain equivalent amounts. The steers of the corn silage experiment were permitted to gain equivalent weights, and, consequently, did not face this problem. Because one of the rations of the corn silage experiment did not contain any roughage, we might expect a sigmoid isoquant with a convex tail on the high concentrate end.

Functional Forms

Conventional functional forms for production function estimation, such as Cobb-Douglas, quadratic, and square root, do not permit sigmoid isoquants. The grafted polynomial approach developed by Fuller (1969) and applied to the beef gain problem by Melton et al. can be used to permit sigmoid isoquants. However, the grafting technique requires some method for estimating a join line. Production functions estimated in polar coordinates provide a more general approach in that functional forms may be chosen which place fewer restrictions on derived quantities. They will permit sigmoid isoquants as well as tipping. Thus, the corn silage production functions were estimated in polar coordinates.

Any point in a rectangular coordinate system can be described as being some distance, d, from the origin. Also, a line from the point to the origin forms an angle, θ, with the horizontal axis. The points of a polar coordinate system are described in this manner. Because the corn silage experiment can be described with only two variable inputs, the data can be transformed conveniently into polar coordinates in the following manner. Let

$$W = f(d,\theta), \tag{5}$$

where W is kilograms of weight gain per steer for the period; d is $(A^2 + B^2)^{\frac{1}{2}}$; θ is tan^{-1} (A/B); A is kilograms DM of concentrate; and B is kilograms DM of corn silage.

Starting Weight Adjustments

The starting weights of the steers in the corn silage study differed across trials. Thus, adjustments were necessary to account for trial-to-trial differences. Dummy variables were used to accommodate different starting weights for the directly estimated isoquants. The actual starting weights were 320 kg., 370 kg., and 395 kg. for trials 1, 2, and 3, respectively. If we let the 160 kg. gain isoquant for trial 1 be

$$A = a_0 + a_1B + a_2B^2; \tag{6}$$

and the 110 kg. gain isoquant for trial 2 be

$$A = b_0 + b_1B + b_2B^2, \tag{7}$$

then, by restricting a_1 to equal b_1 and a_2 to equal b_2, trial 2 can be represented as

$$(A - A_0) = b_0 + a_1(B - B_0) + a_2(B - B_0)^2,$$

where A_0 and B_0 are the unknown quantities of concentrate and corn silage utilized by the steers of trial 1 to achieve the initial 50 kilograms of gain. This equation can be written as

[c] The IV procedure was used to estimate this production function.

tion (2.3) is graphed in figure 2. It is concave to the origin over the data range. Thus, the directly estimated isoquant, equation (1.1), the "traditional" production function estimates, equations (2.1) and (2.2), and the IV production function estimate, equation (2.3), all yield isoquants that are slightly concave to the origin over the data range. We feel that we can conclude that the beef gain soilage-corn grain isoquant derived from the soilage with DES experiment has a nonconvex range. Further, the full soilage ration, which very likely restricted energy intake, masked the nonconvex range in the previous analysis of the data.

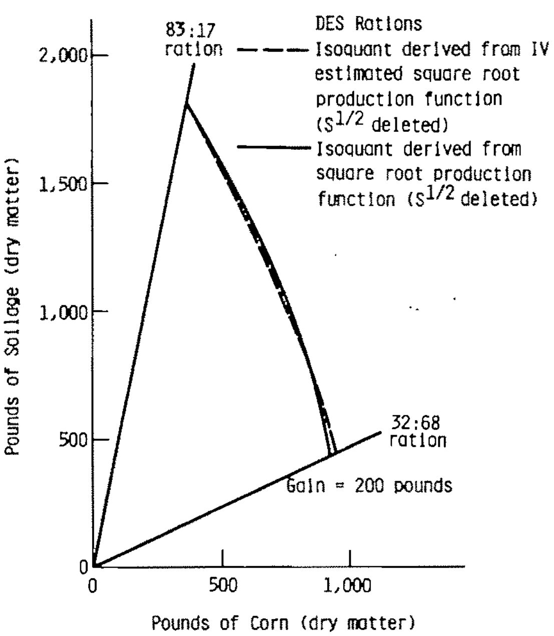

Figure 2. Soilage with DES isoquant—production function estimate versus instrumental variables-production function estimate

Soilage (without DES) Estimates

Data from the soilage without DES experiment also were reanalyzed. The directly estimated 200-pound gain quadratic isoquant is reported in table 1. The graph of equation (1.2) is slightly concave to the origin. But, the coefficient of S^2 is of questionable significance. Thus, the square term was dropped. Equation (1.3), the linear fit, resulted in a lower MSE than the quadratic fit. It is graphed in figure 3.

The production function for the soilage without DES experiment is reported in table 2. All estimated coefficients for equation (2.4) are statistically significantly different from zero at the 0.05 level of probability except for the square root of S and the interaction term. The 200-pound isoquant derived from equation (2.4) is graphed in figure 3. It is very slightly convex to the origin.

The isoquant estimates obtained from the data of the pens which did not receive DES are more nearly linear than those estimated from the DES data. A linear isoquant has the same ration and cost implications as a concave isoquant. Isoquants derived from the nonDES data lie above those derived from the DES data for all rations. This finding is consistent with the popularity of using the hormone addi-

was used to provide estimates of soilage consumption that are independent of the estimates of the quantity of corn consumed such that isoquants could be estimated directly. Linear, quadratic, and cubic functional forms were used to fit the isoquants. The quadratic estimate resulted in the lowest mean square error (MSE). It is reported in table 1. The negative coefficient on the square term for equation (1.1) is statistically significant at the 0.01 level of probability. The isoquant is graphed in figure 1. It is concave to the origin.

Gain production functions also were estimated from the five rations of the soilage experiment which were expected to fall within the concave range of the overall isoquant. Quadratic and square root functional forms were used. The square root estimate resulted in the smallest MSE. It is reported in table 2.[1] The 200-pound isoquant derived from equation (2.1) is graphed in figure 1. It is concave to the origin.

Because the square root term on S in equation (2.1) is of questionable significance, it was dropped and equation (2.2) was estimated. The 200-pound isoquant derived from equation (2.2) is graphed in figure 2. It is also concave to the origin.

As noted previously, if we do not "trust" the results of the F-test regarding OLS bias, and if instruments are available, the full production function can be estimated with the IV procedure. Thus, because isoquants derived from the production functions, equation (2.1) and (2.2), are concave, and because this is the

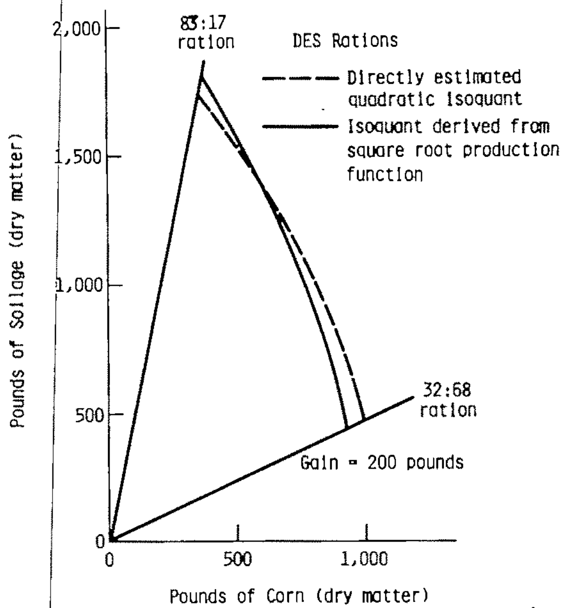

Figure 1. Soilage with DES isoquant—direct estimate versus production function estimate

crucial issue, we utilized the IV procedure to estimate the full production function for the soilage with DES data set.

The procedure is similar to that used in the direct estimation of isoquants. Following Fuller (1976, p. 224), we used time on feed, proportion of roughage in the ration, and the interaction of time with ration as instruments on which to regress C and S. Predicted values from these regressions along with their powers were used in second round regressions to prepare "independent variables" for the production function estimate. The resulting estimate is reported as equation (2.3) in table 2.

The 200-pound isoquant derived from equa-

[1] In the original analysis, a quadratic function was fit. It did not contain an intercept term or dummy variables for the three trials. However, a temperature variable was included (Heady et al.). Unfortunately, the temperature data were not located.

[a] The IV procedure was used to obtain estimates of S and S^2 which are independent of corn grain consumption (S is pounds dry matter of soilage; $D1$ and $D2$ are dummy variables for years and equal 1 for years 1 and 2, respectively, and zero otherwise).
[b] Numbers in parentheses are t-values (absolute value).

When animals are fed *ad libitum,* they, and not the research workers, control the rate of feed intake. Thus, the recorded feed intake quantities may contain a stochastic component which may not be independent of the equation error. Fuller (1977) has developed a statistical test to determine if OLS estimates will be nearly unbiased. The F-test was applied to the data of each trial. The null hypothesis that OLS estimators would be nearly unbiased was not rejected at the 0.05 level of probability for any of the data sets. Thus, we could proceed under the assumption that OLS is appropriate.

Alternatively, if the results of the F-test were not satisfactory, and if variables which can be used as instruments are available, the instrumental variables (IV) procedure can be used to estimate the production function (Fuller 1976).

The IV procedure can be used to obtain consistent estimates of the regression coefficients for both situations involving stochastic regressors as well as situations involving errors in variables. However, the stochastic nature of feed consumption by the animals is probably of greater importance for the present analysis than any "measurement error" associated with the regressors. Hence, the gain production function model is essentially a regression model with stochastic independent variables which may be correlated with the equation error.

Direct Estimation of Isoquants

Sonka, Heady, and Dahm used the IV procedure to estimate directly swine gain isoquants. They used ration protein percentage as the instrument for estimating the quantity of supplement consumed. The isoquant was estimated by regressing recorded values of corn consumption on predicted values of supplement consumption. Burt suggested that the isoquant estimate was not needed because the isoquant could be determined from the initial estimate. This would hold if a theoretical relationship exists between the random independent variables and the instruments and if the relationship is properly specified by the functional form. This requirement is not necessary for the IV procedure.

Our objective is to estimate directly beef gain roughage-concentrate isoquants. The equation to be estimated is

$$C = f(S,\Psi) + U, \tag{1}$$

where C and S are quantities of the two feeds, f is the functional form, Ψ a set of parameters, and U the residual error term. Neither C nor S satisfy the classical regression model assumptions with respect to independent variables. Thus, OLS estimates may be seriously biased as a result of the correlation between U and S. The IV procedure defined by Fuller (1976, p. 220) can be used to obtain consistent estimates if information is available on fixed variables which are correlated with the "independent variables" and not correlated with the random error term of the model. For both experiments, treatments were fed along fixed ration lines. In other words, the percentage of roughage (and concentrate) fed to each pen was fixed experimentally. This variable, call it N, can be used to build instrumental variables to estimate equation (1). In addition, the vector of "ones," along with the dummy variables, call them M, can also be used as instruments.

Powers of S can be used in equation (1) to permit a nonlinear isoquant. Thus, we could estimate

$$S^*,\ S^{2*} = G(N,M), \tag{2}$$

and use the predicted values of S^* and S^{2*} in equation (1). However, we arbitrarily selected the following alternative procedure. First we estimate

$$\hat{S} = G(N,M), \tag{3}$$

and use the predicted values and powers of predicted values from this estimate, call them Z, in "second round" estimates.

$$S^*,\ S^{2*} = h(Z,M). \tag{4}$$

Predicted values from these estimates are used to estimate directly the isoquant, equation (1).

We note that the residuals from equations (2), (3), and (4) "may be a sum of random and fixed components" (Fuller 1976, p. 221), in which case it would be inappropriate to solve them for the isoquant. The appropriate residuals for the isoquant estimate, equation (1), should be based on the recorded values of the "independent" variable. Thus, they were directly computed and used to calculate the estimated variance and t-values.

Soilage (with DES) Estimates

The soilage data were interpolated to a weight gain level of 200 pounds. The IV procedure

distort a slightly concave region and result in an overall convex isoquant as Brokken et al. suggest. Thus, the data were reanalyzed.

Data indicated that the rates of gain were slower on the full soilage ration such that half of the pens receiving that ration did not gain 200 pounds during the pasture season. Therefore, the full soilage ration (100:0) was dropped from the data set, and estimates were obtained from the remaining five rations. The estimated NE_g for these five rations ranged from 0.84 to 1.23 Mcal./kg. Based on the work of Brokken et al., these five rations would be expected to fall in the concave region of the isoquant.

Corn Silage Experiment

The corn silage feeding trial was conducted over a three-year period. Yearling crossbred steers, primarily of Angus and Hereford breeding, were placed on feed in the fall and slaughtered in the following spring. A total of 278 cattle were fed: 96 in the first and third years and 86 in the second.

Six rations were fed. Rations were composed of whole plant corn silage, whole shelled corn grain, dehydrated alfalfa pellets, and a soybean meal base supplement fortified with vitamins and minerals. Corn grain and alfalfa pellets were fed in a constant ratio of two parts corn grain to one part alfalfa pellets on an as-fed basis. This fixed proportion mixture is referred to as concentrate. The DM ratios of corn silage to concentrate, ignoring the supplement, were approximately: 100:0, 82:18, 63:37, 44:56, 23:77, and 0:100. The 100:0 ration was composed entirely of corn silage and supplement. Corn grain, alfalfa pellets, and supplement made up the 0:100 ration. All of the animals were implanted with 30 milligrams of DES immediately prior to the feeding trial. The supplement was fed at a constant rate of about 0.8 kilograms per animal per day.

In each year, twelve pens of cattle were fed. Six pens were fed a constant quantity of metabolizable energy per day. Hence, their intake was restricted. The other six pens were fed *ad libitum*.

The energy concentration, as measured by NE_g, ranged from 0.99 Mcal./kg. for the full corn silage ration, to 1.22 Mcal./kg. for the full concentrate ration (National Academy of Sciences). Based solely on the criterion of energy concentration, these rations would be expected to fall in the concave region of the proposed sigmoid isoquant. However, the National Research Council suggests that a minimal amount of roughage generally is necessary to prevent rumen dysfunction. Morrison also recognized the need for some roughage in the diet to prevent animals from being thrown off feed. Thus, the full concentrate ration might fall outside the proposed concave region.

Estimation Procedures

Traditionally, gain isoquants have been derived from production functions estimated by regressing cumulative weight gain on cumulative feed intake. For example, see Heady and Dillon. Several statistical problems are generally encountered. One potential problem is autocorrelated residuals.

Autocorrelation

Because successive measurements are made on the same experimental units over time, ordinary least squares (OLS) residuals associated with these measurements may be correlated. Several methods have been devised to correct for autocorrelation. If the number of experimental units per trial is relatively large, the full covariance matrix of the disturbance terms can be estimated. For example, see Dahm, Heady, and Sonka. Unfortunately, the number of experimental units, pens, per trial was limited to eight in the soilage study and six in the corn silage study.

A more common method of correcting for autocorrelation is to make an assumption about the autoregressive nature of the residual terms. Animals with low (high) rates of gain in one time period generally compensate with high (low) rates of gain in the next period. The effects of these compensatory gains generally are expected to dissipate in ten to fourteen days. Because the measurement periods for the experiments analyzed ranged from twenty-one to twenty-eight days, a first-order autoregressive scheme seems to be a reasonable assumption (Heady et al.). Transformation matrices were estimated for each trial and the data were transformed for production function estimation (Johnston, p. 260).

Stochastic Regressors

An additional statistical problem may be encountered in production function estimation.

Empirical Investigations of Beef Gain Roughage-Concentrate Substitution

Francis Epplin, Shashanka Bhide, and Earl O. Heady

The shape of the beef gain roughage-concentrate isoquant is examined. Data from two beef-feeding experiments designed to investigate response from alternative combinations of roughage and concentrate are utilized. Isoquants derived from estimated production functions are compared with directly estimated isoquants. The estimates indicate that the isoquant is not strictly convex to the origin. The nonconvex region is more pronounced in estimates obtained from data of steers fed diethylstilbestrol.

Key words: beef feeding, concentrate, instrumental variables, isoquant, roughage.

Several studies published during the last decade have suggested that the beef gain roughage-concentrate isoquant may not be strictly convex to the origin (Brokken et al.; Brokken 1977a, b; Byers, Matsushima, Johnson; Goodrich et al.; Perry and Beeson). In general, the studies suggest that a nonconvex region may exist over a range of rations extending from where the energy concentration is so low that gut fill restricts intake, to where roughage intake is so low (high energy concentration) that digestive problems result. In addition, Brokken's work suggests that successive isoquants tip away from the roughage axis such that the ability of roughage to compete economically with concentrate diminishes as animal weight increases. This tipping phenomenon, along with a nonconvex region in the isoquant, would explain the popularity of feeding high roughage rations to light animals, followed by a high concentrate ration at heavier weights.

Soilage Experiment

A study of soilage (fresh-chopped alfalfa-bromegrass) and corn grain substitution reported by Heady et al. shows isoquants which are convex to the origin. The isoquants were derived from a statistically estimated production function. Given the knowledge of the time, the convex isoquants were deemed acceptable. However, based on more recent findings, we might expect a concave region in the soilage-corn grain isoquant.

Hereford yearling steers weighing approximately 840 pounds were assigned randomly to one of two farms and one of six rations. Rations at one location included diethylstilbestrol (DES) (with DES), while those at the other location did not (without DES). The dry matter (DM) ratios of soilage to corn grain were approximately as follows: 100:0, 83:17, 70:30, 54:46, 41:59, and 32:68. The estimated net energy for gain (NE_g) in terms of megacalories per kilogram (Mcal./kg.) for the six rations was: 0.71, 0.84, 0.94, 1.06, 1.16, and 1.23 (National Academy of Sciences).

Based on Brokken's work, the energy concentration of the full soilage ration was so low that gut fill would restrict energy intake to something less than the physiological demand for energy. Thus, this ration would fall in the convex range of Brokken's proposed sigmoid isoquant (Brokken 1977a). However, the energy concentration of the other five rations was sufficiently high that the physiological demand for energy could be met prior to encountering the gut fill restriction. They would fall in the concave range of the proposed sigmoid isoquant. If the isoquant is sigmoid, a quadratic gain-production function estimate based on the six rations combined could give misleading results. The convex region might

ues was used. It was assumed that cows weighing less than 400 kg. would grade canner, cows weighing 400 to 447.5 kg. would grade utility, and cows weighing 450 kg. or more would grade commercial. These weights were believed to correspond to the body condition-slaughter grade designation of an English breed beef cow weighing about 450 kg. in "normal" range condition.

Ordinary least squares was used to estimate equation parameters for determining utility and canner prices from the commercial price. Data used were 197 observations of monthly average cow prices at Billings, Montana, for the period January 1960 through May 1976. The estimated equations are

$$P_{utility} = -1.011 + \underset{(11.74)}{1.038}P_{commercial},$$
$$R^2 = 0.986 \qquad SE = 0.708$$
$$P_{canner} = -1.1219 + \underset{(86.3)}{0.9703}P_{commercial}.$$
$$R^2 = 0.956 \qquad SE = 1.09$$

(Values in parentheses are t-values.) Thus, the expected immediate returns from decisions to sell cows and terminal values were calculated as (a) (weight) (−1.1219 + 0.9703 Price), for cows weighing less than 400 kg.; (b) (weight) (−1.011 + 1.038 Price), for cows weighing 400 to 447.5 kg.; and (c) (weight) (Price), for cows weighing 450 kg. or more.

Again, the resulting optimal decisions and expected returns from an optimal policy are as one might anticipate. It is, of course, the case that at any stage, the optimal decision and expected returns from an optimal policy for all states where cows would grade commercial will be the same as those presented above from the initial model. Again, remember that the returns pertain to the average yield within the grade; there would be price discounts for lower-than-average yields and price premiums for higher-than-average yields within the grade.

For cows that can be expected to change grade, expected returns for holding and feeding would be increased. This is particularly true of cows that would change from canner to utility grade, where the price differential is greatest. Expected net returns from an optimal policy for light cows in November and December was as high as \$55 under the grade change assumption compared to \$40 under the initial single price assumption. Holding and feeding is an optimal decision through later stages of the planning period, and in some cases the optimal decision is to feed for higher rates of gain. In fact, with the possibility of grade change, holding and feeding cows in the weight range 380 kg. to 395 kg. was the optimal decision in September and October for all prices considered. This is in contrast to the results of the other two solutions where the optimal decision for all states in September and October was sell immediately.

Concluding Remark

Under the single slaughter grade assumption, results indicate that marketing cull beef cows under an optimal policy which includes holding and feeding increases expected returns by \$20 to \$40 per head over selling immediately at early stages of the planning horizon, November and December. The increase amounts to 15% to 20% of the value of the cow when sold at the prices and weights considered in this study. As would be anticipated, expected net returns from an optimal policy decrease at succeeding stages until, ultimately, the optimal decision is to sell immediately, where the expected net return is equal to zero. Slaughter grade differences were incorporated into the analysis by assuming that a cow of specific weights would grade canner, utility, or commercial, and cow prices were adjusted to reflect grade-price differences. Expected net returns from marketing under an optimal policy increased to as much as \$55 per head for cows that would change grade while being held and fed.

are at most $10. For the stages September and October, the optimal decision was to sell cows immediately. This result is subject to the model restriction that cows must be sold by the end of October. It could be the case that if cows could be held for higher prices expected after November and pasture was considered as a decision alternative, the optimal decision, as part of an optimal policy with more than a one or two month horizon, would be different. A complete presentation of the optimal decision rules may be found in Yager.

Cost of Capital

For some states in the above results, expected net returns from holding and feeding a cull cow were quite small, less than $1.00. While this is an additional return above all costs, it suggests that optimal decisions would be sensitive to costs. To test sensitivity to the cost of capital and the risk-of-death losses, optimal decisions and expected returns from an optimal policy were obtained under the assumption that the combined effect of survival and the interest rate was .81025 annually, making $\delta = .9828$; this would imply an annual interest rate of 23% if there were no risk of death loss. Results are as might be anticipated. The expected net returns from an optimal policy are decreased to a range of $10 to $25 at early stages of the planning period compared to the previous $20 to $40 range. At later stages in the planning period, where expected net return was low, the optimal decision is more often sell immediately. On the other hand, the optimal decision at early stages of the planning period is in most cases the same as that obtained earlier. The most changes occur in March and April, where the optimal decisions were to hold and feed for various rates of gain in a majority of states, but under the higher discount factor the optimal decision is to sell most cows immediately.

Grade Changes

The price prediction model and results presented above are based on a single data series, commercial grade cow prices at the Billings, Montana, market, and the implicit assumption that all cows regardless of weight or body condition, are valued at the same per-unit, live-weight price. However, cull beef cows are not necessarily perfect substitutes for one another; there are usually per-unit live-weight price differences for cows of different slaughter grades. Slaughter cattle carcasses are evaluated for quality—". . . the palatability-indicating characteristics of the lean . . ." (USDA Agr. Mktg. Ser., p. 5)—and yield—". . . percent of trimmed, boneless, major retail cuts . . . derived from the carcass . . ." (USDA Agr. Mktg. Ser., p. 5). Quality is evaluated primarily by firmness and fullness of muscling and physical characteristics that are associated with age. Yield is primarily evaluated by amount of fat, ribeye area, and carcass weight.

It long has been believed that producers could affect only the grade of a slaughter cow by changing finish or fatness. Mature cows got heavier by getting fatter and *ceteris paribus*, a fatter cow graded higher. However, recent results show that while lipid comprises 50% of the carcass weight gain, fed cull beef cow carcasses were of higher quality than carcasses from cows slaughtered at culling (Wooten et al. and Price and Berg). The fed carcasses had higher marbling scores, tended to have larger ribeye area, and had more separable lean tissue, particularly from the chuck, rib, and round than did the nonfed carcasses. These experiments suggest that fed cull beef cows not only accumulate body fat but they replenish or add to other body tissues. These results combined with the grade-yield system further complicate the optimization problem; *ceteris paribus*, increasing the amount of fat decreases yield which results in price discounts, and increasing the amount and quality of muscle tissue increases grade which results in price premiums. Solution requires the precise relationship between skeletal size and composition, weight, grade-yield, and price. This has not been determined fully. In fact, slaughter cow prices are reported only on a grade basis, not a grade-yield basis. Thus, the monthly average prices used in this study average not only over time (days of the month) but also over yield differences within a quality grade class. A solution based on grade averages, however, was thought to be useful regarding the potential gains to producers from grade-price differences as well as indicating the importance of the research question, determining the relationship between weight, grade-yield, and price.

To test the sensitivity of the dynamic programming results to grade-price differences, an alternative method of calculating expected immediate returns for selling and terminal val-

[a] Upper figure is optimal decision; lower figure is expected present value of net returns from an optimal policy.

given an optimal policy, for the stages November and April. The curves on each graph are the boundaries between isodecision spaces, identified by the optimal decision alternative number: 1, sell immediately; 2, feed to maintain cow weight; 3, feed to gain 0.25 kg./day; 4, feed to gain 0.50 kg./day; 5, feed to gain 0.75 kg./day; 6, feed to gain 1.00 kg./day; and 7, feed to gain 1.25 kg./day. Table 5 shows the optimal decision alternative and the expected present value of net returns from an optimal policy for selected states, current price, and weight, for the two stages. Expected present value of net returns is the difference between expected present value of returns from the optimal policy and the return from immediate sale (price times weight). Hence, when the optimal decision is 1, sell immediately, the expected present value of returns from the optimal policy is the current market value and the expected present value of net returns is zero.

Present value of expected net returns from optimal marketing policies varies widely within and between stages. The largest expected net returns, in the range of $20 to $40 more than if cows were sold immediately, result from optimal policies initiated early in the planning period, November and December. As would be expected, the optimal decision or target rate of gain tends to vary inversely with cow weight and directly with current price. At early stages in the planning period, expected net returns increase as cow weight increases through the intermediate weights and then decrease at the heavy weights where holding on maintenance or low rate of gain rations is the optimal decision. At intermediate stages of the planning period, expected net returns from an optimal policy are largest at high current price and low cow weight. For all states, present value of expected net returns from an optimal policy decreases at each succeeding stage to a range of $2 to $15 in March. April is the first month that selling immediately, decision alternative 1, is an optimal decision for any stage in the price range of interest. Through the remaining stages, holding and feeding is optimal only at relatively high current prices, and expected net returns to optimal policies

where $t = 1$ corresponds to November. Parameter estimates were taken as known parameters and the disturbance term u_t was assumed normally distributed with mean zero and variance equal to the square of the standard error of the estimate in the regression model which was 0.928, giving an estimated variance of 0.861. The conditional distribution of P_t, given P_{t-1}, is then normal with mean $\alpha_t + \beta_t P_{t-1}$ and variance 0.861.

A numerical calculation routine for computing the finite state transition probabilities was built into the dynamic programming algorithm because these probabilities were used only once in the algorithm, because the structure in (2) changes by month (stage). This approach is in contrast to the usual procedure of calculating the entire set of transition probabilities separately to be used as input for the dynamic programming algorithm. An important advantage of an integrated program for this type of application is the large saving in computer storage requirements.

There is a problem of truncation in using a discrete valued variable to approximate a continuous variable, such as price in the stochastic dynamic programming model. It is necessary to have upper and lower bounds on price, which requires that the probability of price exceeding the upper boundary must be added to the probability of price falling within the highest price interval; likewise, for very low prices and the lower boundary. This problem was handled by defining extra price states on each end of the interval of primary concern, *viz*, \$15 to \$25. States were defined on the interval \$10 to \$30, providing a \$5 buffer zone on each end of the price interval of primary concern. The \$5 buffer should be adequate in view of the estimated standard deviation of less than \$1.

Terminal Values

The terminal value for any state where cows were held was the value of the cow in that state, which was computed in the same manner as expected immediate returns from selling cows: price times weight. For the state where cows had already been sold the terminal value was zero.

Optimal Marketing Policies

For each state and stage the dynamic programming results show the decision that will maximize expected discounted returns and the value of expected returns from an optimal policy. The return is expected present value of returns from selling a cow less expected costs of feed, labor, and facilities for holding the cow from culling at the beginning of the particular stage until she is sold.

Because of space limitations, the only results presented here are the optimal decisions for two stages, figure 1, and the expected present value of net returns from marketing under an optimal policy for selected states for the two stages, table 5. Figure 1 shows for each state (cow weight and price) in the price range of primary interest, the decision alternative that maximizes expected discounted returns,

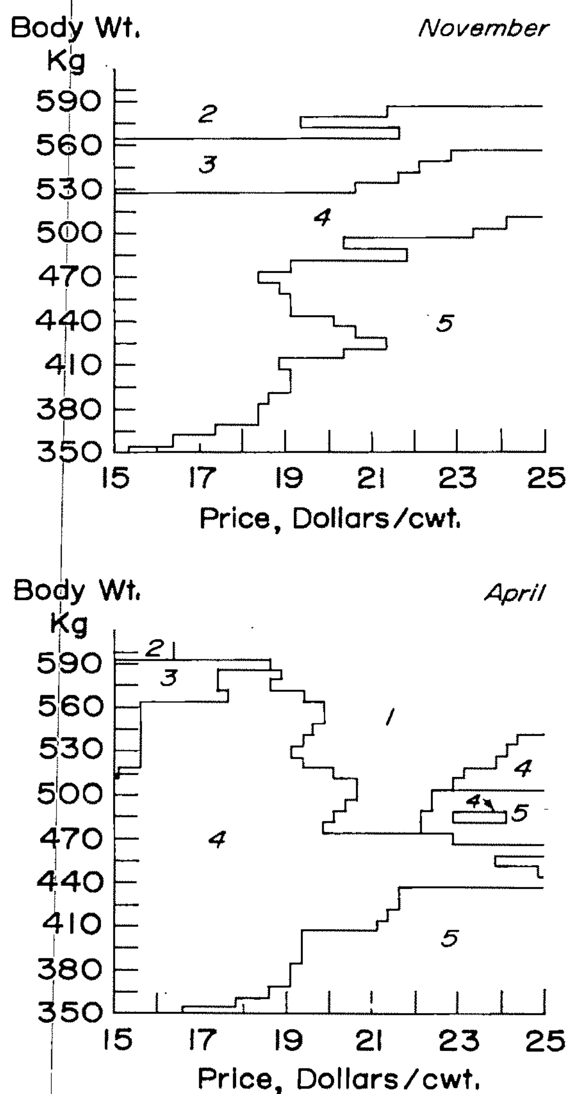

Figure 1. Optimal decisions for cull cow marketing

Table 3. Feedstuffs Considered and Respective Price Per Unit

Feedstuff	Price ($)
Alfalfa hay	
SC-early bloom	40/ton
Brome hay S-C	40/ton
Barley straw	15/ton
Barley grain	5.50/cwt.
Wheat grain, hard red winter	6.00/cwt.
Oats grain	6.00/cwt.
Corn silage	
40% dry matter	14.00/ton
Soybean oil meal 50%	10.25/cwt.
Dicalcium phosphate	14.25/cwt.
Monosodium phosphate	25.00/cwt.
Limestone	1.95/cwt.
Vitamin A supplement	100/cwt.
Dried beet pulp w/molasses	6.50/cwt.
Urea	12.70/cwt.

the high rate of gain rations were composed primarily of the concentrates barley and wheat. The specific blends are fully described in Yager. Daily feed costs are presented in table 4. The anomaly in feed costs at some weight-rate of gain combinations where daily cost was lower for periods of cold than for normal weather results from assumptions on maximum daily intake. During periods of cold, larger daily intake was allowed, which resulted in the substitution of larger quantities of corn silage for concentrates, primarily wheat. The anomaly indicates the interdependence among maintenance requirements, specified rate of gain, daily intake limits, and relative nutrient analysis and prices of feedstuffs considered.

The negative expected immediate return to a decision to hold a cow was then calculated, given a feeding decision, by interpolating over 50-kilogram ranges. The midpoints of the ranges were 350, 400, 450, 500, 550, and 600 kilograms. In those cases where the rate of gain was such that cow weight would change from one 50 kilogram range to another during a month, the different costs per day for the same rate of gain were applied to the appropriate number of days within the month.

Transition Probabilities

The cull beef cow-marketing problem has been formulated as a stochastic decision process, the state of which—at any stage—is controlled by the transition probability density function. Because of the lack of experimental data, weight change was assumed deterministic. Hence, the probability of a given weight is zero or one depending upon the feeding decision made. Only price remains as a stochastic variable in the model.

The price prediction equation for a given month t can be written as

$$(2)\quad P_t = \alpha_t + \beta_t P_{t-1} + u_t, \quad t = 1, 2, \ldots, 12,$$

Table 4. Cost Per Day for Feeding Cull Beef Cows under Various Weather Conditions: Dollars per Day

Decision Alternative k	Rate of Gain (kg./day)	Weather Condition	Cow Weight 350	400	450	500	550	600

		February	1.257	1.381	1.499	1.583	NF	NF

[a] NF indicates not feasible.

rate of gain will depend upon cow weight and the ration fed, i.e., level of nutrition provided. From a subset of rations that produce equal rates of gain, a profit-maximizing rancher will choose the least-cost ration. Thus, it is sufficient to specify average rates of gain as decision alternatives if variability of gain is not brought into the analysis. The seven decision alternatives are shown in table 2.

Maintaining, or perhaps increasing, cull cow weight (body condition) on pasture was not considered as an alternative. While it may be that in specific years or at particular times a year pasture, primarily native range in Montana, is a relatively low-cost source of nutrients, daily nutrient intake and performance are even more difficult to predict than is the case with harvested feedstuffs. Decision rules reported later suggest that it would be rare to hold and feed cull cows during the pasture season.

The Discount Factor

The appropriate value for β, the discount factor, represents the opportunity cost of capital, where $\beta = 1/(1 + i)$ and i is the cost of capital. But we also have the multiplicative factor α entering (1) symmetrically with β, where α is the probability that a cow survives one more month. Because of the symmetry, we can simply define a single factor $\delta = \alpha\beta$, which reflects the joint effects of economic discounting and the probability of survival. The results reported here are for $\delta = .9926$ which is equivalent to an annual factor of .9147. For example, an annual discount rate of 6% and survival probability of .97 would correspond to $\delta = .9926$, but many other combinations of discount rates and survival probabilities also would be appropriate for the same factor δ. We note that the economic discount rate should be defined as net of inflation, not the nominal money rate.

Table 2. Decision Alternatives

k	Alternative
1	Sell cows
2	Feed the least-cost ration to maintain cow weight
3	Feed the least-cost ration to produce gain of 0.25 kg./day
4	Feed the least-cost ration to produce gain of 0.50 kg./day
5	Feed the least-cost ration to produce gain of 0.75 kg./day
6	Feed the least-cost ration to produce gain of 1.00 kg./day
7	Feed the least-cost ration to produce gain of 1.25 kg./day

Expected Immediate Returns

At any stage where the decision alternative is to sell a cow, the expected immediate return is the product of the two state variables, price times weight. For any alternative where cows are held and fed, the expected immediate return is negative and equal to feed cost plus a lot charge which assigns a value for facility use and labor allocation. The value for facility use and labor allocation assigned in this study was \$1.50 per cow per month.

Calculation of feed costs, which will vary with cow weight, target rate of gain, and climatic conditions, is a linear programming problem. The objective function to be minimized is a cost equation with price per unit times quantity of each feedstuff constituting the separate terms of the equation. The constraints are nutrient requirements, both maxima and minima, with each term representing the nutrient analysis per unit and quantity of each feedstuff and, of course, nonnegative feedstuff quantities.

Nutritional requirements for many classes of livestock fed for alternative levels of production have been determined and published by the National Research Council. The exception is beef cows fed for changes in body condition—weight gains. Thus, for this study specifying the linear programming constraints necessitated several assumptions, particularly with regard to the energy required to produce various rates of gain on an English breed cow of varying body condition. The assumptions regarding specific daily nutrient requirements, energy requirements for maintenance and for gain, and additional energy required for maintenance during periods of cold (January and February when the mean daily temperature was less than the calculated critical temperature) are fully described in Yager. The feedstuffs considered and respective prices per unit are presented in table 3.

One hundred-eight least-cost rations, one for each of the six cow weights for six rates of gain for three weather conditions, were calculated. The weight maintenance and low rate of gain rations were composed primarily of barley straw. In the intermediate rate of gain rations, straw was replaced by corn silage, while

price elasticities (P-L-H, p. 137) and of income elasticities (Pinstrup-Andersen and Caicedo, p. 407, table 3) in which the respective price and income coefficients for the food commodities are the same or nearly the same (in absolute value). It seems inconceivable for twenty-two food commodities or groups to have the same (absolute) price and income elasticities and is contrary to the empirical evidence available from other studies using time-series data (George and King, Hassan and Johnson 1976, Brandow, Mundlak).

The low (relative to more aggregated commodity groupings) budget proportions of the food commodities (beef was the highest at 10%–12%) used by P-L-H explain how their calculated direct price elasticities could be the same (in absolute values) as the income elasticities. However, if P-L-H's price elasticities based on the Frisch method differ from the true elasticities by amounts similar to the differences in group three of table 1, our suggestion, based on the theoretical and empirical analyses cited earlier, that a higher money flexibility coefficient would be more appropriate would cause P-L-H's Frisch-generated price elasticities to be even further from the true elasticities. This is not inconsistent, however. It only adds to our conviction that the assumption of want independence is not applicable for individual food commodities and that the Frisch method is inappropriate.

P-L-H (p. 136) indicate that data on quantities consumed, prices, and income were collected for two periods in time. An alternative to the Frisch method for estimating price elasticities might be the one used by Hassan and Johnson (1977). Although Hassan and Johnson indicated that their model and method were not elaborate, the estimates of the price elasticities based on cross-section data collected over a one-year period were plausible and consistent with estimates from time-series data.

In conclusion, the authors are to be commended for developing a procedure to examine nutritional impacts of alternative commodity priorities in agricultural research. This, along with their later article (Pinstrup-Andersen and Caicedo), identifies the need to examine the implications of policy recommendations for improving nutritional intake across commodities and across income strata. However, we are disturbed by the seemingly inappropriate application of a technique that was never intended for use in this manner by the original author (Frisch).

The Impact of Increasing Food Supply on Human Nutrition: Implications for Commodity Priorities in Agricultural Research and Policy: Reply

Per Pinstrup-Andersen

The author of the comment rightly points out that the validity of the assumption of want independence depends on the level of aggregation of the goods in question and the way in which the aggregation/disaggregation is accomplished. We also agree, as we state in our original article (p. 133), that the assumption of want independence is likely to be violated for some of the commodities included in our analysis. We did not then, nor do we now suggest that the Frisch method be used for estimating price elasticities of demand for individual food commodities, if a better alternative is available. In fact, if the only purpose of the analysis had been to estimate price elasticities of demand, the utility of the exercise would have been questionable. But, as stated on p. 133 of our article, "since the primary purpose of the study was to develop and empirically test a methodology for estimating the nutritional impact of supply expansions, and not to estimate price elasticities per se, it was felt that direct application of the scheme developed by Frisch would provide sufficiently accurate elasticity estimates."

In the particular case, we saw no feasible alternative approach for estimating price elasticities except for a few staple commodities as mentioned below. Thus, the issue at hand was whether the violations of the want independence assumption were sufficiently strong to introduce unacceptable biases in our results. In view of the goal of the analysis, as stated above, the data situation in most developing countries, the urgency of the problem on which the analysis was focused, and the urgency of the related policy decisions, we would settle for directions and orders of magnitudes if great precision could not be obtained. Furthermore, the primary purpose of the analysis was to develop and test an approach and to illustrate its utility for policy making. Providing empirical results for a particular geographical region played a minor role in our objectives, and we stress in the article that the empirical results should be interpreted with caution.

Price elasticities of demand by income group are of paramount importance in studies of the distributional effects of supply shifts among consumers. Income elasticities are obtained with relative ease. Therefore, if budget proportions are known, the income effects of price changes can be estimated. But the substitution effect cannot. Therefore, some recent studies of the market price effects of supply shifts have ignored the substitution effect of price changes. Such an approach is unacceptable in most circumstances, because the income effect of price changes is very sensitive to the budget proportion. The most promising longer-term approach to the estimation of price elasticities of demand for individual food commodities and income strata in developing countries appears to be time-series analyses based on an improved data base. Such data base could be obtained through periodic (repetitive) household surveys. Such data collection is under way in some countries.

In our work, data were available for two time periods. Direct price elasticities of demand were estimated for six staple commodities, simply by comparing prices, quantities consumed, and incomes for the two points in time. The observed change in consumption after adjusting for family size and compositions, was assumed to be due only to price and income changes. Then, the effect of income change was estimated on the basis of income elasticities obtained from cross-sectional data, and the remaining quantity change was assumed to be caused by the observed price change. The six resulting price elasticities were used to obtain six estimates of the money flexibility for each income stratum. As stated on p. 136, these six estimates were not significantly different for any of the income strata. Contrary to the argument made by the author of the comment, the assumption of want independence did not enter into the estimation of these price elasticities.

I am concerned about the use of time-series estimates to judge whether cross-sectional estimates are biased, as done by the author of the comment. There is, I believe, no reason to assume that the former, as a rule, is any closer to the truth than the latter. In a comparative analysis such as the one shown in the comment, this point deserves more than a footnote.

Finally, we acknowledge the error pointed out by the author of the comment with respect to the goal of grouping the commodities. The purpose is, of course, to reduce or eliminate want dependence among groups.

Per Pinstrup-Andersen is a research fellow at the International Food Policy Research Institute in Washington, D.C.

In our original article we attempted to develop and test a method for estimating nutritional effects of supply shifts and to illustrate the utility of the results for policy making in an area, where additional analytical work is urgently needed. If our analysis has contributed to an expansion of the work by others in that area, including the development of better methods or better data bases for estimating the relevant quantity-price relationships, our efforts were not wasted.

The Demand for Agricultural Research: A Colombian Illustration: Comment

Dana G. Dalrymple

> This is one of those cases where even to argue with a position is to compliment it—one grants it a hypothetical prior existence in order to criticize its "consequences". . . . Gary Wills (p. 125)

In a recent and otherwise fine note, Grant Scobie provides some curious suggestions on the motivation for investment in international agricultural research through the Consultative Group on International Agricultural Research (CGIAR). His comments were not derived from nor proven by his accompanying economic analysis, but rather are conjecture. Even so, they raise important policy issues.

The Scobie Proposals

Basically, Scobie suggests (p. 543) that the motivation for investment in the CGIAR has a domestic "economic rational." While "one should not infer that humanitarian motives are irrelevant," Scobie states that "the returns from that investment come, in part, from cheaper imports, increased export demand, and an enhanced environment for multinational business. . . . The potential benefits" to the donors' consumers "may not be an irrelevant consideration in voting public funds for agricultural research in the tropics." In this way, he notes, the evolving institutional mechanism may be viewed, in part, as serving the same ends as colonial and bilateral precursors "while presumably being more internally palatable."

While it might not seem unreasonable to suggest a combination of economic and humanitarian motives, the critical questions concern the nature and balance of each. With respect to nature, Scobie's proposed internal/domestic economic rational—which I shall refer to as SPIDER—may suggest a mild case of neocolonialism. He is less than precise with respect to balance: both SPIDER and humanitarian motives are posed as "not . . . irrelevant," which gives him a fair amount of room for dodging. Yet the former seems to be emphasized. If so, I would like to suggest the opposite for the 1970s: that humanitarian motives were dominant, while SPIDER was of minor, perhaps negligible, importance. Some less pernicious economic factors may be of increasing importance in the 1980s.

There are, however, methodological problems in resolving these differing perspectives. The subject deals with motivation, and it is difficult to convincingly prove or disprove purity or impurity of motive under the usual rules of evidence.[1] But since Scobie has presented one viewpoint, it may not be inappropriate for me to suggest another and indicate why I hold it. My views are based on an association with the major donor to the CGIAR since 1972—the U.S. Agency for International Development—and participation in CGIAR affairs since 1974. I turn to the past and then to the future.

The Past: The 1970s

The CGIAR was established in 1971 and first provided funding for calendar 1972. As Sir John Crawford, chairman of the Technical Advisory Committee of the CGIAR, put it in 1975 (cited, oddly, by Scobie as support for his rationale):

> The impetus for this action was the desire to encourage more research to assist developing nations increase the quantity and improve the quantity and quality of their agricultural output and thus to raise standards of living. All parties realized that increased agricultural productivity was essential to economic and social development in the great majority of these countries. (p. 281)

As the CGIAR system has evolved, increasing attention has been given to staple food products produced by poor farmers and eaten by poor consumers in the same country.

AID's motivation for support to the CGIAR, insofar as I have witnessed it, has been entirely humanitarian. I have never heard or seen SPIDER used, in whole or part, as a rationale for the pro-

Dana G. Dalrymple is an agricultural economist with the U.S. Department of Agriculture, on detail to the U.S. Agency for International Development, Washington, D.C.

The views expressed in this note are his own and are not necessarily those of his employers. The author received helpful suggestions from many colleagues—most of whom, he suspects, would rather stay anonymous.

[1] I recall one radio thriller of the 1940s, "The Shadow," which had as its prelude: "Who knows what evil lurks in the hearts of men? The Shadow knows . . . Chortle, chortle, chortle." Perhaps Scobie, even though a New Zealander who may never have heard of the Shadow, has inherited some of his occult powers.

gram. Nor have others in, or formerly in, the agency with whom I have discussed the issue.

But the agency is only part of the story; the source of funding, Congress, must also be considered. It is quite possible that Congress, or some members, may have given more attention to economic factors. But which ones? One which comes to mind has changed over to time. Prior to the late 1960s, agricultural development was not seen as a stimulus to agricultural exports from the United States: in fact, AID was constrained from providing assistance for commodities which were in surplus, such as wheat and rice (National Academy of Sciences). Since that time, it has been recognized gradually that agricultural development in other nations will lead to increased export demand for U.S. agricultural products.[2] This realization may have led to increased congressional support for AID's overall agricultural programs in recent years.

Two other aspects of SPIDER—cheaper imports and "an enhanced environment for multinational business"—played, I suggest, a negligible role. The CGIAR does not support work on the traditional export crops in the developing nations. If some of the basic crops are exported (Scobie notes the case of cassava for animal feed in developed nations), it is a by-product which is heavily influenced by domestic economic conditions and does not necessarily harm the exporting nation or benefit the donor (cassava has a highly inelastic domestic demand; exports from Colombia to the EEC are hardly of benefit to Canada). The effect of CGIAR-sponsored research on multinationals, which base themselves in many countries, is difficult to demonstrate, except as such firms may have been involved in exports of agricultural products and fertilizer from the United States. Whether this process led to significant congressional support for the overall AID agricultural program in the 1970s is most uncertain.

AID, in any case, provides only about 25% of the total CGIAR funding. What can be said of the other twenty-eight donors and 75% of the funding in 1979? Of these, fifteen were other national governments (one of which was a developing nation), four were foundations (counting IDRC of Canada), and nine were international or regional organizations. It is doubtful that the developing nation and the two latter groups—representing, in aggregate, 31% of the funding—had SPIDER as a motive. This leaves the other fourteen developed nations, who contributed 44% of the total funding. I have not seen any evidence to suggest that their motives are other than humanitarian.

The Future: The 1980s

What of the future? I expect to see more of the same motivation: principally humanitarian, with perhaps a growing place for one component of SPIDER—exports to developing nations. In addition, one relatively new factor may emerge.

As agricultural research, along with other factors, stimulates agricultural development, and in turn more general economic development, it may well lead to further imports of agricultural products by developing nations. (These may, however, be different products than those normally consumed and may have a higher price and income elasticity of demand.) The results of this growth process could be beneficial for both exporter and importer. In some cases, the exporter may be another developing nation.

There is another potential benefit which has been hitherto neglected: the potential benefit of the research done in the CGIAR system to the donor. Recently, I have been studying the extent to which the semidwarf wheat and rice varieties developed by CIMMYT and IRRI have been utilized in breeding and production programs in the United States (Dalrymple). There is a definite connection, and it could be expected to grow as the use of semidwarf varieties increases in this country. Obviously, this type of benefit largely will be limited to crops grown in the donor nation, but perhaps some of the research on other crops will have a spillover effect.

A key question is: to what degree concern with benefits dominates the actions of the donor and in turn leads to pressures on the type of research carried out? As long as the returns are a by-product of the systems and do not influence the course of research at the centers, they could be socially useful. If they come at the expense of the welfare of the developing nation, then it is quite a different matter.

Summary

Scobie suggests that both some rather selfish economic motives and perhaps some humanitarian motives may lie behind support for the CGIAR. He appears to rate the former more important than the latter. If this is a correct interpretation, I suggest a different balance. I propose that support through the 1970s was almost wholly based on humanitarian grounds. In the 1980s, however, certain economic motives may begin to play a greater role—but these motives differ and will be of a more benign nature than those suggested by Scobie. Return with us on judgment day in 1990!

The Demand for Agricultural Research: A Colombian Illustration: Reply

Grant M. Scobie

> In the United States . . . aid to developing countries has been continuously argued as being in "our country's best interest." (Gunnar Myrdal, Nobel Memorial Lecture, 1975)

My paper made some tentative explorations into the political economy of agricultural research in a developing country. Economists have devoted considerable effort to measuring the impact of technological change stemming from agricultural research. Yet, much less attention has been paid to understanding the forces that bring about public investment in research.

Most of that investment, even in the developing countries, comes from the national fisc. In examining the Colombian case, the major concern of my paper was to offer an explanation for both the level and changing sources of funding for rice research. However, perhaps in the interests of completeness, I included some parallel comments about the motivation for international investments in research. Here, on a relatively minor aspect of the paper, the editors granted me freer rein.

Dalrymple's concern is that I overstepped the bounds of scholarly rigor and offered only some speculation for why we continue to see the industrial nations investing public funds in agricultural research in the less developed countries (LDCs). He states that my comments were not "derived or proven . . . but rather are conjecture." He is correct, of course; and to the extent that conjecture is inadmissable I stand guilty as charged. I must further apologize for the parochial nature of my antipodean origins, alluded to by Dalrymple in his first footnote. My cultural upbringing was certainly not sufficiently rich to capture all the subtleties of his arachnoid analogy!

The central question which Dalrymple raises is whether economic self-interest is a relevant explanatory variable in understanding variations in the level of investment in agricultural research.[1] We both seem to agree that humanitarian motives are important; and despite Dalrymple's defense, the integrity of USAID was not in question. As he goes on to note, it is the source of funding, the Congress, where the interplay of economic and humanitarian interests are focused.

All I claimed was that economic motives may not be irrelevant. Dalrymple strengthens my speculation by citing the explicit congressional constraints placed on AID which, during the 1960s prohibited investment in commodities for which the United States had overproduced. A specific case concerned agricultural research stations in Peru, where no AID funds could be used to support cotton or tobacco research. I am certain that a diligent search of congressional materials would provide ample evidence of such "selfish economic motives."

There is a further test of the hypothesis which awaits only a willing graduate student. Suppose all aid were granted purely on humanitarian grounds. There would be no reason to suppose that the resulting pattern of dispersion of U.S. largesse necessarily would coincide with the self-interest of domestic consumer and producer groups. As a result, a set of potential rents (both positive and negative) would arise. Whenever the decisions of government generate rents (always?), we would expect both potential losers and gainers to expend real resources in endeavoring to modify the decisions—a perfectly rational consequence of a relatively unfettered democratic system.

Such selfish action (called lobbying) will, however, persist only if the expected net returns to the activity are positive. But this can be the case only if the lobbyists are at least partly successful. So that the mere existence of groups presenting evidence before congressional foreign aid hearings would constitute *prima facie* evidence that some economic motives creep in to be mixed with the national humanitarian conscience.[2]

But let me not compound the speculation further. Dalrymple has made an adequate case for the existence of some economic self-interest in the 1960s. Investment during the colonial era in tropical products research (to benefit temperate zone consumers and expatriate plantation owners) provides further historical weight to the argument.

Finally, he concludes that while the 1970s were the golden years of humanitarianism in U.S. foreign

Grant M. Scobie is an associate professor in the Department of Economics and Business, North Carolina State University, currently on leave as a research fellow in the trade program, International Food Policy Research Institute, Washington, D.C.

[1] Dalrymple draws support for his position by arguing the CGIAR has paid increasing attention to research in staple food products. While this may be true in absolute terms, the proportion of the CGIAR budget devoted to basic crop research fell throughout the 1970s as research on livestock production and diseases were funded.

[2] For an example of economic analysis of political (lobbying) markets, see Magee.

aid policy, some grubby bits of self-interest may be creeping into the 1980s. So two of the three decades he chose to present support the simple point: economic motives may not be irrelevant (with the possible exception of the 1970s).

Financial Impacts of Government Support Price Programs: Comment

Peter J. Barry

Michael Boehlje and Steven Griffin (BG) provide a timely, relevant analysis of the financial impacts of U.S. government price programs that is rigorous in its use of valuation concepts under risk, practical in its simulation approach, and clearly in the spirit of responding to needs for policy-related research. Their major objective is to evaluate how price support programs influence investment and financing behavior of agricultural producers with different financial characteristics and sizes of operation. They reason that indexed support prices will provide greater certainty in farmers' cash flows and thereby reduce financial risks, with more rapid farm growth resulting from increased bid prices for durable assets, especially land, increased debt capacity, and higher financial leverage.

Their simulation analyses for farms differing in size, capital structure, and farmer characteristics under selected parameter values indicate that smaller, more highly leveraged operations generally will receive fewer benefits from a cost-of-production-indexed price support program than will larger operations with lower financial leverage. As a result larger, higher-equity operations can bid higher prices for land and should show more rapid growth in net worth, land ownership, and standard of living. The authors conclude with a plea that future analyses more fully account for policy impacts on farms with different financial, economic, and producer characteristics.

My response to this kind of analyses is quite positive and I fully support BG's efforts. My comments here consist of two sets of concerns whose resolution should further clarify their analytical approach, strengthen the generality of their results, and perhaps provide for extended analysis. One set of concerns addresses the need for more information to understand fully the specifications and assumptions embodied in their simulation model. The second set, which is closely related to the first, considers how the initial estimates of bid prices for land might respond to changes in some of these model specifications and assumptions. While Boehlje and Griffin attribute much of their results to differences in farms' financial characteristics and debt-servicing capacity, I suspect that the interrelationships of those financial characteristics with the influences of several other factors are more important than their article implies. My approach is to identify these other factors, briefly discuss their implications, and then use an alternative valuation model to show some of their effects on initial bid prices for land.

The model assumptions, specifications, and other factors needing clarification and explanation are (*a*) the farmers' planning horizon, (*b*) the farmers' risk properties, (*c*) the derivation of capitalization rates, (*d*) income tax specifications, (*e*) financial constraints, (*f*) economies of size, (*g*) land indivisibility, and (*h*) leasing.

The valuation model specified by BG in equation (1) (p. 286) shows a perpetual income stream $E(R_t)$ which, in turn, implies an infinitely long valuation horizon. However, the characteristics ascribed by BG to their three farm situations, upon which numerical analysis is based, imply important differences in planning horizons. Surely the youthful operator of Farm A has a longer horizon than the "more typical" operator of Farm B, who in turn has a longer horizon than the "well-established" operator of Farm C. If so, then these differences may influence the structure of the valuation model as well as resulting bid prices and growth potential.

Information on risk properties that characterize the operators of the three farms also is difficult to identify. BG indicate that the "potential land purchasers are risk-averse." They include an undefined δ term as a determinant of cost of capital in equation (10) (p. 287) which presumably reflects the degree of risk aversion. However, no information is given about the level of risk aversion, how it differs among the three farmers, how it responds to changes in wealth during the simulation period, and how changes in these specifications might influence the results. Similarly, expectations held by the three farmers are assumed the same.

Additional information on these risk properties appears essential. As it stands now, one is led to conclude that there should be important differences in risk aversion, expectations, or both, among the three farmer types. Suppose, for example, that the beginning portfolio compositions of Farmers A, B, and C are optimal with respect to a decision criterion like expected utility maximization. Furthermore, the asset mixes and expectations of the three farms essentially are identical. They differ primarily in financial structure and in farm size. Then, the differences in financial structure largely should be attributed to differences in risk aversion. Spe-

Peter J. Barry is a professor of agricultural economics at the University of Illinois.

cifically, the lower leverage and therefore lower financial risk for Farmer C implies that he has higher risk aversion than Farmer B, who in turn has higher risk aversion than Farmer A. If risk aversion indeed does differ among the three farm situations, then the model should show this through differences in capitalization rates which may strongly influence resulting bid prices.

Procedures used to derive numerical estimates of the capitalization rate in equation (9) (p. 287) are not clear. BG indicate that their capitalization rate is related functionally to the values of several variables according to a specific form used by Lee and Rask. However, Lee and Rask assumed a specific capitalization rate based on opportunity costs of capital and used this rate together with cash flows determined by several other variables to estimate bid prices for land. Hence, the linkage between the Lee and Rask approach and BG's procedure is obscure.

Furthermore, it is not clear how BG derived the specific numerical values for their capitalization rates. First, the capitalization rate used for Farm C is higher than for Farm B which is higher than for Farm A. This pattern is consistent with differences in risk properties identified above, although the lack of any discussion of risk properties makes this explanation doubtful. Instead, the differences in capitalization rates may be due to differing income tax rates for the three farm situations.

A second concern is BG's specification that the capitalization rate is reduced by the expected rate of growth in land values. As shown in finance literature (e.g., Van Horne, p. 22), it is appropriate to value a perpetual income stream that is expected to grow at a constant rate (g) by capitalizing the first period's nominal income value at a rate that is reduced by the expected growth rate. However, there is no single growth rate in BG's analysis. In fact, five inflation rates apparently are used. Production costs inflate at a 6% annual rate, prices received at a 2% rate, net income per acre at a 3% rate, land prices at a 5% rate, and general prices at a 6% rate. In addition, crop yields increase at a 1% annual rate. Given this complex of rates, what basis is there for reducing the capitalization rate by the expected rate of growth in land value, especially since this growth rate only indirectly affects growth in annual income through the indexed price support mechanism?

Procedures used to account for the effects of income tax obligations in the valuation model also are obscure and ambiguous. It is difficult to tell whether the analysis occurs on a before-tax or after-tax basis. The authors indicate that the capitalization rate [equation (9), p. 287] is functionallly related to the marginal tax rate, although it is not clear how tax obligations are expressed in its calculations. The text (p. 289) also indicates that expected annual income is measured on an after-tax basis; however, calculation procedures illustrated in table 2 (p. 291) do not show the deduction of income taxes from annual income, only the deduction of land taxes. Perhaps this specification of the valuation model means that accounting for income taxes in the income flow and in the capitalization rate have offsetting effects, leaving bid prices the same on a before-tax or after-tax basis.

The authors' specifications of financial constraints in equations (12) and (13) (p. 287) for the three farms appear consistent with those used in rural financial markets by commercial banks, production credit associations, and federal land banks. However, these specifications allow potential levels of debt use that are inconsistent with each farm's initial financial structure and implied risk properties. Farmer C, for example, has a financial structure with much less leverage and financial risk than Farmer A. Now, however, C is allowed to outbid A for land primarily on the basis of his operation's greater debt capacity. But, will he indeed do so if his aversion to risk and preference for liquidity exceed those of A?

Economies of size and the forty-acre indivisibility assumption are model specifications that significantly affect numerical results. However, they are treated quite lightly in the analysis. For size economies, is it reasonable to assume that the differences in economies continue to hold as the three farm types grow over time? Or, does narrowing of differences enhance the bidding potential of small operations for land as growth occurs?

The forty-acre lower bound on incremental land acquisition most heavily affects smaller operations like Farm A. Forty acres may be a realistic lower bound, although greater flexibility in sizing of land tracts appears to be occurring in order to make land acquisition more feasible for more purchasers. Varying the indivisibility specification might be useful in further analysis.

Finally, the analysis could be extended to account for the effects of price support programs on leasing assets. Leasing is an especially important resource control method for farm land due to high land values and farmers' limited financing capacity. Analogous to the author's present approach, one could estimate maximum rents that could be bid for land under various assumptions on farm size, capital structure, behavioral and other operator characteristics, and price support provisions.

BG's results can not be reproduced exactly here due to the complexity of the simulation model and its lack of availability. Hence the following analysis formulates an alternative valuation model in order to illustrate the effects of variations in several model specifications and parameter values on the initial bid price for the three farm types.

The model is formulated as

$$NPV = -INV_{dp} + \sum_{n=1}^{N} \frac{P_1 (1+g)^n (1-t)}{(1+i)^n} - \sum_{n=1}^{N} \frac{F_{nt}}{(1+i)^n} + \frac{V_N - T_N - D_N}{(1+i)^n},$$

Table 1. Parameter Values

	Farm A	Farm B	Farm C
Planning horizon (n)	30 years	20 years	10 years
Initial annual income (P_1)	\$56.68	\$66.18	\$100.75
Growth in annual income (g)	3%	3%	3%
Initial land value (INV)	\$1,770	\$1,770	\$1,770
Growth in land value (a)	5%	5%	5%
Marginal tax rate (t)	22%	32%	50%
Discount rate ($i = .0544 + \delta\ \sigma^2$)	10%	12%	14%
Discount rate after taxes	7.80%	8.16%	7.00%
Risk aversion (δ)	1.0741	1.5905	2.1069
Down payment ($INV.20$)	\$354	\$354	\$354
Mortgage interest rate	9%	9%	9%
Loan length	30 years	30 years	30 years

where NPV is net present value, INV_{dp} is the down payment requirement for land price INV, g is the annual growth rate of net income, t is the marginal tax rate, and F_{nt} is the annual debt amortization commitment adjusted for any tax savings associated with the interest portion. Variable V_N is the land's value at the end of the planning horizon. It is defined as $V_N = INV(1 + a)^N$ where a is the annual rate of increase in land value. Variable T_N is any tax obligation on capital gains and D is debt outstanding at the end of year N. Variable i is the discount rate defined as $i = (i_f + \delta\sigma^2)\ (1-t)$, where i_f is a risk-free rate, σ^2 is the variance of income, and δ is a risk coefficient.

Initial parameter values are shown in table 1. Marginal tax rates, levels and growth rates of annual income, and land appreciation are the same as in BG. Different lengths of planning horizon reflect the farm characteristics discussed earlier. Financing terms for land include a 20% down payment with the balance repaid in equally amortized annual payments over thirty years at 9% interest. Levels of risk aversion are selected arbitrarily to yield before-tax discount rates of 10% for Farm A, 12% for Farm B, and 14% for Farm C. On an after-tax basis, these rates are 7.80%, 8.16%, and 7.00% respectively.

Initial bid prices shown in table 2 are calculated as the land's asking price (\$1,770) plus or minus the $NPVs$ derived with the valuation model. Results are shown first for equal planning horizons and then for different horizons. In each case, $NPVs$ are derived without either debt financing or income taxes, and then with these specifications included. The top row of table 2 indicates bid prices without either debt financing or income taxes, and with a ten-year horizon for each farm. Farm A exhibits the highest bid price, followed by C, and then B. Moving down the table shows the important effects which taxes, financing, planning horizon, risk premiums, and their interrelationships have on ranking and level of investment profitability. Substitution of lower cost debt for higher cost equity increases the profitability of the land investment for each farm, although favoring the larger operations whose size economies provide for larger annual incomes. Moreover, on an after-tax-basis debt financing favors farms (e.g., Farm C) with higher tax rates due to higher tax savings arising from payments of tax-deductible interest.

Lengthening the planning horizon to thirty years for Farm A and twenty years for Farm B increases the present values of the annual income flow due to the added years of discounted income. However, longer horizons also reduce the present value of the land's terminal market value because the discount rate exceeds the annual rate of increase in land value. The net effect here is that the reduction in

Table 2. Initial Bid Prices for Land

	Farm A	Farm B	Farm C
10-year horizon			
No debt or taxes	\$1,499.11[a]	\$1,345.44	\$1,361.59
No taxes	1,583.53	1,577.59	1,719.27
No debt	1,899.77	1,588.02	1,751.47
Taxes and debt included	1,712.08	1,773.87	1,991.06
Different planning horizons	30 years	20 years	10 years
No debt or taxes	1,132.29	1,083.91	1,361.59
No taxes	1,248.98	1,378.72	1,719.27
No debt	1,407.49	1,444.23	1,751.51
Taxes and debt included	1,523.50	1,700.97	1,991.06

[a] Initial bid prices are calculated as the land's asking price INV = \$1,770, plus or minus the net present values derived with the valuation model.

present values of terminal market value outweighs the increases in present value from annual net income, thereby reducing the bid prices for land as the planning horizon lengthens.

The resulting order and magnitude of bid prices in the bottom row are about the same as the initial bid prices found by BG (table 2, p. 291). Moreover, the higher risk premiums for Farms B and C do not change the ordering of bid prices, although they do reduce the differences in bid prices that would occur if each farm had the same level of risk aversion. Further calculations show that the before-tax discount rates for Farms B and C would have to be about 15.2% and 44.5%, respectively, in order to yield the same bid prices as Farm A ($1,523.50) in the bottom row of table 2.

In concluding, my major points are that further explanation on model specifications and assumptions should clarify BG's analytical approach, and that the causal factors explaining why larger, higher equity operations tend to be favored by indexed price support programs may be broader than their analysis indicates. The alternative valuation model used here is much less detailed than BG's, and still fails to consider factors such as indivisibility, renting, and changes in size economies; however, it yields results that appear substantive enough to warrant further analysis with their model. Planning horizons, tax obligations, debt financing, size economies, and risk-liquidity properties all play important, interrelated roles. And, hard as they are to measure, we still do not know enough about farmer's risk and liquidity preferences, and how they respond to changes in business and personal characteristics. Nonetheless, they too need consideration in policy analyses like this one.

Financial Impacts of Government Support Price Programs: Reply

Steven Griffin and Michael Boehlje

Peter Barry has provided an insightful and constructive comment on our evaluation of the financial impacts of government price support programs. He raises several issues which require further clarification and explanation.

Planning Horizon

Our assumptions concerning the planning horizons of the representative farms were not made clear in the original article. Barry, however, did surmise correctly that the three farm situations imply important differences in planning horizons. The "youthful" operator of Farm A was assumed to have a longer planning horizon (thirty years) than the "more typical" operator of Farm B (twenty-five years), who in turn was assumed to have a longer horizon than the "well-established" operator of Farm C (twenty years). These parameters were inadvertently left out of table 1 (Boehlje and Griffin, p. 290).

As Barry states, "longer horizons increase the present values of the annual flow of net income from the land due to the additional years of income to be discounted." However, longer horizons reduce the present value of the land's terminal market value if the discount rate exceeds the assumed rate of increase in land value. Additional analyses with the simulation model indicate that if Farms B and C were assumed to have the same planning horizon as Farm A (thirty years) and other parameter settings remain unchanged, the maximum bid prices for land are slightly smaller than the original estimates. In year 1, for example, Farm B's maximum bid price with a thirty-year planning horizon is \$1,593 compared to \$1,638 with a twenty-five-year horizon; Farm C's maximum bid with a thirty-year horizon is \$1,938 compared to \$1,955 with a twenty-year horizon. Because the small farm's maximum bid price is now closer to that of the larger operator, its growth potential would be expected to be enhanced. However, simulation results indicate the converse is true. With longer planning horizons, and lower bid prices for land, the larger and/or high equity farms acquire acres even faster while the smaller, low equity farm still does not have sufficient cash flow to implement a purchase.

Related to the planning horizon is the amortization period of the loan. The Lee and Rask formulation of the capitalization model used in our study constrains the amortization period of the loan to less than or equal to the planning horizon (Lee and Rask, p. 986). Consequently, we did not analyze situations, such as Barry presents (in his table 1), where the planning horizon is significantly shorter than the loan length.

Risk Properties

The risk parameter (δ) is calibrated by the following equation

$$(1) \qquad \delta = (W_2 - CC_o)\ \sigma_{p_o}{}^2,$$

where W_2 is the maximum allowable opportunity cost of capital (after taxes), CC_o is the after-tax opportunity cost of capital in the base period, and $\sigma_{p_o}{}^2$ is the price variance in the base period. CC_o was assumed to be 8%, W_2 was set at 10% (table 1), $\sigma_{p_o}{}^2$ was calculated at $(.1968)^2$ (see figure 2, panel 3 of the original article), and therefore δ was equal to .000746 for all farm situations. Note that relative risk aversion does not respond to increases in wealth and that price risk (on a per acre basis) is the only source of risk (i.e., there is no production risk or price risk on inputs).

We also would note that differences in financial structure between farms may not necessarily represent relative aversion to risk. The financial structure of a firm at any point in time may be as much (or more) a function of the initial endowment or the number of years the firm has been in existence as risk aversion. Also there are a number of ways to handle risk, such as diversification and use of various marketing strategies in addition to leverage and portfolio adjustments; so differences in financial structure need not imply differences in risk aversion.

The Capitalization Rate

We assumed the value of an asset, V_t, is equal to the expected income stream $[E(R_t)]$ capitalized by the appropriate rate (k_t) (Boehlje and Griffin, p. 286).

Steven Griffin is an assistant professor, Department of Agricultural Economics, Texas A&M University; Michael Boehlje is a professor in the Department of Economics, Iowa State University.
Tech. Art. TA15800, Prg. 6346, Texas Agr. Exp. Sta.; Jrnl. Pap. 9927, Proj. 2066, Iowa Agr. & Home Econ. Exp. Sta.

Thus, the implicit capitalization rate can be determined as

$$K_t = \frac{E(R_t)}{V_t}. \tag{2}$$

By means of the capitalization formula suggested by Lee and Rask (p. 986), the V_t of equation (2) above can be calculated. Eleven variables or parameters are required to solve the Lee-Rask model for the maximum bid price, V_t (P^* in Lee-Rask notation). These include $\bar{P}$, the average price per acre from recent sales of comparable parcels; CC, the buyer's opportunity cost of capital after taxes [Boehlje and Griffin, equation (10), p. 287]; m, the buyer's planning horizon in years; ANI, the expected annual net return per acre before taxes; GNI, the expected annual rate of growth in annual net returns per acre; MTR, the buyer's marginal income tax rate; DP, the proportion of the purchase price paid down; n, the nominal rate of interest charged on the mortgage loan; t, the amortization period on the loan; GLV, the expected annual rate of inflation in land values; and finally, T^*, the tax rate that will apply to the capital gains income realized at the end of the planning horizon. For simulation purposes, $\bar{P}$ was assumed to be the previous year's "market" price for land, n was equal to t, and T^* was equal to one-half the marginal tax rate.

Therefore, we can determine the implicit capitalization rate, k_t by equation (2) above since $E(R_t)$ is the variable ANI just defined. Differences in capitalization rates between the farm situations simulated result primarily from differing marginal tax rates, amortization periods, and planning horizons.

The Lee-Rask formula treats capital gains in farm land values in the conventional manner (i.e., computing the present value of the capital gains after taxes when the property is sold or at the end of the planning horizon). Therefore the capitalization rate does not reflect any value of unrealized capital gains (Plaxico and Kletke). Unrealized capital gains do however facilitate the implementation of a purchase since such land value increases add to the wealth (equity) of the owner and reduce the degree to which equity is leveraged.

Barry also questions the basis for "reducing the capitalization rate by the expected growth rate in the value of land." The adjustment for the "expected annual rate of inflation in land values" is included explicitly in the Lee-Rask formulation of the capitalization model (Lee and Rask, p. 986). This parameter was defined as GLV in our analysis and specified at 5%. Our description of this adjustment may have been confusing. In footnote 6, we were merely reminding the reader how a capitalization rate can be less than the lowest possible (risk-free) discount rate of the buyer. We did not intend to imply that the capitalization rate derived from the Lee-Rask model was (once again) reduced by the expected growth in the value of land.

A further issue is whether or not one should allow the farm operators to adjust their expectations (especially with regard to land price inflation) to the growth rates experienced during the simulation. We did not include such adjustments. If farmers are assumed to "learn the game," especially the manner in which the support program validates any land price increases, the time path of land values is particularly explosive (Harris). It would be unreasonable to expect that farm policy makers would allow such an explosive mechanism to track very far into the future.

Income Tax

As suggested by the Lee-Rask formulation of the capitalization model, all calculations are on an after-tax basis. In table 2 of the original article, these adjustments already have been accounted for in determining the implicit capitalization rate. Contrary to Barry's comment, Lee and Rask found the maximum bid price for land to be "relatively insensitive to changes in the marginal tax rate" (Lee and Rask, p. 987).

Income tax rates also have an effect on the optimum amount of leverage which should be employed. If the opportunity cost of capital is less than the after-tax rate of interest, the highest maximum bid price would occur with a 100% downpayment. In our simulation analysis with the base opportunity cost of capital assumed to be at 8% and mortgage money available at 8.75%, the marginal tax rate would have to be less than 9.14% before high down payment financing would yield higher maximum bid prices.

Financial Constraints

Our analyses assumed that farmers are constrained financially by their lenders (i.e., no internal capital rationing is assumed). As Barry agrees, the constraints incorporated in the model are consistent with those used by lenders in rural financial markets.

We would caution that determination of an asset's "worth" is not synonymous with the feasibility of its purchase; consequently, our analyses separated the determination of the bid price from the process of implementing and financing a purchase. The point to be emphasized (which is not part of Barry's model or analysis) is that the financial feasibility (i.e., the ability to obtain the downpayment and service the annual debt obligations) of a purchase must be evaluated separately from the determination of an asset's value.

Economies of Size

In our analyses, the smaller farms are assumed to move down the long-run average cost curve as they

grow larger. Therefore, the smaller farm which grows over time to 640 acres reaps the economies of size which benefited the 640-acre larger farm initially. Inflation over time does shift the long-run average cost curve vertically.

The Minimum Incremental Land Purchase

In the original analysis, purchases of land could be made at the "national average" price if the farm could meet the down payment, cash flow, and financial ratio requirements for a minimum size parcel of 40 acres. While we agree with Barry that a minimum size of 40 acres has a more serious impact on small or low-resource farms, a similar plight affects them in reality. Subsequent analyses assuming a minimum tract size of 20 acres did enable the smaller, low equity farm (Farm A) to expand from 160 to 253 acres compared to no expansion in the original analysis, but this expansion occurred primarily during the last five years of the planning horizon. Furthermore the 20-acre minimum enhanced the growth rate in acreage and net worth of the two larger farms as well, although the change was not as large percentage-wise as with the smaller farm.

Leasing

Extending our analysis to include leasing as an alternative method of resource control would indeed be interesting. Leasing does provide the small landowner-operator the means to gain economies of size without the outlays and financial requirements of outright land purchase. However, one would expect that financial differences (leverage, taxes, etc.) among farms would be reflected in their maximum bid prices for annual leases in a similar fashion as occurs in the maximum bid price for land purchases. Competition among farmers for leased land could be expected to drive rental rates up to the point where zero net returns to leasing occur for the most efficient leasee. Thus, the primary economic benefit of leasing for the small landowner would be the extra residual income from his owned land due to his lower average cost of production with the larger total acreage.

In summary, we appreciate Barry's review and constructive comments. His questions have enabled us to clarify our analysis procedures, and he has encouraged us to examine in more detail the causal forces underlying our empirical results and conclusions. This reexamination based on additional numerical analyses corroborates our original results and lends further strength to our conclusions.

Cattle As a Store of Wealth in Swaziland: Comment

Lovell S. Jarvis

In a recent article in the *Journal*, Doran, Low, and Kemp (DLK) argue that Swazi herders hold cattle as a store of wealth apart from their productive value. In Swaziland, "insofar as cattle are regarded as an end in themselves, they cannot be likened to conventional disposable productive assets which are held as long as their capital value in production exceeds their current market value" (DLK, p. 42). DLK believe that the store-of-wealth motive induces herders to maintain individual animals beyond the age of optimum slaughter (for beef purposes) and to increase the herd beyond the size which would maximize beef production. In support of this hypothesis, DLK draw on a variety of beef industry statistics.

DLK then argue that a failure to consider the store-of-wealth motive has led to the implementation of counterproductive livestock development programs in Swaziland in recent years. They believe these programs have exacerbated, rather than alleviated, the overgrazing problem, inducing an increase in the national herd greater than the increase in forage. They propose that measures be implemented to induce stockholders to sell more cattle or, if necessary, to enforce control of cattle numbers below the current level.

I believe DLK misunderstand the link between beef production and the use of cattle as a store of wealth and exaggerate the depressing effect of the latter on the former. The principal production problem in Swaziland, overwhelmingly so, would seem to be the communal grazing system used by Swazi herders. This factor by itself is capable of explaining the overgrazing, advanced age of slaughter, and the other herd characteristics cited in their article as being evidence of the store-of-wealth motive. If a choice has to be made as to which of the two factors is the most damaging to beef production, the theoretical and the empirical evidence appear strongly in favor of communal grazing.

Accordingly, I feel DLK have not presented convincing evidence that the livestock development programs enacted in Swaziland have been counterproductive. They will not solve the communal range problem, which requires decisions currently politically unpalatable, but the development programs being implemented appear to be attractive second-best alternatives. Beef production has grown rapidly in recent years in spite of the communal range problem, probably because of these development programs, and the latter may gradually help induce Swazi herders to convert public ranges to a system of private control.

The Store of Wealth

DLK provide no precise theoretical definition of the term store of wealth, nor a framework within which its impact on resource allocation can be rigorously analyzed. Their concept of the store-of-wealth function is broad, however, apparently including both the benefits received from cattle used as a money substitute (whether in trade or for asset accumulation), and also those received directly from ownership, such as security and prestige. DLK believe that Swazi herders maintain animals largely for these benefits and hold that Swazi herders are little motivated by market incentives.

Nonetheless, considerable evidence is given in DLK's article that Swazi producers are commercially oriented. I will comment later on this evidence. I believe that cattle serve as a store of wealth in Swaziland precisely because they are widely perceived to be productive assets. Their exchange value, determined chiefly by their use as a source of milk, beef, and hides, and as draft animals, is established in orderly markets. Cattle have value because of their ability to convert forage into useful products, and wealth can be invested in cattle with the likelihood of increase, not just preservation. The wide appreciation of their value, and their relative ease of transport (on foot), means that cattle can be liquidated easily. Owners of cattle derive security from the exchange value of their animals, and may obtain status and prestige among other persons because of this economic wealth. However, owners will find it profitable to prolong the life of an individual animal only so long as its daily production (including future beef) exceeds its current value as beef and hide. Individual animals cannot be kept beyond some specific age except at an economic loss.

While cattle can produce store-of-wealth benefits of the type suggested by DLK, these benefits will be joint products with beef.[1] The production of both

Lovell S. Jarvis is a lecturer in the Department of Economics, University of California, Berkeley.

The author would like to thank especially DLK for data they graciously provided him, an anonymous referee, and also John Lipsky and Joseph Ramos for helpful comments.

[1] While Swazi herders also maintain cattle for their milk and for draft purposes, I will refer exclusively to beef as the commercial product sought in the rest of this paper. Inclusion of the other products complicates the model without changing any important results in the current context. These other products should be remembered when designing agricultural policy, nonetheless.

store-of-wealth benefits, and also beef, will induce producers to accept a rate of return on the capital invested in cattle lower than it would be if beef were the only product. The allocational impact of the store-of-wealth function is then comparable to a reduction in the interest rate. As is shown later, the magnitude of this impact in Swaziland is surely small.

Evidence on the Beef Production Motive in Swaziland

What evidence contained in the article by DLK supports the hypothesis that Swazi herders produce animals for commercial ends?

First, DLK indicate that cattle prices in Swaziland are determined by those in South Africa, which is the major export market for Swazi cattle. DLK actually use South African prices as a proxy for Swaziland prices in their empirical work. Swazi herders have access to a viable commercial beef market whose magnitude, in both physical and value terms, has grown significantly during the last two decades. The prices quoted by DLK indicate that cattle have substantial value when slaughtered. It is a simple, but strong, argument that producers in this situation will be aware that wealth can be optimally accumulated by selling older animals when they have reached the economically defined age of slaughter, reinvesting in younger animals.

Second, individual Swazi citizens are said to have the opportunity to earn cash, including South African Rands, through various means—cattle, cotton, and tobacco production and wage employment in South African mines. Their pursuit of these activities indicates an interest in obtaining cash which, as a monetary asset, seems widely demanded and accepted. Cattle are another asset which may satisfy exchange and accumulation needs, but would have significant disadvantages vis-à-vis cash, save that they increase in value as they grow.

Third, the offtake rate from the cattle herd is estimated to average about 9%, but DLK mention additional growth in the herd of about 3% per year over the period studied. These data suggest an extraction rate of about 12% per year. This may be compared with the extraction rates in Uruguay and in Brazil, two other countries in which commercial cattle ranching with land-extensive technology is important, and with that on European-owned ranches in Swaziland. In the period 1950–60, previous to the introduction of improved pastures, the extraction rate in Uruguay averaged about 16% (Perez and Secco). In Brazil in 1970, the extraction rate was 15% (Lattimore and Schuh). Within Swaziland itself the extraction rate from European-owned herds, said to be efficiently operated on freehold land, is estimated at 14% (IBRD). The extraction rate from the Swazi herd is lower, as one would expect given the sector's lower development and its communal ranges, but it is still significant. Swazi producers appear concerned with the sales aspect of their cattle enterprise.

Fourth, DLK indicate that government-owned and managed ranches have been established in recent years to fatten Swazi cattle prior to slaughter. The average slaughter value of animals finished on these ranches, when compared with that of animals finished on a Swazi grazing area, is US $50 higher. An increasing number of Swazi cattle have been directed to these ranches since their establishment, indicating a desire by individual herders to obtain greater output and income.

Fifth, DLK empirically confirm a negative short-run price response of cattle slaughter in Swaziland. Jarvis (1974) has shown that this is the expected result where cattle producers are attempting to increase beef output in response to a beef price increase, i.e., where cattle production is essentially commercial. DLK instead argue that this result occurs because producers are not interested primarily in the beef production potential of cattle. They state that producers sell animals only "to meet specific cash needs (so that) the minimum number will be sold. Factors that increase the market value of cattle will enable the owner to meet his cash needs by selling fewer animals" (DLK, p. 42). I will show later that the empirical evidence contained in DLK does not support their hypothesis, while it does support that of Jarvis. Accordingly, I feel the negative price response is additional evidence of commercial interest on the part of Swazi herders.

The Relative Impact of the Store of Wealth and of Communal Ranges on Production of Efficiency

Assuming that cattle are held principally for income production, but also may provide benefits as a store of wealth, I now examine the impact of the latter factor on beef production. Simultaneously, I can analyze the allocational problems associated with the use of communal (as opposed to private) range lands in Swaziland. I then compare the two effects.

The discussion which follows is based on the argument presented in Jarvis (1974). Under conditions of private range ownership, perfect competition in product and factor markets, and producer efforts to maximize income, the unit price of beef, P; the cost of inputs required by the animal, including feed, C; and the interest rate, r, will be determined endogenously to the livestock sector (or the economy as a whole). However, individual producers must take these values as given, from which they determine the optimum stream of inputs, $\hat{I}$, to be provided to animals, and the optimum age of slaughter, $\hat{\theta}$. Given the resources available, including land, individual efforts will optimize the value of sectoral output.

Change in the parameters P, C, and r, brought about by exogenous events, will affect producers' decisions regarding $\hat{I}$ and $\hat{\theta}$ in a predictable fashion. In particular, an increase in beef price, or a de-

crease in feed cost or in the rate of interest, will cause a short-run reduction in slaughter. Heuristically, the negative short-run price response is explained as follows. A price increase leads producers to expand production. Production is composed of both slaughter and the change in herd size. To increase future slaughter, current slaughter is reduced; steers will be fattened to heavier weights and additional females will be retained for the breeding herd. In the longer run, slaughter will increase.

Given this framework, the impact of the demand for animals as a store of wealth on beef production can be shown to be small. If individuals are willing to receive part of their return from investments in livestock in the form of services, the average return to cattle investments, as measured by their slaughter receipts, will be forced lower in a competitive market. The impact is similar to that caused by a reduction in the interest rate, r, which will extend the optimum age of slaughter and reduce the optimum feed input. However, the store-of-wealth effect does not introduce a market distortion. To the extent that it exists, producers choose to substitute one benefit for another and no welfare loss is implied. Further, the store-of-wealth effect will have no severe impact on beef production because it affects the feed-beef conversion process only at the margin. Only a small proportion of the herd is affected directly. As the total forage available is not affected by the decision to slaughter animals at an older age, an increase in the number of older steers will cause the opportunity cost of feed to rise temporarily. This rise will induce a slight reduction in the rest of the herd, so that the net increase in the equilibrium herd as the result of the lower r is small. Moreover, the optimal feed input to each animal will be only slightly smaller than that when the discount rate was higher, so that most animals in the herd will continue to convert feed to beef at approximately the same rate as when the store of wealth effect did not exist.

The beef production decline caused by the store of wealth effect is determined by the differential growth of those older animals which would not have been included in the herd previously, versus that of the younger animals who are no longer maintained. The younger animals which are displaced will have an age distribution approximately equal to that of the herd in its original situation, i.e., some will have been nearly as old as the older steers retained. This moderates the effect even more. As an illustrative example, if the slaughter age of steers were extended from four to five years by a reduction in the discount rate from 8% to 4%, a rough calculation indicates that total beef production would decline by about 6%. I believe this figure significantly overstates the decline which may be expected in practice from the store-of-wealth effect.

Consider now the impact of communal ranges. The use of communal range lands in Swaziland alters the economic system so that several of the results which would occur with private range lands suffer important changes. With communal ranching, the cost of feed to the individual herder is zero. As there are few other inputs of economic importance, the cost of the input stream as a whole falls greatly. However, while the individual herder can add animals to the national herd at will, he has no control over the amount fed his animals.[2] The total feed available is given and must be shared equally among the animals in the herd, whatever their number. The result is an increase in the size of the herd, and a decrease in total beef production, as is explained in the following analysis.

Assume an initial situation with private range management in which the cost of feed represents its marginal productivity, with the livestock herd in respective equilibrium. Then, because of the implementation of a communal range instead of private lands, feed costs are reduced sharply for all herders. Assuming no change in the demand for beef, further investments in cattle will be privately attractive, the profitability of breeding calves having increased dramatically. The number of animals in the herd will increase. However, because the total forage available is fixed, efforts to increase the number of animals will lead to a decline in the feed available per animal. This is a situation of overgrazing, relative to private management, which will result in lower total output.[3]

The "simultaneous" reduction in the cost, and in the quantity, of feed will extend significantly the optimal age of slaughter. Under a private range system, $\hat{\theta}$ occurs where

$$\frac{(\dot{P w})}{P w} = r + \frac{C i}{P w}, \tag{1}$$

where w is the animal's weight.

Under a communal range system, however, where feed costs are zero, the growth of the animal's value during the year must cover only the interest rate. If the price of beef is not strongly dependent on age, the animal's value depends on its weight. Then, with a real interest rate of, say 8%, herders will find it profitable to hold an animal until its weight gain has slowed to this rate, which will occur close to physical maturity. Communal ranching also will lower the feed rations available individual animals, reducing their rate of growth throughout their lives

[2] The situation in Swaziland is thus described: "Rights to the use of communal resources, such as pasture land, woodland and water, are held communally and not exclusively. An individual is not confined to any particular area—for example, all Swazis are theoretically permitted to use grazing land anywhere in the country; in practice, each individual restricts his activities to areas accessible to the homestead. After harvest, plowed land with standing crop residues reverts back to communal use and the community grazes stock without hindrance" (IBRD).

[3] Overgrazing will decrease pasture quality through time, resulting in less total forage availability, not only less per animal. I ignore this problem in the discussion, though it is an issue of great importance.

and further extending their optimal age of slaughter.[4]

The only resource controlled by the individual herder in a system of communal ranges is the capital invested in the cattle he owns, whose return he seeks to maximize. His principal decisions concern whether to purchase animals or to sell, which affect the slaughter of mature animals and the production of calves. When aggregated across all herders, such decisions determine total herd size. The livestock sector is in equilibrium when the feed resources available each animal, given the price of beef, permit the internal return earned on the capital invested in animals to equal the market rate of interest.[5] In equilibrium, however, the competitive efforts of individual herders to extract value from the common range will have led to its overexploitation. The economic rent of rangelands will be totally dissipated and the value of production (assuming a perfectly elastic demand) will be reduced by this amount. This situation is akin to that which has been analyzed for fisheries (Gordon).

Because the commons problems induces a serious market distortion, a real welfare loss is involved and the beef production decline is much larger than that caused by the store-of-wealth effect. Without detailed information on the productivity of the range lands under proper control, it is impossible to estimate the beef decline precisely. However, judging from the relative values of land and cattle stocks in other countries having extensive range systems, the production loss could equal one-third.

Within the context of communal ranges, the marginal conditions yield a negative short-run slaughter response to price changes, as was the case under private range management. An increase in beef price will make cattle herding more profitable, inducing an increase in herd size. However, the net effect will be small. Contrary to the case of private range management, without collective action no increase in total feed resources will occur in response to a higher price. Any increase in herd size therefore will reduce further the average feed ration, resulting in yet lower herd technical efficiency. Therefore, although an increase in price will result in an increased value of total output, it will be small, and the quantum of marketed beef could actually decline.

Other effects of communal ranching may be mentioned briefly. The composition of the herd will reflect the low technical efficiency achieved; there will be a high proportion of cows because the weaning rate is low, and there will be a higher proportion of older steers because their slaughter age is advanced. Herd offtake will be low because only a low proportion of steers and cows will be slaughtered. Nearly all heifers will be required for replacement, so that a herd buildup, when desired, can be achieved only gradually. A significant proportion of the short-run response to prices is likely to be of the speculative type, with herders deciding to sell mature steers or withhold them for another year on the basis of future price expectations.

Climatic conditions and the use of unimproved pastures in Swaziland are likely to exacerbate the situation described above. These factors should cause a high seasonal variation in forage available per animal, which again is given to the individual herder. Animals will gain weight in a rachet-like manner; a significant proportion of what is gained in seasons of abundance will be lost in seasons of scarcity. An animal will require several years to reach adequate size, after which the producer will consider slaughter whenever there is sufficient forage for fattening. If forage is abundant in a particular year so that weight gain for large steers is good, producers will retain such animals longer than usual because their rate of growth will also have increased. When this period is ended, the animal will be sold.

DLK cite evidence of production inefficiency in Swaziland, attributing this to the store-of-wealth motive. Instead, I would attribute most of this inefficiency to the system of communal ranges. Consider the specific points mentioned by DLK.

First, DLK argue that Swazi cattle are sold at an older age than would occur if herders were interested in maximizing income. Detailed data are not presented, but they indicate that Swazi cattle are not sold until they have reached at least three years of age and that most cattle are marketed in excess of five years of age. However, for DLK to use the age of slaughter as support for the store-of-wealth hypothesis, they must show that it is not only high, but greater than the profit-maximizing age, given the conditions faced by individual Swazi herders including extensive grazing practices, unimproved pastures, and communal ranges. The latter factors have such important effects that there appears to be room for little impact from the store-of-wealth motive. For example, the reported slaughter ages are not so markedly different from those reported in Brazil and Uruguay, two countries which also use extensive grazing practices and which still have many unimproved pastures. In Brazil, as of 1970, steers were slaughtered between four and four and one-half years of age (Lattimore and Schuh). In Uruguay, two-thirds of the steers and 95% of the cows slaughtered exceeded three and one-half years of age in 1972–75 (Perez and Secco). A significant proportion of steers in Uruguay, those raised on poorer pastures in the north, are about five years old at slaughter. With otherwise equal conditions, but communal ranges, the slaughter ages in each of these countries would be extended.

Furthermore, the Swazi herd does not contain

[4] The lower feed ration also will lead to a higher age of first service for heifers, lower fertility rates for breeding animals, and higher mortality rates for the herd as a whole, relative to a system of private range management.

[5] I ignore the question whether, due to an absence of capital markets, there is a single market rate of interest.

Table 1. Swaziland Cattle Herd Composition—1975

Age	Swazi Owned		Non-Swazi Owned		Total
		(%)		(%)	
0–1 year males	31,387	7.4	8,590	9.8	39,997
0–1 year females	29,952	7.1	8,961	10.3	38,913
1–2 year males	31,837	7.5	8,111	9.3	39,984
1–2 year females	32,863	7.8	7,748	8.9	40,611
2–3 year males	44,936	10.6	6,943	8.0	51,879
2–3 year females	53,811	12.7	8,094	9.3	61,905
Cows	180,461	42.6	36,474	41.8	216,935
Bulls	18,074	4.3	2,372	2.7	20,446
Subtotal	423,321	100.0	87,293	100.0	510,614
Oxen	102,843		8,264		111,107
Total	526,164		95,557		621,721

Source: Ministry of Agriculture

such an unusually high percentage of older steers. Table 1 shows that male cattle two to three years old comprise 10.6% of the herd (oxen are excluded in making this calculation). The corresponding figure for the non-Swazi herd is 8.0%. The number of two- to three-year old males in the Swazi herd exceeds the number of one- to two-year-old males by 40%, suggesting that steers over three years are lumped into the two- to three-year category. But the difference mentioned suggests that steers older than three years account for only 3% of the herd. The impact of the store-of-wealth effect seems exaggerated after examination of these data.

The old age of slaughter in Swaziland may have another partial explanation. The Swazi herd contains a very large number of oxen, animals which differ from steers only by the fact that they have been trained to pull plows or carts. These animals, 20% of the herd, are kept until long after the optimum age of slaughter for beef production because they are needed for draft purposes. They are slaughtered when age causes their draft value to decline. If no distinction is made regarding steers and oxen at slaughter, the average age of slaughtered "steers" will be biased upwards, and producers will appear to have kept steers to an uneconomically old age when these actually will have been retained for draft purposes. Although some older steers also could be misclassified as oxen in the census figures, I doubt that this bias is as great.

Second, DLK indicate that overgrazing is the result of the store-of-wealth motive. I have argued that there is little evidence of the retention of older animals for this purpose, and that the overgrazing is doubtlessly the result of communal ranges, which would introduce a more uniform expansion of the herd.

Third, DLK indicate that the composition of the herd in Swaziland is unusually constant over the cattle cycle. They argue this would not occur if more females than males were withheld in response to price increases, and vice-versa, as they believe would take place if producers attempted to maximize incomes. However, a constancy in the herd is expected in Swaziland because of low technical efficiency, due again principally to the commons problem. In addition, because real cattle prices increased rapidly on several occasions, by 38% between 1964 and 1968 (8.4% per year) and by 36% between 1972 and 1975 (11% per year), short-run speculation probably induced herders to withhold steers to greater ages during these periods. This withholding also would tend to preserve the constancy of herd composition.

The Store of Wealth and the Negative Price Response of Slaughter

As mentioned earlier, DLK explain the negative price response of cattle slaughter by postulating a sale-for-specific-cash needs theory. This theory is consistent with their store-of-wealth argument, where cattle are treated as a "savings account" (p. 42). However, if cattle are sold only to meet herders' specific cash needs, one would expect aggregate cattle receipts to be fairly constant from one year to another.[6] This is not the case.

I estimated total herd receipts by multiplying the total Swazi herd (table 2) by DLK's offtake rate (to obtain the animals slaughtered), and multiplied this by DLK's real cattle price. The resulting series has a coefficient of variation of 0.39. However, the number of Swazi herders has increased during the period studied. To obtain a series which would better reflect per capita receipts, I deflated the total herd receipts by 2% per year, the rate of growth of Swazi population during the last decade. This series still has a coefficient of variation of 0.24, remarkably high for any index expected to represent variations in annual consumption expenditures at a national level.[7] However, the variation in slaughter

[6] The cash needs of individual producers might vary somewhat, but their aggregate expenses should be relatively stable.

[7] The coefficient of variation of the deflated cattle prices is 0.29.

Table 2. Swaziland Cattle Herd Census: 1950–75

Year	Swazi Owned	European Owned	Euro-African Owned	Totals
1975	526,164	85,722	9,835	621,721

[a] Observations for these years have been estimated by geometric interpolation.

receipts is of the same order as those encountered in other commercial cattle sectors (Barros, Jarvis 1974 and 1977, Lattimore and Schuh, Nelson and Spreen, Rivas and Valdés), suggesting that producer response to changing cattle prices is a good explanation of this variation.

Another test of the cause of variation in slaughter can be obtained from the theory outlined above. Variations in the capital value of cattle, which would induce temporary and permanent variations in the rate of slaughter, can be brought about by variations in P, C, and r. A change in the demand for animals as a store of wealth would imply a change in the discount rate. In the short run, a higher demand could increase the "capital" value of animals, reflecting the increased value of the store of wealth service, and reduce slaughter. However, if Swaziland actually faces an elastic demand for the animals slaughtered, as DLK assert, a change in the store-of-wealth demand would not affect slaughter prices. And, because DLK have shown that changes in slaughter are highly correlated with changes in beef prices, it appears that it is the change in the latter, and not in the demand for a store of wealth (changes in r), that explains slaughter variation.

DLK also argue that the negative price response they encounter is different from that found in the other studies cited because "the response (in Swaziland) holds over a long period of time (27 years)." However, the price variable used by DLK in their regression analysis to explain changes in the rate of offtake has the long-term price trend removed. Thus, DLK are looking precisely at the effect of changes about the trend, or the cyclical changes. Their argument regarding the "long term" therefore seems invalid.

The Counterproductiveness of Livestock Development Programs

DLK assert that the livestock development programs being implemented in Swaziland in recent years are counterproductive. They argue that these programs have exacerbated rather than improved the overgrazing situation by stimulating producers to increase the number of animals owned for nonproductive purposes, resulting in a declining offtake rate for the herd.

I do not believe the evidence provided is conclusive. First, it is not clear that the offtake rate has

declined. Second, even if the offtake rate has declined in recent years, the herd extraction rate, which is a better index of technical efficiency, has risen.

The data in DLK's table 1 show that the choice of subperiods is crucial to any judgment regarding the offtake rate. The average offtake for the period 1954–61 is 8.93%, while that for 1968–76 is 8.90%. Save the exceptional period 1962–64 (and possibly 1965–67, for which no data are given), there is no obvious change in the offtake rate over the last twenty-three years.

The unusual increase in 1962–64 may have an explanation unrelated to technical efficiency. I suspect it is caused by Swazi herders having purchased animals from Europeans who were liquidating their herds (because of political uncertainty regarding the then impending Swaziland independence), fattening these animals and subsequently slaughtering them. Given that a large percentage of Swazi animals are kept for milk and draft purposes, a relatively small increase in animals kept and slaughtered for beef could cause the extraction rate to rise significantly. This argument also would explain why the extraction rate declined to normal levels after the European herd had stabilized. If this conjecture is valid, there has been no change in the offtake rate over time, when appropriately adjusted.

Regardless of the behavior of the offtake rate, the extraction rate (slaughter plus change in herd), which is a better indicator of technical efficiency because it includes the effect of herd variation, has risen over time. Data on the offtake rate, the average rate of herd increase, and their sum, the extraction rate, is shown in table 3. The offtake rate for 1950–64 appears higher than that for 1968–75, but much of this difference is due to the unusual rise in the extraction rate for 1962–64, already discussed. In any event, the offtake rate shows only one part of the picture. The high growth rate of the Swazi herd in the period 1968–75 meant that Swazi herders were making larger investments during this period, responding to higher prices, instead of sales. When these investments are taken into account, the extraction rate is seen to have risen in the more recent period.

This achievement is even more impressive when it is remembered that an expansion in herd size under a communal range system, as occurred following the large price increases after 1964, should have resulted in lower herd technical efficiency, including a lower extraction rate. The rapid herd expansion since 1969, without a significant decline in the extraction rate, reflects positively rather than negatively on the beef development programs implemented.

Conclusions

This paper does not suggest an absence of problems in the Swazi livestock sector, but rather questions what is the root of the low technical efficiency observed and the course of action by which the situation may be improved. DLK believe that Swazi herders maintain animals for purposes other than to produce beef, principally as a store of wealth, and are little motivated by market incentives. On the contrary, I believe that Swazi herders respond to market incentives similarly to cattle producers in other commercial livestock sectors, although I do not deny that cattle may serve as a store of wealth.

I have shown that the store-of-wealth effect is not inconsistent with a market orientation. Indeed, cattle must be valued for their beef if they also are to serve as a store of wealth. More important, it easily is shown that any economic incentive to encourage beef production will have the desired effect whether or not the store-of-wealth effect exists. Thus, conventional livestock development programs will be effective when animals are held as a store-of-wealth.

If Swazi herders are not market-oriented, however, neither higher prices, improved pastures, government fattening ranches, nor even the establishment of private ranges will lead to increased production. The introduction of administrative controls from outside the sector would be necessary to achieve higher production, not simply to limit herd size, but to govern all aspects of herd reproduction, maintenance, and slaughter. The motivation of Swazi herders is thus important, being fundamental to the design of government livestock policy.

It is perhaps surprising, given our differences in the analysis of the problem, that DLK's final policy prescription is similar to mine in at least one important respect. This similarity occurs, however, because their recommendation is inconsistent with their analysis. DLK concludes that Swaziland needs measures either to induce herders to sell more cattle (by increasing herders' cash needs or

Table 3. Period Averages from the Offtake and Extraction Rates

Year	(1) Average Offtake Rate	(2) Rate of Herd Increase	(3) Extraction Rate
1950–64	10.0	1.8	11.8
1950–61	9.5	1.8	11.3
1968–75	8.9	3.2	12.1

Source: Column 1, DLK, table 1; Column 2, calculated from table 2; Column 3 equals Column 1 + Column 2.

by reducing the relative attractiveness of cattle as a store of wealth), or to force herders to reduce cattle numbers by administrative fiat. Having posed these alternatives, DLK state that it is unrealistic to expect by changing land tenure to decrease herders' desire to hold cattle as a wealth store, and DLK fall back on administrative control of cattle numbers as the solution. Of the policies DLK consider, however, only the increase in the availability of alternative assets is appropriate if the store-of-wealth demand for cattle is important. The administrative control of cattle numbers would not be suitable. Because the store-of-wealth effect introduces no market distortion, the use of administrative controls to bring herd size below the level desired by producers would reduce, not increase, total sectoral welfare.

A permit system is appropriate as a solution for a common range system, however. In this situation, some change in the assignment of grazing rights is needed. The subdivision of the range for private use is the economically preferred policy, but it appears to be politically unfeasible in the intermediate run. The implementation of direct controls on the number of animals which individual herders will be permitted to graze is the next best solution. Thus, although DLK and I differ in our diagnosis of the problems facing the Swazi livestock sector, we agree on this aspect of the solution.[8]

This leaves only one aspect of the livestock development programs to be discussed. Although private initiative will be constrained sharply until a solution to the common range problem is found, the livestock development programs initiated in recent years include some policies which should be beneficial in the meantime. I refer particularly to the establishment of government breeding and fattening ranches which permit strict herd control within their boundaries. These ranches will increase output and also should demonstrate the attractiveness of private feed stocks. This demonstration may induce Swazi herders to accept private range allocations or permit systems more willingly in the future.

[8] The precise design of the control system is outside the scope of this comment, but I believe it should allow as much room for individual initiative as possible, perhaps by permitting herders to purchase and sell permits, once issued.

Cattle As a Store of Wealth in Swaziland: Reply

A. R. C. Low, R. L. Kemp, and M. H. Doran

Jarvis believes that there are four main differences between us.[1] He maintains that: (*a*) whereas we believe that the store-of-wealth effect seriously reduces beef production, he attributes the poor technical efficiency observed in Swaziland much more to the existence of communal ranges; (*b*) whereas we believe that the negative price response of cattle slaughter is consistent with noncommercial attitudes, he believes it is more likely to be evidence that they are responsive to market incentives; (*c*) whereas we hold that Swazi herders exhibit a negative price response because they maintain cattle as a store of wealth and only sell to meet specific cash needs, he maintains that Swazi herders' decisions to sell are based on the profit-maximizing motive; and (*d*) whereas we believe that recent livestock development programs may exacerbate the overgrazing problem and thereby reduce technical efficiency, he does not believe that technical efficiency has fallen and believes that the livestock projects have had a positive effect.

In this reply, we accept his argument in respect of point (*a*), agree that the position he adopts in respect of point (*b*) is as valid as ours, but continue to disagree with him on points (*c*) and (*d*).

The Comparative Effects of the Store-of-Wealth Motive and Communal Grazing on Technical Efficiency

We accept Jarvis' criticism of our original analysis in respect of the evidence we provided for the store-of-wealth hypothesis which also can be explained in terms of the communal grazing system. In the light of Jarvis' comments, we agree that the advanced age of slaughter and constant herd composition do not provide convincing evidence that Swazis keep cattle as a store of wealth.

The authors are currently working in the Ministry of Agriculture, Swaziland. M. H. Doran is an agricultural economist supported by the Australian Development Assistance Bureau. A. R. C. Low is a Ministry of Overseas Development (U.K.) agricultural economist, and R. L. Kemp is a computer programmer supported by U.S. AID. The authors alone are responsible for the views expressed here and the interpretation of the data presented.

[1] There are a number of details in Jarvis's comment with which we would take issue. The exclusion of oxen in the examination of herd structure is one. The suggestion that Swazis bought European-owned cattle and fattened and slaughtered them in 1964 is another. These are not the only passages that demonstrate a lack of understanding of the Swaziland situation. Because we do not comment on them, they should not be taken as being accepted by us. We are concerned to focus on what seem to us to be the major issues of general relevance and interest rather than argue about specific details.

The Meaning of the Negative Price Response

Similarly, since a negative short-term price response is equally consistent with the store-of-wealth and profit-maximising motives, it cannot be used, in itself, to support the store-of-wealth hypothesis. Low already has stressed the weakness of using price response data to argue for or against the commercial motivation of traditional cattleowners.

The Reason for the Negative Price Response

We cannot accept Jarvis' rejection of our explanation for the observed negative price response based on our sale-for-specific-cash-needs theory. Jarvis bases his rejection on the fact that the estimated cattle slaughter receipts have not been constant from one year to another as one would expect if cattle are sold only to meet herders' specific cash needs. But herders' cash needs from cattle sales are not constant from one year to the next. They vary according to annual changes in cash supply received from other income-earning opportunities as well as changes in cash needs, particularly for the purchase of food, depending on the previous season's maize harvest.

We have related annual variations in cash needs and cash supply to cattle sales in a cash needs/supply model described in detail elsewhere (Low, Kemp, Doran). The estimated linear regression equation was

$$\underset{(6.1)^*}{Y = 6.0} + \underset{(4.0)^*}{7.5X_1} + \underset{(3.1)^*}{0.1X_2} - \underset{(-3.9)^*}{0.4X_3},$$

where Y is the estimated offtake rate from the Swazi herd; X_1, the Swazi human population relative to the value of the Swazi cattle herd; X_2, the seasonal cash need (reflected in low rainfall and poor harvests in the previous season) relative to the value of the Swazi cattle herd; and X_3, the annual earnings from mine employment relative to the value of the Swazi herd. R^2 is the coefficient of determination. The coefficient of determination corrected for degrees of freedom, $\bar{R}^2$, was .68; the Durbin-Watson statistic 1.19, the F-statistic for the regression, 18.4, and finally, the asterisks denote t-ratios, significant at the .01 level.

Thus, if the growth of the human population or the increase in the need to purchase food requirements are greater than the increase in the value of the cattle herd, the rate of offtake will increase. But an increase in alternative cash incomes relative to

Table 1. Average Herd Sales Rates (%)

All herds	4.3	3.6	3.5	7.9
—herds of 1–17 head	4.3	3.9	3.6	11.1
—herds of 18+ head	4.3	1.8	3.2	6.8

Note: Own-slaughter rate averaged 4.6% over all herds, giving an offtake rate of 8.9%.

the value of the cattle herd will result in a reduced rate of offtake. Cash receipts from cattle sales can therefore be expected to increase over time as the human population grows, as well as to exhibit annual variations according to the success of the previous season's food harvest and the level of alternative cash income earned.

The point is that receipts from cattle sales are not equivalent to annual consumption expenditures. They represent the balance of expenditures that cannot be met from alternative sources (wages or own-food production). Thus, a variation in receipts from cattle sales is entirely consistent with the store-of-wealth motive and we are able to explain 70% of the observed annual variation in these terms.

Further evidence for the sale-for-specific-cash-needs hypothesis has been obtained in a recent cross-sectional cattle-marketing survey. The results of this survey indicate that sales rates among Swazi cattle herds vary considerably according to their size and the ecological region in which they are herded (Low and Fowler). Table 1 shows that sales rates are higher in the lowveld than in the high or middlevelds and that, within these regions, sales rates are higher in smaller herds than larger ones. These observations can be explained in terms of households' different levels of cash needs from cattle sales relative to the value of the herd owned. In the lowveld, cash needs are greater than in other regions because crop yields, especially of maize—the staple food—are much lower and because wage-earning opportunities are not so good. Thus, even though lowveld households own larger herds than others, their sales rates are higher. Within regions, the cash needs of households can be expected to be relatively constant, and thus households with larger herds will have a smaller sales rate.[2]

The Effect of Production-Orientated Development Programs on Technical Efficiency

Jarvis presents data to show that the average extraction rate between 1950 and 1964 is lower than it was between 1968 and 1975. He argues from this that the livestock development programs enacted during the latter period have had a positive effect on technical efficiency because he would otherwise have expected the extraordinary price rise since 1968 to have resulted in reduced offtakes, higher stocking rates, and lower technical efficiency. This reasoning leads him to challenge our suggestion that the recently enacted production-oriented development programs may be counterproductive, and suggest, instead, that they may be a second best alternative, while direct grazing controls remain politically unpalatable.

We cannot accept this line of argument because it is inconsistent with both the available data on technical efficiency and with Jarvis' own theoretical analysis. Figure 1 shows how the extraction, calving, and overall death rates have varied between 1954 and 1977.[3] Multiple linear regression analysis

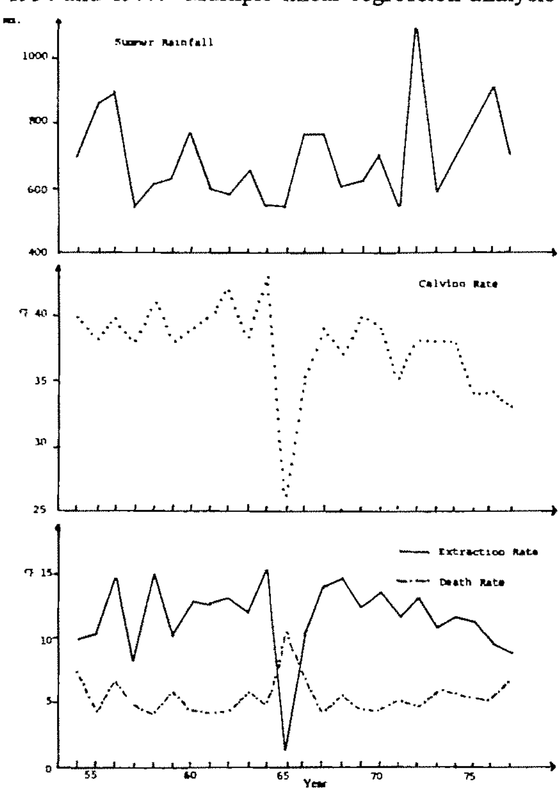

Figure 1. Rainfall and cattle data

[2] Household size is relatively constant compared to variations in the size of herds owned.

[3] Calving rate is defined as the number of 0–1 year olds as a percentage of cows at the annual census. It therefore includes the 0–1 year old death rate. No aggregate data on the number of calves born is available.

suggests that 70% of the annual variation in the extraction rate between 1954 and 1977 can be explained in terms of the calving and the overall death rates. These parameters exhibit different trends before and after the 1964/5 drought-cum-foot-and-mouth years (see table 2). Prior to 1964/5 calving rate appeared to be on the increase and death rate to be falling, although the trends are not statistically significant. This resulted in a significant positive trend in the extraction rate between 1950 and 1964. Between 1967 and 1977, the picture is different. Calving rate has exhibited a significant negative trend, while there has been a significant positive trend in the death rate. The result has been a highly significant downward trend in the extraction rate over the period.

Jarvis's presentation of the data is therefore misleading. While the average extraction rate for the 1950–64 period is marginally lower than that for 1968–75, it was on the increase in the former period and has been on the decrease since 1967. Furthermore, the decrease occurs in the period in which the substantial investment in production-increasing programs took place (from 1973).

As there has been no significant downward trend in rainfall between 1967 and 1977, we conclude that increasing grazing pressure is the main cause of the decreasing trend in technical efficiency over this period. Jarvis suggests that the increased grazing pressure has come about as a result of the recent substantial increases in the price of cattle. We would agree with him that the increasing value of cattle has induced herders to reduce their offtake rates (although we differ on their motives for doing so). But we do not agree with his suggestion that recent production improvement programs have had a positive effect sufficient to compensate for the negative effect of the price increase. Nor do we understand why he expects otherwise, since production improvements work in the same direction as price increases: they increase the growth of the value of cattle between one time period and the next.[4]

Jarvis seems to be inconsistent in expecting technical efficiency to increase as a result of production-improving measures when he accepts that price increases will reduce technical efficiency.[5] It is concievable that productivity improvements may be sufficiently large in the short term to counteract their immediate efficiency-reducing effect through increased grazing pressure. But, since they will result in an increase in grazing pressure over time greater than it would otherwise have been and, since increasing grazing pressure will reduce the impact of the production-improving measures on technical efficiency, productivity improvements eventually will be self-defeating. Where overgrazing exists, and in the absence of direct control on the numbers of animals which individual herders will be permitted to graze, it is illogical to expect production improvement measures to result in a lasting increase in the level of technical efficiency. This reasoning holds whether cattleowners are believed to behave according to the profit or the store-of-wealth motive.

Conclusion

Although Jarvis has some justification for challenging our assertions on the basis of the evidence we provided in our original article, we believe that the

[4] We would not go so far as to suggest that the production improvement programs have, as yet, contributed significantly to the decrease in technical efficiency. They have not yet been extended widely enough or for long enough to have had such an impact.

[5] Jarvis accuses us of inconsistency in suggesting that changing land tenure will not decrease herders' desire to hold cattle as a store of wealth. We suggest no such thing. We argue that a change to private land ownership will reduce the store-of-wealth motive but reject it as a feasible policy alternative under the current political climate.

Table 2. Trends in Technical Efficiency Parameters and Rainfall

	Extraction Rate (%)	Calving Rate (%)	Death Rate (%)	Summer Rainfall (mm.)
1950–1964				
Slope	0.32			
Intercept	9.10			
Corr. coefficient	.59**			
1954–1964				
Slope	0.33	0.21	−0.12	−14.06

Corr. coefficient	.91**	.74*	.73*	.22

Note: The ** denotes significance at the .01 level; * denotes significance at the .05 level.

additional evidence provided here reinforces the main contentions of our paper. These are that (*a*) Swazi cattleowners hold cattle as a store of wealth and sell mainly to meet specific cash needs, and (*b*) production-oriented development programs in Swaziland can be expected to be counterproductive in the absence of a change in the land tenure system or effective grazing controls.

Our understanding of Jarvis' analysis leads us to the conclusion that (*b*) does not depend on (*a*) and remains valid even if Swazi cattleowners keep cattle mainly to produce beef. Thus we do not agree that production-oriented development programs are second-best alternatives in the absence of a definitive solution to the communal grazing problem. To suggest that they might be is dangerous because it enables planners and politicians to evade the real and difficult issues (of grazing control or land tenure changes) by promising that improved productivity, of itself, will lead to an increase in technical efficiency and alleviate the overgrazing problem.

The significance of the store-of-wealth (sale-for-specific-cash-needs) motivation is that, where it pertains, cattle development programs cannot be considered sensibly in isolation from other household activities such as food or cash cropping and off-farm wage employment. Developments in these other fields will crucially affect cattle offtake rates and have longer-term repercussions on technical efficiency and overgrazing.

Jarvis and we agree that the definitive solution would be to change the tenure system to one of private rather than communal control of the range. This would reduce the desire to hold cattle as a store of wealth and would result in an increase in technical efficiency as Jarvis indicates. But this is a political issue which aid donors and planners cannot directly overcome. They can only provide technical assistance in the form of conventional production development programs. The question we pose is: can these production-oriented programs have a lasting positive impact on technical efficiency and production in countries such as Swaziland, while the political problems remain unresolved? We think not; Jarvis seems to think otherwise.

Editorial Notice

The Effects of the New Copyright Law on the *Journal* of the American Agricultural Economics Association

A new copyright law became effective 1 January 1978. Under the old law, a transfer of copyright from authors to the American Agricultural Economics Association was assumed to be implicit in the process of submitting a manuscript and having it refereed and accepted for publication in the *Journal*. On submission, authors state that the material has not been published, is not being considered for publication elsewhere, does not infringe upon copyrighted material, and that the authors grant to AAEA the right to publish and copyright the material. Our copyright notice was printed on the masthead page of each issue, and was taken to apply to the issue as a whole as well as to every one of the articles in the issue separately. Thus the Association not only could publish the *Journal*, but also could distribute reprints of selected articles, authorize others to reprint selectively or cover-to-cover, permit indexing and abstracting services to use material from the *Journal*, and allow free fair-use copying by individuals and libraries. This traditional practice has enabled the individuals and firms to have controlled access to material from the *Journal* while simultaneously safeguarding the rights of authors and the Association.

The new United States copyright law has changed this situation in several important respects:

1. Statutory copyright becomes effective at the moment of completion of a document, rather than at the time of publication or registration, and the copyright remains with the author or the author's employer unless he or she formally assigns it to a publishing journal or other party. This provision applies whether an author makes a living by writing or publishes simply as an adjunct to research.

2. Copyright in a journal is distinct from copyright in an individual work. Authors, or their employers if it is a "work made for hire," retain copyrights unless formally transferred to the journal publisher.

3. The doctrine of "fair use" developed by the courts now has statutory recognition. It refers to the use of copyrighted material for nonprofit research and educational purposes without permission of or compensation to the copyright owner.

The new law stipulates that, in the absence of a formal written assignment of copyright to the *Journal*, the submission of a manuscript for publications gives the *Journal* the right to publish it once. A separate copyright needs to be obtained for each individual article and a copyright notice should appear on its first page. The Association now requires the transfer of copyright from authors (and employers where appropriate) at the time of acceptance of an article, and will assume responsibility for copyright acquisition.

Any articles written by U.S. Government employees as part of their official duties are in the public domain.

An author will continue to hold all traditional rights other than copyright, such as the right to use his (her) contribution after it has appeared in the *Journal*, without charge, in any book of which he (she) is author or editor. By acquiring the copyright to individual articles, the Association will offer to those who wish to obtain permission to reproduce or reprint materials from the *Journal* a single office to which to address their requests. For all requests to reprint articles in their entirety, the Association will attempt to obtain the author's approval for the requested use; the Association's authorization for reprinting of excerpts may not necessarily be cleared with the authors. These new copyright procedures are consistent with the Association's policy to encourage and grant permission for appropriate use of materials from the *Journal* for educational purposes. Thus the Association will continue to act, as in the past, toward the advancement of theory and in support of the application of theory to practical problems.

The new copyright law affects the *Journal*, its contributors, and its readers. This new policy (approved by the AAEA Board) on the formal transfer of copyright is essential to the well-being of the *American Journal of Agricultural Economics*, and will allow the scientific and educational communities timely and broad-based access to its contents.

Books Reviewed

Duft, Kenneth D. ***Principles of Management in Agribusiness.*** **Reston, Va.: Reston Publishing Co., 1979, x + 470 pp., $15.95.**

The author has attempted to provide a textbook containing the principles of management for nonfarm agricultural enterprises. He states that it is directed at second- and third-year college students enrolled in an introductory agribusiness management course. The book is divided into nine chapters, beginning with an introduction to agribusiness and the evolution of basic managerial principles. Chapter 3 deals with personnel and employee relations and includes sections on alternative supervisory styles and effective communications. Chapters about basic accounting concepts and financial management are followed by long-range planning. The last three chapters of the book contain a conglomerate of topics on operational challenges for management, organization and management theories, inflation, energy, and farmer cooperatives.

The book reads well at a level appropriate for second- and third-year college students. However, much of the content seems to be directed toward established agribusiness managers. Many of the topics included in personnel, finance, and operational challenges to management appear to focus more on the "fine-tuning" dimensions rather than the basics of agribusiness management.

Of more serious concern are those topics omitted in the text that should be included in an introductory agribusiness management course. These topics would include: a discussion of the traditional fixed and variable costs and the cost categories relevant for decision making, such as incremental, opportunity and semivariable costs, the role of the Small Business Administration (SBA), the impact of government regulations, and product or service marketing.

The book contains a good discussion of pricing techniques and advertising strategies. Topics on managerial marketing strategies, such as sales forecasting and channels of distributions and logistics, should be included in an introductory course.

Another concern deals with the organization of the book. Unrelated topics appear in several of the chapters. For example, chapter 8, "Managerial Methodology," contains a discussion of management by objective but also includes inventory control methods.

The basic financial accounting statements of the firm and the more commonly used financial ratios are well-described. A good explanation of breakeven analysis as a financial-planning strategy also is provided.

Few textbooks are available for introductory agribusiness management courses. This book contains many of the topics that should be covered in an introductory course. It will, however, require the use of supplemental material, particularly in the areas of production costs and marketing concepts, policies, and strategies, if it is used as the primary text in an introductory agribusiness management course.

Healy, Robert G., and John S. Rossenberg. ***Land Use and the States,*** **2nd. ed. Baltimore, Md.: Johns Hopkins University Press for Resources for the Future, 1979, xvi + 284 pp., $18.00, $4.95 paper.**

The nationwide momentum for an increased public role in land use management probably reached its peak in the early 1970s. Yet land use remains an important social issue and is prominent on the legislative agenda in many states and municipalities. There also seems to be a greater level of maturity in the thinking of policy makers and the public about land use management. There is now a general recognition that the problems encompassed by this topic are enduring, require a continuing analytical effort, and involve difficult social choices.

The increased role of state government in land use decisions, an important development in the evolution of land use policy in the United States, is the subject of the book under review. Robert G. Healy and John S. Rosenberg have revised and updated Healy's original book (published in 1976). The objectives of the book are to develop the rationale for increased state involvement in controling the use of privately owned land, to compare and evaluate some of the most significant statewide land-use policy experiments, and to explore the bounds for a successful state-local partnership in land-use control.

This book contains eight chapters. The first two chapters document the diverse nature of land-use conflicts and present the theoretical basis for questioning whether the responsibility for implementing land-use policy is best left entirely to local government. This presentation makes it very clear why states have begun to take back some of the land-use control authority that historically has been delegated to local governments.

In chapters 3, 4, and 5, Healy and Rosenberg present a detailed examination of the actual implementation experience with three major state land-use programs adopted in the early 1970s—Vermont's Act 250, the California Coastal Zone Conservation Act, and the Florida Environmental Land and Water Management Act. Each of these

programs was adopted in response to unique land-use problems in each state. These case studies are particularly useful for developing an understanding of what a state role in land-use policy can and cannot accomplish. Beyond this the case studies illustrate that there is a big difference between abstract analysis of program structure and the laborious task of describing and analyzing program functioning and performance.

In the last three chapters, the authors examine the implications of the case studies for a state role in land-use control. They identify the kinds of land uses for which a state role in land-use control is appropriate, describe the alternative ways in which the state can influence land-use decisions, explore the issues (economic, political, and social) raised by state regulation, and outline the elements of an effective state land-use control program.

This book is rich with examples of land-use conflict. It provides an excellent overview of land-use problems and some of the public policy responses at the state level. It seems safe to say, however, that many analysts will argue with some of Healy and Rosenberg's conclusions. Particularly provocative is their recommendation that the adoption of land-use controls should not await the completion of comprehensive land-use plans. While many may disagree, the experience with statewide land-use policy in this country provides considerable evidence in support of a regulate first-plan later approach.

This book will be useful to land-use policy makers, land-use planners, and citizen activists. Many economists may be disappointed by the absence of a well-developed analytical framework for evaluating the effectiveness of land-use programs. In addition, the economic content of the book is neither comprehensive nor rigorous. Extensive footnote references partially compensate for the fact that detailed analysis of the economic impacts of land-use controls is beyond the scope of a book directed at a broad audience. Despite these limitations, this book is important background material for resource economists with research or teaching responsibilities in land-use policy.

Hillman, Jimmye S. *Nontariff Agricultural Trade Barriers*. Lincoln, Ne., and London: University of Nebraska Press, xv + 236 pp., $13.50.

Agricultural trade and trade policy have been receiving increasing attention in recent years. This book provides the student of this subject a well-written and scholarly addition to the literature. The book does not pioneer new analytical approaches, nor does the author originate new hypotheses or evidence on the subject, but he does not claim this to have been his objective. Rather, its value lies in describing and backgrounding an important problem area that complicates the conduct of agricultural trade and trade negotiations. Beyond this, it also adds historical and geopolitical perspective on why trade impediments are devised and why they are difficult to dismantle.

Jimmye S. Hillman's work is a descriptive case study of how nontariff measures are employed by the major trading nations to insulate their domestic producers from the pressures and vagaries of competition. It is noted that while some success has been made in removing or reducing traditional specific and ad valorem tariffs as protective instruments, a decline in the general level of protectionism in the world agricultural trade arena is not a corollary result. Nontariff barriers have replaced tariffs as the most important means of impeding international agricultural trade. These instruments exist in a variety of forms including import quotas, restrictive licensing, variable levies, voluntary restraint agreements, mixing regulations, foreign exchange controls, border taxes, export subsides, sanitary and health regulations, packaging and labeling regulations, state trading, export controls, and other measures that interfere with trade flows and responses to market signals that would occur in their absence. The use of these various measures is inventoried in the book for a cross-section of selected countries with the useful result that the reader gains a better perspective of just how pervasive these devices are. A case study of the use of nontariff barriers in the red meat industry illustrates this point in even more vivid detail. The book closes with a final chapter devoted to issues that Hillman considers fundamental to the negotiation of nontariff barriers. The reviewer came away from this section with the feeling that it would have been much more effective if it had arrived in print in the earlier phases of the Tokyo Round of multilateral trade negotiations which are now completed. Nevertheless Hillman states the issues well and they will be relevant to future negotiations of nontariff barriers once they are updated by the lessons learned and for events that occurred in this last major round of trade negotiations.

Hillman eloquently presents the reminder that domestic farm policies are often the genesis of restrictions in international commerce of farm products. He observes correctly that nontariff measures are more complicated to deal with than traditional customs measures. He casts the subject into historical perspective and warns that ignoring the impact of domestic policies buttressed by nontariff instruments could increase the likelihood of a breakdown in international trade such as the one witnessed in the 1930s. The forte of Hillman's work is possibly the forceful and convincing way that he utilizes the King's English to state such points. Among our colleagues, one is seldom accustomed to such eloquence as he commands.

Hillman's book is not, of course, to be considered to be a complete and final treatment on the subject of nontariff agricultural trade restrictions.

To bring nontariff barriers into international negotiations, the level and extent of protection and distortion created by these devices need to be identified and documented. This work is a step in that direction to the extent that it chronologizes the evolution and describes the characteristics of nontariff restrictions in agricultural trade. However, no new analytical or empirical avenues to measuring the level of protection or the consequences of specific nontariff barriers upon consumer welfare and production and marketing efficiency are developed. Consequently, those looking for a rigorous analytical treatment of the subject will be disappointed. However, it is unfair to criticize the study on this basis. It still performs the useful function of inventorying and describing restrictive agricultural trade instruments and articulates the importance of the subject in such a forceful manner that it may well stimulate other investigators to plow the subject matter further.

Hite, James C. ***Room and Situation: The Political Economy of Land-Use Policy*****. Chicago: Nelson-Hall, 1979, x + 340 pp., $18.95, $9.95 paper.**

James Hite provides a comprehensive survey of land-use policy in the United States. The approach is that of institutional analysis. The focus is land-use policy in urban areas. The treatment is broad; Hite introduces the historical, ideological, political, and economic aspects of public policies affecting the use of land. Chapters also are devoted to expenditure and revenue policies as these affect land use, and the author considers implications for planning posed by levels of and changes in information, knowledge, and technology.

Citizens interested in and concerned about land-use policy in this country are the intended audience for this book. The author does an excellent job of organizing and presenting diverse and complicated materials for this audience. Theory and concepts that might seem dry in another context are blended with history, quotes, examples, and current issues to form a rich and palatable blend.

Room and Situation also would serve well as the principal text in an undergraduate course with a multi-disciplinary approach to land use. Within each discipline, individuals can find points of contention and will not learn a great deal more about land use as approached within their discipline. But perspectives also may be broadened significantly by exposure to approaches outside their own discipline.

Planners may find *Room and Situation* both interesting and provocative. Such professionals would not learn new approaches to planning. Rather, Hite's analysis of the political roles and political tactics of planners might be of interest to such an audience. This analysis strips away certain mystiques surrounding planning and planners. Hence, professional planners may find the work provocative.

The incorporation of political analysis in the approach to studying land-use policy is a major strength and distinguishing characteristic of *Room and Situation*. Political analysis is used in two ways. Models and concepts from political science are applied to foster understanding of the current situation; that is, to explain the types of land-use policies we have and those that we do not have. Concepts of politics also are brought to bear on the often overlooked task of analyzing how particular abstract proposals might actually evolve if made subjects of public policy. The concepts and models from political science are diverse, drawing from one thread or another as appropriate to the subject being considered. The public choice approach is given considerable emphasis in a concluding chapter.

Analysis of the roles of information and knowledge in land-use policy and land-use politics is another strong point of this text. The author notes problems created by both the paucity and abundance of information and knowledge in areas related to land use. Also analyzed are the ways in which control of information is both a source of power and a factor that must be considered in understanding the shape and direction of land-use policy.

Athough the book strongly emphasizes the description and understanding of land-use policy, the author does consider some prescriptions for problems identified in the analysis. Among other prescriptions, the author gives most attention to the need to make information about land use widely available at low cost in order to allow citizens to participate in the formulation of land-use policy. The author describes how such an information system might be developed and reports on recent experiments with such systems. Here, the author falters in his otherwise superb application of political concepts to the understanding of public policy. When providing goods, a political system seeks information not only on what individuals want, but how badly they want it. One way in which the latter type of information is conveyed is through logrolling. That process is superbly developed by the author. Another way in which a political system measures how badly people want something is by making participation costly. Just as for private goods, intensity of preferences or demand is measured—albeit crudely—by how much people are willing to pay. Hite's proposal would significantly subsidize major costs of political participation. The author does not consider implications of his prescription for efficient allocation of publicly provided goods and for the needs of decision makers for information on salience needed to retain political support. Subsidization of the costs of participation may be defended on egalitarian principles. Perhaps the author would judge that such benefits outweigh disadvantages. But we do not know

because the political functions of costly participation are not considered by the author.

Such lapses are to be expected in a book with such a broad scope. The text remains an excellent introduction to land-use policy for citizens and students seeking a broad, highly readable, and carefully developed understanding of urban land-use policy in the United States.

Oregon State University

Hutchinson, T. W. *Review of Knowledge and Ignorance in Economics.* Chicago: University of Chicago Press, 1977, 186 pp., $5.50 paper.

This little book consists of an introduction, three chapters, and an appendix. On casual inspection a methodological treatise on knowledge and ignorance in economics might not appear to be of great relevance to agricultural economists. But a thoughtful reading will benefit almost any applied economist, although it must be emphasized the book will be of value only if it is read with reflection and introspection with respect to one's own thought processes. It will not yield dividends to the person who is seeking a "quick fix" methodology of economics. Many of us as agricultural economists have committed the errors that Hutchinson warns about and it is, therefore, most appropriate that it be reviewed in this *Journal*. The prospective reader should be aware that some passages will be meaningful only if the reader is familiar or is willing to become familiar with some of the recent literature on the methodology of science. The remainder of the book will be accessible to anyone having familiarity with theoretical and applied economic literature.

The introduction argues that the most dangerous kind of ignorance is that regarding the limits and limitations of one's knowledge. The author believes that ignorance of this kind on the part of economists will result in their causing noneconomists to have excessive expectations regarding the value of economic studies. The consequence is "disappointment and disillusionment" (p. 5) by those who have been led to believe economics can deliver more than it is capable of delivering. The introduction ends with some thoughts on graduate training and an approving quote from Jacob Viner to the effect that good teachers at the college level will never come from those who have been trained to think only within the limits of one subject or from the point of view of one subject.

Chapter two deals with prediction. Hutchinson accepts the notion that a principal aim of economics is to improve prediction; and that it is, to some limited extent, a feasible aim. As one might expect, the author moves quickly to deal with the methodology of science which has become associated with Sir Karl Popper. It is, of course, Popper's belief that the criterion for judging a science is its predictability, its capacity to "forbid" something from happening. Only in this way can conjectures be made that are capable of refutation. Hutchinson contrasts Popper's position to the argument advanced by Theil, which seems to concede that "scientific" prediction in economics and econometrics is not possible. The author takes a position intermediate between that of Popper and Theil. He believes that most predictions in economics are extrapolations of trends or deductions based on trends. Even though such a procedure has obvious weaknesses, Hutchinson believes that economists have no alternative. He argues, but does not document, that quite naive extrapolation in some cases has been shown to be superior to more elaborate deductive model building. The conclusion is reached that attempts to make economics "scientific" by reliance on mathematical model building is a methodological "dry hole" because any prediction must be based on trends, and trends will never provide the necessary completeness for a theory which will have the capacity to "forbid" events. This methodological discussion is followed by a discourse on whether predictions in economics are improving or not. Without attempting to summarize all of this discussion, one factor working to improve prediction is the availability of more accurate and current statistics; a factor working in the opposite direction is the increased complexity of modern economies.

Chapter three on the history and philosophy of science and economics permits the author to relate the viewpoints of Kuhn and other recent writers on the philosophy of science to those of Popper. Hutchinson speaks approvingly of attempts to understand the history of science. He warns, however, that there is danger that normative-positive confusion can develop easily, as it did with many in their interpretation of Kuhn. He also warns that different sciences have different histories, and this must be expected since they have different materials with which they must work. He says the labels "mature" and "immature" sciences are misleading because they lead to expectations that eventually the "immature" sciences will be comparable to the "mature" sciences. (Kenneth E. Boulding believes that "secure" and "insecure" would be better adjectives. See "Science, Our Common Heritage," *Science* 22 February 1980, volume 207, no. 4433.) He does not believe that economics can ever be like physics, but he does believe the rigor developed by the philosophers of science in advancing what constitutes "good" scientific procedure can be used in economics to prevent economists from becoming excessively dogmatic in the advice they extend to policy makers. Hutchinson presents examples of policy advice by economists where the methodological limits of economics have either been ignored or improperly observed.

Chapter four is concerned with the crisis of abstraction in economics. Hutchinson thinks the

stakes are high because he believes that economics can make a contribution to the maintenance of freedom by that which it contributes to the standards of discussion. If economics becomes more and more irrelevant to the real problems of the world because of excessive abstraction, its contribution to freedom will decline in a corresponding fashion and, if freedom dies, so will economics according to the author. He deplores the virtual absence of history in the study of economics at the present time and believes that a greater familiarity with past events would tend to discourage the excessive abstraction which results in irrelevant and unrealistic theoretical treatments of economic problems.

It is a pleasure to recommend this book. As noted, it contains much of value to any applied economist but it will be of special interest to the teacher and student of research methodology in economics.

Emery N. Castle
Resources for the Future

McCoy, John H. *Livestock and Meat Marketing*, 2nd ed. Westport, Conn.: 1979, AVI Publishing Co., x + 479 pp., $26.50.

The second edition of *Livestock and Meat Marketing* reflects the maturity and soundness of McCoy's important initial contribution to livestock marketing. His applied approach, intended for undergraduate programs and as a reference for graduate students interested in livestock and meat marketing, gives both the instructor and student a firm base upon which to build an individualized class.

McCoy has chosen neither to add nor to delete any of his initial sixteen chapters of the first edition. However, within several chapters, the discussion has been either expanded or contracted to reflect the dynamics of developments within the changing livestock industry. Of course, the numerous tables and charts were updated to reflected 1977–78 published data, where available.

The first five chapters, which deal with the historical perspective of livestock marketing, economic theory and principles, and production and consumption, are unchanged from the first edition. This section is fraught with the problem of covering microtheory in 100 pages. However, the important elements needed for further analysis at least are introduced.

Chapters 6 through 9 describe the institutions that perform several marketing and pricing functions in livestock and meat marketing. Many analysts of the industry would agree that substantial changes have occurred, and are occurring, in the structure of the meat-packing industry. McCoy has chosen throughout the book to ignore, or to avoid offering suggestions of industry change that may be occurring. His book may appear a bit dated without this visionary approach.

Major revisions occur in chapters 10, 11, and 15, which deal with futures markets, grades, and marketing costs, respectively. Just as in the first edition, McCoy does a good job of introducing the futures market, its functions, basis, and he provides several hedging examples. Then a new section dealing with research on livestock-hedging strategies is introduced with no orientation to any of the technical or fundamental analysis utilized in selective hedging. This may leave the reader, inexperienced in hedging, somewhat bewildered. With adequate supplementation, an intstructor can lead a class to the importance of McCoy's conclusions. However, it is omissions such as this that may induce the instructor to use McCoy's book as an important reference, but not as the main text of a livestock-marketing class.

The print in the second edition is larger, and the layout is appealing to the intense reader. If you found McCoy's first edition useful, the second edition is a welcome and excellent text. If you are not familiar with the text, and have an interest in livestock marketing, I would recommend you seriously consider the text as a good reference.

Morgan, Dan. *Merchants of Grain*. New York: Viking Press, 1979, xiv + 385 pp., $14.95.

World trade in grain is dominated by five huge, shadowy, privately held, multinational grain companies controlled by but seven families. This book attempts to document this position by weaving history, the economics and politics of food, political intrigue, economic greed, and personal glimpses into a fascinating book which often times reads more like a mystery and intrigue novel than a chronicle of the real world. Dan Morgan is a journalist for the *Washington Post* who spent three years probing the international grain business and the people that he suggests dominate it. He admits frankly that the story he weaves is a composite of factual knowledge, rumor, and his own perceptions about the current grain-trading system. He was forced to this approach because of the shortage of research material and the general unwillingness of major participants to be interviewed. At some points, Morgan seems almost to be writing an exposé as the final paragraph of his introduction indicates. "I was left with no doubt that the companies at the center of the grain distribution system are not only wealthy but important and very powerful. The time for them to stand up and take a bow is long overdue" (p. xiv). It is possible that some of the families would have preferred their debut to be later and on their own terms. But that aside, the book provides some fascinating glimpses into multibillion dollar business that deals in the world's basic commodity—food.

Morgan is not an economist nor a historian. Thus, the book is not overloaded with deathless

technical jargon nor is it organized in a typical stereotyped way. It reads more like a mystery thriller with seven major and many minor characters who have lifespans of over one hundred years whom the reader must keep track of. The book is the story of five grain companies—Cargill, Continental, Bunge, Louis-Dreyfus and André—which handle, by most peoples' estimates, more than 80% of the world grain trade—and the seven families—Cargill, MacMillan, Fribourg, Borne, Hirsch, Louis-Dreyfus and André—that own them. The book begins with a brief review of the Russian grain purchase of 1975, but immediately reverts to historical sketches of the evolution of the grain trade in the nineteenth century, particularly after the repeal of the Corn Laws in 1845. The first four characters—the Fribourgs, Louis-Dreyfuses, Bunges, and Andrés—are introduced as merchants in the early grain trade. Next, we switch to the evolution of the U.S. grain industry in California and the Midwest and are introduced to Friedlander, Pillsbury, Washburn (General Mills), and Will Cargill. The next three chapters provide a rambling review of developments from 1850 to the present. But lest the reader think the book is a simple chronology, the story darts backward and forward with reckless abandon. Chapters 7 and 8 attempt to define the current dimensions of these multinational giants including substantial doses of family history. Chapter 9 is the closest thing in the book on how a multinational firm actually operates. Chapter 10 presents a set of anecdotes which try to demonstrate the global power of the firms. Chapter 11 deals extensively with U.S. attempts to wield food power against the Soviets in 1975. Chapter 12 is a fascinating treatise on the world rice trade and Tongsun Park. Chapter 13 chronicles the rise and fall of Ned Cook. The last chapter draws the distinction between the commercial grain business and world hunger and concludes that the merchants of grains are concerned only with the former.

Readers will appraise the book differently depending on where they are coming from. Historians might decry the lack of documentation, the dizzying forays back and forth through time, and the personalization of major economic and political events. Economists will be stunned by the absence of hard numbers, formulas, and supply and demand curves. International relations experts might view the geopolitical analysis as overemphasizing food as opposed to bilateral military power and oil. Grain traders would fault some of Morgan's simplifications of the trade. Finally, the grain families no doubt could punch holes in some of Morgan's conjectures should they choose to come out from behind their veils of secrecy. But be that all as it may, the book provides extremely valuable as well as interesting insights into the grain business, even though it is not, nor was it intended to be, a complete description and analysis of the grain trade. One comes away with the sense that the companies' greatest assets are information, superior marketing skills, and entrepreneurial derring-do which often is at variance with widely held social and ethical values.

On first reading, this reviewer was tempted to fault Morgan for not drawing his valuable insights into a tight set of conclusions which portrayed the reality of the grain trade circa 1978. But on rereading the book, this would have destroyed some of its intrigue and readability. Morgan leaves it to the reader to draw his or her own conclusions, though it is quite clear where he stands.

Every serious student of the international grain trade should read this book. It provides more insights into a highly complex, dynamic business than any dozen academic treatises one could select.

Alex F. McCalla
University of California, Davis

Purcell, Wayne. ***Agricultural Marketing: Systems, Coordination, Cash and Futures Prices.*** **Reston, Va.: Reston Publishing Co., 1979, viii + 472 pp., $15.95.**

This text is intended primarily for the use of the intermediate level undergraduate, with a principal objective "to foster and nuture the problem-solving ability of the marketing student . . . charged with making marketing decisions" (p. 15). In contrast to the theoretical approaches emphasized in most intermediate-level texts, Purcell devotes relatively little time to theoretical models per se, and concentrates instead on the application of theoretical results to contemporary problems. As a result, Purcell's text serves both as a sourcebook of contemporary marketing patterns and as an overview of economic principles relevant to decision making. The descriptive detail, particularly of the livestock industry and of the role of government in price determination and information collection, is not equalled by other texts of this level.

A reduced emphasis on the development of theoretical principles requires expedient application of the implications of economic theory. Unfortunately, the text contains a number of errors and misstatements. For example, quality differentials in cotton grades are presented as evidence of monopolistic competition in production (p. 44); "theory generally supports the position that large size gives market power and market power usually means higher prices and larger profit margins" (p. 73); variables should be retained in models as long as standard errors are less than coefficient estimates (p. 169); hedging in futures markets "often comes at the expense of a significant decrease in the average profit level" (p. 300); spatial equilibrium prices differ by transfer costs only if all countries have identically sloped demand curves and identically sloped supply curves (p. 402).

A second distinctive feature of the book is the emphasis on futures markets. As Purcell points out,

futures markets have been neglected in most texts and nearly one-fourth of the book is devoted to this topic. Unfortunately, Purcell's discussion is devoted largely to chart-reading techniques. Breakouts, congestion areas, head and shoulders, double bottoms, flag formations and other patterns of futures prices are analyzed in great detail. This section provides, at best, a misleading view of futures trading, as there is no theoretical reason or empirical evidence to suggest that successful speculation has been achieved on the basis of a chart-reading strategy. "Buy cheap and sell dear" would have been equally sage advice and would take considerably less space. The important behavioral issues, such as the theory of the cost of storage or the existence of a risk premium, are ignored, and the reader emerges from Purcell's discussion with little understanding of the functions of futures markets.

The emphasis on systems analysis is a third distinctive feature of the book. Purcell considers systems analysis necessary because of the "slow but persistent trend towards vertical integration" (p. 436), the inability of the price mechanism to transmit proper signals to the producer at the end of an increasingly long marketing chain (p. 445), and the potential efficiency gains revealed by a holistic view. Whether systems analysis can contribute substantively to the understanding of market behavior and the role of the price mechanism as a method of inducing change is a controversial topic, and Purcell presents little substantive evidence which might influence the outcome of this argument. The price mechanism for feeder cattle, for example, is asserted to fail because buyers and sellers of feeder cattle have different opinions of ideal animal characteristics, and these differences are not reflected in feeder cattle prices. But the observation that consumers and producers bring different objectives in the market is not surprising. To prove failure of the price mechanism requires a demonstration that consumers place a value on the unpriced characteristics, and Purcell provides no evidence on this issue. The sole example of the ability of a holistic perspective to discover new sources of increased efficiency involves a systems analysis of integrated cattle marketing. Returns on investment for the integrated system increase by less than 2% over decentralized systems (p. 364). Given the large data requirements and the resultant uncertainty of the results of systems analysis, it is difficult to have confidence in such marginal differences.

Purcell's approach is an ambitious one, and the attempts to teach principles through illustrations and relevant examples are admirable. But the distinction between assertion and the implications of theory is critically important to this approach, and Purcell frequently fails to make this difference sufficiently clear. The discussion of futures markets is particularly weak in this regard, and the behavioral aspects of futures markets are almost completely ignored. Finally, little evidence is provided to suggest that systems analysis provides a necessary or useful alternative means of studying the economic principles of marketing behavior.

Eric Monke
University of Arizona

Sinden, John A., and Albert C. Worrell. ***Unpriced Values: Decisions without Market Prices.*** **New York, Toronto: A Wiley-Interscience publication, John Wiley & Sons, 1979, xvi + 511 pp., $25.95.**

The authors, both economists, state that "many people feel it is impossible to place value on [scenic views, California condors, improvements in health, savings in commuting time]. Others feel that they can only be compared by assigning monetary prices to them. We do not agree with either of these views. We believe it is possible to determine comparative values for unpriced things and that valid comparisons can be made without always resorting to monetary prices" (vii). The text is organized in three sections. "Part I considers the nature of values, the kind of value information needed for decisions, the usefulness of comparative values, and the nature and application of basic concepts. Part II gives the reader an appreciation of the large number and wide range of methods that have been developed to measure unpriced values and of how each fills a special niche. Part III considers why decisions involving unpriced values are perceived as difficult and shows how appropriate analyses can overcome this" (viii). Parts I and II are recommended to administrators and policy makers; Parts II and III, to analysts and planners.

These lengthy quotes from the preface are included here to emphasize that the book really is not for the professional economist—or even for students who already have developed an economics perspective. Whether administrators, policy makers, and planners will be likely to pursue the 500-plus pages is another issue, although I will agree with the authors it could do them some good.

The six chapters of Part I basically are devoted to convincing the reader that various unpriced things (goods, experiences, feelings) create utility for people, therefore they have value. While the conventional unit for valuation has been a monetary one, any index that can express benefits in terms comparable with cost, express values of all alternatives in comparable units, or express values for all individuals in comparable units will serve, depending on the specific problem in question. Problems and planning are specific issues, and universal values are not necessary. As with the rest of the book, the arguments are presented lexicographically. Tabular displays and decision trees are abundant. If I had not already believed in the possibility of unpriced values, the authors would have convinced me. However, after 116 pages, I was left with a

nagging feeling of overkill. Only one of the six chapters is specifically on economics as the basis for evaluation—it focuses on elementary concepts of supply, demand, and utility.

In Part II, the next 295 pages, the authors review essentially the whole stock of valuation methods and studies from an applied point of view. Each method and study is classified as to its appropriate problem area and data requirements. Discussion of the pros and cons of alternative methods is pragmatic. There is little discussion of theoretical issues. There are 324 items in the book's list of references—most relate to studies referenced in Part II. Thus, this section takes the form of a meticulous compilation of "abstracts" or of a brief (for each) but lengthy (in total) review of the literature. Topics range from studies using direct questions on value, to discovery of value using signal detection theory. With a few exceptions, the reported studies were published previous to 1976. Part II could be used as a thesaurus of evaluation methods, but for continuous reading it is the least successful part of the book.

In Part III the authors return to the argument for making unpriced evaluations, and give several detailed examples of how such evaluations have been made in reputedly difficult cases. It is a cogent summary of when to use a monetary, utility, or mixed approach to evaluation for decision making.

The final sentence, however, is the best statement in the whole book: "The model of value in Equation 3.5 provides a basis for valuing unpriced benefits and costs of any kind and under any circumstances" (p. 490). Equation 3.5 is

$$Vi = Ui - DUi,$$

where Vi is the value of thing i, Ui is its utility, and DUi is the disutility involved in obtaining it. That equation was given 333 pages previously. From this reviewer's point of view, the space between the equation and the final statement could have been a good deal shorter.

I am left with mixed feelings about this meticulously crafted effort. The work put into it is appreciated, but I am afraid most people will not have the strength of character to sort through the mass of information to obtain the particular technique the authors specify as "right" for their problems. Having done so, they would still need to investigate the specific literature in detail. Thus the book offers little to an evaluator who is familiar with the literature. An administrator or policy maker is likely to be put off by the sheer volume of material. As a text for student analysts, it would serve as an outline to be supplemented with the analyses themselves.

Thiam Tan Bock, and Ong, Shao-er. *Readings in Asian Farm Management*. Singapore: Singapore University Press, 1979, x + 350 pp., $15.00.

The book is the culmination of the efforts of a group of farm management teachers in Asian universities who met under the auspices of the Agricultural Development Council, New York, and felt the need of a book on farm management in the Asian context. Thus, this book is not a comprehensive treatment of the subject matter of farm management, but rather a collection of articles selected by a committee consisting of experienced teachers in Asian universities.

In all, twenty-four articles have been selected from respectable journals, articles considered relevant for farm management courses in Asian universities. The articles present farm management problems and data from most of the Asian countries and successfully present an Asian, rather than an individual country, outlook. The articles are grouped in five parts which would represent a major topic in any course on farm management. The four articles in Part I deal with economic principles and applications. The principal tools of farm management, such as production function analysis and linear programming, have been presented with practical examples from the Asian agricultural economy. All articles selected are technical, empirical, and useful for the course.

Part II deals with farm business and management analysis. Here there are also four papers touching on problems of data collection, data analysis, decision making in the adoption of new high-yielding varieties of rice and optimum combination of farm resources in livestock production, and so on. Though all four articles are technical and empirical, yet one feels the lack of an article dealing with total farm business analysis of small farms combining both crop and animal husbandry enterprises. This would have increased the awareness of both teachers and students on the decision making process on small farms. The article by V. H. Park on behavior of farm resources in livestock production on semi-subsistence farms does not fulfil this need.

Part III deals with institutional factors affecting management. The four articles in this section discuss credit, cooperation, joint farming, and crop insurance. Whereas the authors have comprehensively dealt with the various aspects of these topics, one wonders why an article on land tenure, the biggest institutional factor in agricultural development in Asia, has not been included.

Part IV includes six well-chosen articles on the "Economics of Technological Innovations." The articles deal with the most important technological changes in recent years, such as farm mechanization, implication of green revolution, responsiveness of subsistence farmers to new ideas, rice-harvesting techniques, and demonstrate how technological changes modify farm management decisions. The articles should increase the teachers' and students' understanding of farm management problems vis-à-vis technological innovations.

Part IV includes six well-chosen articles on the and implications, and deals with such topics as allocation efficiency in a developing agricultural econ-

omy, impact of high-yielding varieties of rice on economic aspects of animal husbandry, farm income distribution, and choice of techniques in rice milling. These articles highlight the use of farm management studies on policy formulation and its impact on farmers income. Here, again, one feels a lacunae, the need of an article on price policy, so vital an issue to farm policy in Asia.

Since farm management is a compulsory course in all undergraduate programs in agriculture and agricultural economics in Asia, and because there is a woeful lack of textbooks with Asian data, this book fulfills a great need. The articles have been well selected and integration of economic theory with farm management problems has been achieved in the book to a considerable extent. The book should prove useful both to teachers and to students of the subject in Asia.

Information on Submitting Manuscripts

1. **Cover letter.** In a cover letter, the author(s) must state (*a*) that the material in this manuscript has not been published and is not being published or being considered for publication elsewhere, and will not be submitted for publication elsewhere unless rejected by the *Journal* editor or withdrawn by the author(s); (*b*) that the material in this manuscript, so far as the author(s) knows, does not infringe upon other published material protected by copyright; (*c*) that the employer of the author(s), if any, either does not assert an ownership interest in the manuscript or is willing to convey such interest to the American Agricultural Economics Association (AAEA); and (*d*) that submission of this manuscript gives the AAEA the exclusive right to publish, to copyright, and to allow or to deny reproduction of the manuscript, in whole or in part. If the applicability of point (*a*) is unclear, the author(s) should explain.
2. **Author's identification.** In order to protect their anonymity in the review process, authors should avoid identifying themselves in the manuscript. Attach a separate page including the names of the author(s) and appropriate biographical information, as well as the title of the manuscript. Include only the title on the first page of the text.
3. **Typing.** Double-space all material, including footnotes, tables, quotations, and references, on 8½-by-11-inch standard weight white paper with margins on all sides of at least 1¼ inches.
4. **Style.** Follow *A Manual of Style* by the University of Chicago Press as well as previous issues of this *Journal.*
5. **Mathematical notation.** Use only essential mathematical notation; such notation is costly to typeset and may limit the readership. Avoid using the same character for both superscripts and subscripts, using capital letters as superscripts or subscripts, and using overbars, tildes, carets, and other modifications of standard type. Asterisks, primes, and small English letter superscripts are suitable substitutes.
6. **Footnotes.** Number footnotes consecutively throughout the paper, not page by page. Type the footnotes, double-spaced, on a page following the article. The institutional paper number and acknowledgments, if any, should be placed at the beginning of the list of footnotes. Footnotes should be only explanatory and should not be used for citations or for directing the reader to a particular work. This information can be incorporated into the text itself.
7. **References and citations.** Place all references, alphabetized by author, in a list at the end of the paper entitled "References." Only cited works should be included in the reference list. All citations should appear in the text and contain the author's name and page numbers, when necessary. Citations can be inserted parenthetically, e.g., (Doe) or (Doe, p. 5). Specify the date of publication if the same author appears more than once in the reference list, e.g., (Doe 1971, p. 5). If the author's name appears as part of the sentence, a parenthetical reference is unnecessary unless you need to cite page numbers or a date. A style sheet on references and citations is available upon request.
8. **Tables.** Place each table on a separate page; double-space all material; omit vertical rules.
9. **Figures.** Prepare figures on heavy white paper or acetate sheeting using black India ink or paste-up types suitable for black and white reproduction by a photographic process. Typescript is not suitable.
10. **Three copies.** Send the typed original and two carbon copies or photocopies. All copies should be inspected for completeness and quality of reproduction.
11. **Abstract.** Instructions for the preparation of an abstract will be sent when the manuscript is accepted for publication.
12. **Page charge.** Major support for this *Journal* is provided by page charges of $40 per printed page, or fraction thereof, payable by the supportive institution or granting agency. Payment does not affect acceptance, scheduling, or form of publication. Instructions for making payment are provided with galley proofs.

American Agricultural Economics Association

Objective

The AAEA seeks to further the systematic development of knowledge of agricultural economics in order to improve agriculture and agriculture's contribution to the general economy. The activities of the AAEA include:

—publishing the *American Journal of Agricultural Economics;*
—planning and conducting two annual meetings of the membership;
—sponsoring annual awards for outstanding extension programs, distinguished teaching, and outstanding research;
—recognizing outstanding agricultural economists through a fellows program;
—supporting a literature retrieval system in cooperation with the U.S. Department of Agriculture;
—publishing periodically a biographical directory of the AAEA's members;
—supporting an employment registry for agricultural economists in cooperation with the U.S. Department of Labor.

Membership and Subscriptions

Membership in the AAEA is open to individuals having a professional interest in agricultural economics. Dues, payable at the beginning of each calendar year, are as follows: regular members, $25, senior members, $12.50, and junior members, $12.50. Senior membership is open to persons, upon written request, who are sixty-five years of age or older and have retired from active professional work. Junior membership is for students and is limited to three years; students should use application forms available from and signed by the head of the department in which they are studying. Members receive this *Journal*.

Any firm, corporation, association, or partnership may become an institutional member upon payment of $100 per year; institutional members receive three copies of each issue of the *Journal*. Library subscriptions are $35 per year. Individual issues of this *Journal* are $10.00.

Payment of membership dues, correspondence regarding subscriptions, orders for individual copies of the *Journal*, changes in address, or inquiries about the general affairs of the AAEA should be sent to John C. Redman, Secretary-Treasurer, American Agricultural Economics Association, Department of Agricultural Economics, University of Kentucky, Lexington, Kentucky, 40546.

American Journal of Agricultural Economics

Volume 62 Number 4

November 1980

The *American Journal of Agricultural Economics* is published five times a year (February, May, August, November, December) by the American Agricultural Economics Association. Prior to 1968, this *Journal* was the *Journal of Farm Economics*.

Printed for the AAEA by Heffernan Press, Inc., Worcester, Massachusetts, USA.

Second class postage paid at Lexington, Kentucky, and additional mailing offices, Pub. No. 019500.

ISSN 0002-9092

Editorial Policy

The purpose of the *Journal* is to provide a forum for creative and scholarly work in agricultural economics. Thus, acceptable manuscripts should have a relationship to the economics of agriculture, natural resources, or rural and community development. Contributions, methodological or applied, in the business, extension, research, and teaching phases of agricultural economics are equally encouraged.

Editorial Communications

All manuscripts and editorial correspondence, except as noted below, should now be addressed to the new editor, James P. Houck, Department of Agricultural and Applied Economics, University of Minnesota, St. Paul, MN 55108

Communications concerning book reviews and books submitted for announcement in the *Journal* should be sent to the new book review editor Ronald A. Schrimper, Department of Economics and Business, North Carolina State University, Raleigh, NC 27607

Wheat Cartelization and Domestic Markets

Robert G. Chambers and Michael W. Woolverton

The effects of cartelization in the international wheat market are analyzed. Particular attention is given to the relationship between the level of cartel profits and the price farmers receive for their wheat. Sufficient conditions are established for a rise in cartel profits to be associated with a rise in the farmgate price of wheat. The potential stability of a cartel formed by the major trading companies also is investigated and a means of preventing cheating is introduced and discussed.

Key words: cartels, cartel price, farmgate price.

In the last decade there has been a series of startling events in the international grain arena which has evoked an increasing amount of attention on the part of agricultural economists. An important topic of discussion in the resulting flurry of theoretical and empirical literature has been the competitive structure of the international wheat and other grains markets. McCalla (1966) appears to have been the first entrant into the fray with his pathbreaking duopoly model of the world wheat market. Subsequent work includes a triopoly model of the world wheat market (Alaouze, Watson, Sturgess) and another important contribution by McCalla (1977) outlining an array of strategies that market participants might attempt to follow and the resulting market situations that could arise from their actions. Most recently, Carter and Schmitz have presented empirical evidence which they feel suggests that the major wheat importers are charging approximately an optimal tariff.

The idea of forming an international wheat-trading cartel made up of major exporting firms and national trading entities has received widespread attention both in and out of the economics profession. Many students of international trade reject such a cartel as impractical, but the idea persists. For instance, the popular slogan "food for crude" and the attention given to this issue by the popular media suggest that there is some popular sentiment (in the United States at least) for exercising potential monopoly power in world grain markets. Such sentiment, if sufficiently backed by popular pressure on legislators, could lead to a significant easing of current anticartel laws, which would allow exporters a chance to reap some of these potential monopoly profits. Even without changes in antitrust legislation, multinational firms and state exporters may form such a trading agreement sub-rosa. And yet, the question remains: will formation of a cartel benefit individual farmers as well as members of the cartel? We hope to illuminate this problem in the succeeding pages.

Relatively little attention has been given to the formation of optimal strategies for some of the major participants on the supply side of the international grain trade—the large grain companies such as Cargill, Continental, Bunge—and the effect such practices could have on farmers in the exporting nations. At first glance, the optimal strategy is rather apparent; i.e., these large sellers should exploit any monopoly-monopsony power they possess. This, however, does not take into account the fact that most of the operations of these firms are located in the United States and other major exporting regions. Hence, one must recognize that the exporting regions, for political and other reasons, may not allow these firms a free hand. Specifically, it is assumed in the ensuing analysis that the exporters are not allowed systematically to extract economic surplus from the domestic suppliers; i.e., they

Robert G. Chambers is an assistant professor in the Department of Agricultural and Resource Economics, University of Maryland, and Michael W. Woolverton is an assistant professor in the Department of Agricultural Economics and Rural Sociology, Ohio State University.

Scientific Article No. A2711, Contribution No. 5758, of the Maryland Agr. Exp. Sta.; Ohio Agr. Res. Develop. Ctr. J. Art. No. 134-80.

The authors wish to thank, without implicating, C. M. Alaouze, F. E. Bender, J. Daberkow, I. Hardie, K. E. McConnell, V. Norton, I. Strand, and an anonymous reviewer for helpful comments and suggestions.

are forced to act in a relatively competitive manner in buying the grain.

The present paper investigates in a general framework the optimizing behavior of a cartel formed by, say, the dominant grain export firms or even by these firms and the marketing boards of large exporting nations (Canada, Australia). Because an important argument for the formation of a cartel is that it allows exporting nations to capture some otherwise unrealizable monopoly profits, an examination of the effect on the ultimate suppliers of the wheat (i.e., farmers) is vital to any discussion of cartel behavior. Hence, it will be argued that formation of a cartel might in fact lead to a lower farm level price for wheat, even if the cartel acts competitively in buying the grain domestically. The link between the level of cartel profits, the farmgate price of wheat and the cartel price, also is examined by using comparative static analysis to investigate the effects of changes in the international demand situation. Under certain assumptions, it is possible to demonstrate that higher cartel profits will be linked with a higher farmgate price and a lower cartel price. In general, however, it is demonstrated that there is no a priori reason to expect that the price farmers receive for their grain will vary positively with the level of cartel profits. The last section of the paper is devoted to examining the stability of such a cartel. Because it is demonstrated easily that each member of the cartel will have an incentive to cheat, the problem of deterring cheating is crucial to any discussion of cartel stability. Accordingly, Osborne's quota rule, which is designed to prevent cheating, is introduced, and its implications for the cartel under discussion are examined.

The Model

Consider an industry with m firms, each of which buys grain in the domestic market and then markets it internationally. Assume that the firms act together so as to maximize joint overall profits.[1] It is assumed that each member of the cartel is forced to act as a price taker in buying grain and any other inputs to the marketing process. Also, suppose there exists a given, convex technology for taking unprocessed grain from the farm level, processing it, and bringing it to the market place, that can be represented by the functional relationship,

$$Q = \sum_{i=1}^{m} Q_i = F(\mathbf{x}),$$

where Q is grain as marketed; $\mathbf{x}$ is a vector of inputs to this processing function including unprocessed grain, storage, transportation, and such capital equipment as dryers and aerators; and F is a twice continuously differentiable, concave, and increasing function of its arguments. Following Diewert (pp. 74–75), the monopoly power of the cartel will be represented by the price relationship $p = wD(Q)$, where p is the price of the grain sold by the cartel, D is assumed to be differentiable, and $w > 0$ represents a shift parameter reflecting demand conditions in the market.[2]

The solution to the cartel's profit-maximization problem defines the profit function,

$$(1)\quad \pi^*(w,\mathbf{v}) = \underset{p,Q,\mathbf{x}}{\text{Max}}\ (pQ - \mathbf{v}'\mathbf{x}),$$
$$= \underset{\mathbf{x}}{\text{Max}}\ \{wD[F(\mathbf{x})]\ F(\mathbf{x}) - v'\mathbf{x}\},$$

where $\mathbf{v}$ is a column vector of input prices. Hotelling's lemma, or a direct application of the envelope theorem, yields

$$(1a)\quad \Pi^*_w \equiv \frac{\partial \pi^*(w,\mathbf{v})}{\partial w} = DQ = \frac{pQ}{w} \equiv R(w,\mathbf{v}),$$

$$(1b)\quad \Pi^*_i \equiv \frac{\partial \pi^*(w,\mathbf{v})}{\partial \mathbf{v}_i} = -\mathbf{x}_i(w,\mathbf{v}),$$

$$(1c)\quad \pi^*(\lambda w,\lambda \mathbf{v}) = \lambda \pi^*(w,\mathbf{v}) : \lambda, w, \mathbf{v} > 0.$$

[1] If the cartel is composed only of large firms, it is probably accurate to suppose that profit maximization of the cartel would be their joint goal. On the other hand, if some of the large government marketing boards are involved in the cartel, then, following Bieri and Schmitz, it may well be inaccurate to presume short-run profit maximization since a marketing board may find it advantageous to manufacture price stability by manipulation of its stockholding policy. Their model, however, assumes that the cartel is concerned with the level of return to producers. Such is not necessarily the case if the major export firms are involved in the cartel.

[2] For example, w could be disposable personal income or even a linear homogenous function of other factors affecting international demand (see Diewert). Hence, this specification allows sufficient flexibility for the existence of competitors in the international market. Note that the more usual inverse demand formulation, $p = D(Q)$, is a special case of the above specification where $w = 1$. Thus, any conclusions drawn here extend directly to this more familiar case. For heuristic purposes the reader might conceptualize $D[F(\mathbf{x})]F(\mathbf{x})$ as a pseudo-production function as suggested by Diewert; w would then be the "price" associated with this pseudo-production function and the resulting profit function would be a function of input prices and the "price" of the pseudo-output.

This specification also implicitly assumes that the cartel is allowed to exercise its monopoly power over the consumers in the home countries of the cartel. Obviously this is somewhat unrealistic but considerably sharpens the results. Alternatively one could rely on a heroic assumption often used in trade analysis, i.e., there is no domestic consumption of the commodity in question by the exporting regions, to justify this specification.

That is, partial differentiation of the profit function with respect to w yields revenue deflated by w or the deflated revenue function; differentiation with respect to the ith factor price obtains minus the profit-maximizing demand $[\mathbf{x}_i(w,\mathbf{v})]$ for the ith input; and the profit function is linear homogenous in w and $\mathbf{v}$. Letting

$$\Pi^*_{iw} = \frac{\partial^2 \pi^*(w,\mathbf{v})}{\partial \mathbf{v}_i \partial w},$$

it follows that $\Pi^*_{iw} = \Pi^*_{wi}$. A direct consequence of this fact, the concavity of $F(\mathbf{x})$ and $(a - c)$, is that the matrix defined by

$$\text{(2)} \quad \begin{bmatrix} \Pi^*_{11} & \Pi^*_{12} & \cdots & \Pi^*_{1n} & \Pi^*_{1w} \\ \Pi^*_{21} & \Pi^*_{22} & \cdots & \Pi^*_{2n} & \Pi^*_{2w} \\ \cdot & & & & \\ \cdot & & & & \\ \Pi^*_{n1} & \Pi^*_{n2} & & \Pi^*_{nn} & \Pi^*_{nw} \\ \Pi^*_{w1} & \Pi^*_{w2} & & \Pi^*_{wn} & \Pi^*_{ww} \end{bmatrix} \equiv \nabla^2 \Pi^*$$

is positive semidefinite and symmetric; and further, that (see Diewert, p. 75)

$$\text{(2')} \quad \nabla^2 \Pi^* \begin{bmatrix} \mathbf{v} \\ w \end{bmatrix} = \mathbf{0}_{n+1},$$

where $\mathbf{0}$ represents a vector containing only zeroes. Put another way, the fact that the profit function is linear homogenous in factor prices and $w(c)$ coupled with its derivative property (a and b) implies, by a basic property of homogenous functions, that the derived factor demands of the cartel are homogenous of degree zero in factor prices and w, which in turn implies that $\nabla^2 \Pi^*$ is singular.

Because a cartel operates on the basic principle of increasing profits by effectively rationing the amount of processed grain it sells, one might expect that cartel sales are lower than sales associated with free trade. Obviously, this need not always be true since there may be certain demand and supply conditions under which the volume of sales would coincide. Furthermore, in a dynamic framework with the possibility of stockholding, there could exist cases where the cartel might actually sell more than under competitive conditions. At any one point in time, however, it does not seem unreasonable to assume that cartel sales usually will be lower than those under competition. If this is the case, and the possibility of storing processed grain is abstracted from, the formation of a cartel should lead to a lower processing rate than under free trade. Heuristically, a lower processing rate is associated with a lower factor utilization rate and hence a lower derived factor demand. This should be especially true of the main ingredient to the process $F(\mathbf{x})$—unprocessed wheat. At an intuitive level, one thus expects that the demand for unprocessed wheat under a cartel is less than under a competitive system. It is important to recognize that this does not follow from an attempt by the cartel to extract monopsonistic profits from suppliers of raw materials, rather it is a direct result of the fact that monopoly profits generally accrue as a result of restricting the level of sales and an effective auctioning policy. Although the equilibrium price for wheat at the farm level in the final analysis will be the result of demand and supply interaction, it might be expected that under certain realistic conditions the farmgate price (and farm revenues) will be lower under a cartel than under competition because it is likely that the demand for unprocessed wheat under a cartel will be less than under competitive conditions. Therefore, it appears that farmers may have no incentive to participate in this type of cartel unless there is some effective means to obtain a portion of the monopoly profits that accrue to the cartel. One means that does not affect cartel sales is to tax profits of the cartel at a constant rate and redistribute the proceeds to farmers. That is, if the government decides to tax away $(t \times 100)\%$ of the cartel profits, the cartel's profit maximization problem becomes

$$\underset{\mathbf{x}}{\text{Max}}\ t^*\{wD[F(\mathbf{x})]\ F(\mathbf{x}) - v'\mathbf{x}\},$$

where $t^* = (1 - t)$. Of course, the solution to this problem in terms of the utilization of $\mathbf{x}$ is the same as for the original cartel problem. Hence, pretax cartel profits and factor utilization are the same as in the original problem. However, the taxing authority now has $t\pi^*(w,\mathbf{v})$, which can be redistributed among the various factors.

The interested reader should note that this result actually is a much weaker result than that reported in a recent paper by Carter, Gallini, and Schmitz. Their paper shows that producers conceivably could be worse off under a government-operated export cartel—i.e., one which actually takes producer surplus at the farm level into account—than under free trade. Furthermore, Carter, Gallini, and Schmitz present some empirical evidence to suggest that under present demand and supply conditions this would be the case if such a government-operated cartel is formed.

The Linkage between Cartel Profits, Factor Payments, and Cartel Prices

These assumptions and results can be used to investigate further the relationship between conditions in the international market (as represented by w) and the domestic market for the factors of production. First, note that by (1*a*) and (1*b*) above, an increase in w (caused by, say, a shortfall in world production such as a failure of the Soviet crop) or a decrease in any factor price will increase cartel profits.

Before proceeding to the general analysis, however, it is convenient to state as a lemma a partial version of a theorem due to Takayama. This result plays an important role in the ensuing analysis of the linkage between cartel profits, factor payments, and cartel prices.

LEMMA: *Let B be an $n \times n$ matrix whose off-diagonal elements are all nonnegative. Then the following conditions are mutually equivalent:*

(*a*) *There exists a vector* $\mathbf{x} \geq 30$ such that $B\mathbf{x} < 0$.

Proof: See theorem 4.*D*.3 of Takayama (p. 393).

This result is particularly important because of the singularity of $\nabla^2\Pi^*$. In carrying out the comparative static analysis of the model, it is essential to have conditions which insure consistent invertibility of the fundamental comparative static equation.

Using (*b*), simultaneous equilibrium in the factor markets is representable as

$$(3) \quad -\Pi^*_i\,(w,\mathbf{v}) = S_i\,(\mathbf{v}_i) = Q_i \qquad i = 1, 2, \ldots, n,$$

where $S_i\,(\mathbf{v}_i)$ is the domestic supply situation and Q_i is the equilibrium quantity exchanged. Note that all sources of demand for the factors of production other than the cartel are abstracted from in the following. Hence, the comparative static effect of a change in w on factor prices in matrix form is

$$(4) \quad \begin{bmatrix} (-\Pi^*_{11} - S_{11}) & -\Pi^*_{12} & -\Pi^*_{1n} \\ -\Pi^*_{21} & (-\Pi^*_{22} - S_{22}) & -\Pi^*_{2n} \\ \vdots & & \\ -\Pi^*_{n1} & -\Pi^*_{n2} & (-\Pi^*_{nn} - S_{nn}) \end{bmatrix} \begin{bmatrix} dv_1 \\ dv_2 \\ \\ dv_n \end{bmatrix} = \begin{bmatrix} \Pi^*_{1w} \\ \Pi^*_{2w} \\ \\ \Pi^*_{nw} \end{bmatrix} dw,$$

where $S_{ii} = \dfrac{\partial S_i}{\partial v_i}$. Converting to elasticity form obtains

$$(4') \quad \begin{bmatrix} (\epsilon_{11} - \Theta_{11}) & \epsilon_{12} & \epsilon_{1n} \\ \epsilon_{21} & (\epsilon_{22} - \Theta_{22}) & \epsilon_{2n} \\ \vdots & & \\ \epsilon_{n1} & \epsilon_{n2} & (\epsilon_{nn} - \Theta_{nn}) \end{bmatrix} \begin{bmatrix} \hat{\mathbf{v}}_1 \\ \hat{\mathbf{v}}_2 \\ \\ \hat{\mathbf{v}}_n \end{bmatrix} = - \begin{bmatrix} \epsilon_{1w} \\ \epsilon_{2w} \\ \\ \epsilon_{nw} \end{bmatrix} \hat{w},$$

where $\epsilon_{ij} = \dfrac{\partial \mathbf{x}_i}{\partial \mathbf{v}_j} \dfrac{\mathbf{v}_j}{Q_i} = \dfrac{-\Pi^*_{ij}}{Q_i}\,\mathbf{v}_j$, $\Theta_{ii} = \dfrac{\partial S_i}{\partial \mathbf{v}_i} \dfrac{\mathbf{v}_i}{Q_i}$, $\epsilon_{iw} = \dfrac{\partial \mathbf{x}_i}{\partial w} \dfrac{w}{Q_i} = \dfrac{-\Pi^*_{iw}}{Q_i}\,w$, and carets denote percentage change. Without loss of generality, let us examine $\hat{\mathbf{v}}_1$. Cramer's rule implies

$$(5) \quad \frac{\hat{\mathbf{v}}_1}{\hat{w}} =$$

$$\frac{\begin{vmatrix} -\epsilon_{1w} & \epsilon_{12} & \epsilon_{1n} \\ -\epsilon_{2w} & (\epsilon_{22} - \Theta_{22}) & \epsilon_{2n} \\ \vdots & & \\ -\epsilon_{nw} & \epsilon_{n2} & (\epsilon_{nn} - \Theta_{nn}) \end{vmatrix}}{\begin{vmatrix} (\epsilon_{11} - \Theta_{11}) & \epsilon_{12} & \epsilon_{1n} \\ \epsilon_{21} & (\epsilon_{22} - \Theta_{22}) & \epsilon_{2n} \\ \vdots & & \\ \epsilon_{n1} & & (\epsilon_{nn} - \Theta_{nn}) \end{vmatrix}} = \frac{\begin{vmatrix} -\epsilon_{1w} & \epsilon_{12} & \epsilon_{1n} \\ -\epsilon_{2w} & (\epsilon_{22} - \Theta_{22}) & \epsilon_{2n} \\ \vdots & & \\ -\epsilon_{nw} & \epsilon_{n2} & (\epsilon_{nn} - \Theta_{nn}) \end{vmatrix}}{\begin{vmatrix} (-\epsilon_{1w} - \Theta_{11}) & \epsilon_{12} & \epsilon_{1n} \\ (-\epsilon_{2w} - \Theta_{22}) & (\epsilon_{22} - \Theta_{22}) & \epsilon_{2n} \\ \vdots & & \\ (-\epsilon_{nw} - \Theta_{nn}) & & (\epsilon_{nn} - \Theta_{nn}) \end{vmatrix}}$$

The second equality follows from (2′), which implies that $\sum_{j=1}^{n} \epsilon_{ij} = -\epsilon_{iw}$ and the fact that adding columns of a matrix does not change its determinant (e.g., theorems 1.5.2 and 1.5.7 of Graybill). General statements about the sign of (5) do not seem available; however, some important special cases do exist. For example, suppose that the supply of each factor is perfectly inelastic ($\Theta_{ii} = 0$); the immediate conclusion from (5) is that $\frac{\hat{v}_1}{\hat{w}} = 1$. If factor supply is perfectly inelastic a strengthening in international demand reflected by an increase in w leads to an equal percentage increase in the level of all factor prices. Also recall that by (2′),

$$(6)\quad \begin{bmatrix} -\Pi^*_{11} & -\Pi^*_{12} & \cdots & -\Pi^*_{1n} \\ -\Pi^*_{21} & -\Pi^*_{22} & \cdots & -\Pi^*_{2n} \\ \vdots & & & \\ -\Pi^*_{n1} & -\Pi^*_{n2} & \cdots & -\Pi^*_{nn} \end{bmatrix} \begin{bmatrix} v_1 \\ v_2 \\ \vdots \\ v_n \end{bmatrix}$$

will be negative (positive) if the vector $\Delta' = [\Pi^*_{1w} \text{----} {}^*_{nw}]$ is negative (positive). Given that all $S_{ii} > 0$, this implies

$$(6')\quad \begin{bmatrix} (-\Pi^*_{11} - S_{11}) & -\Pi^*_{12} & & -\Pi^*_{1n} \\ -\Pi^*_{21} & -\Pi^*_{22} - S_{22} & & -\Pi^*_{2n} \\ \vdots & & & \\ -\Pi^*_{n1} & -\Pi^*_{n2} & & (-\Pi^*_{nn} - S_{nn}) \end{bmatrix} \begin{bmatrix} v_1 \\ v_2 \\ \vdots \\ v_n \end{bmatrix}$$

will be negative if Δ is negative. If it is further assumed that all of the off-diagonal elements of the matrix on the left-hand side of (4) are nonnegative, i.e., all factors of production are substitutes (in the sense that $\Pi_{ij} < 0$), then the above lemma implies that the solution vector $dv = [dv_1, \ldots, dv_n]'$ associated with (4) will be positive. Thus, in the case where $\Delta < 0$ and all factors are substitutes an increase in w leads to an increase in all factor prices. In two special cases, therefore, it is possible to unambiguously sign the vector dv.

Consider, however, what it means for Δ to be negative. Recall that $\Pi_{iw} = \Pi_{wi} = \frac{\partial R}{\partial v_i}$. Thus, for each element of Δ to be negative, it is necessary that the marginal effect on cartel revenues (deflated by the shifter w) of a change in each factor price be negative. In other words, an increase in any factor price, *ceteris paribus,* must lead to a fall in adjusted revenues. Further, it follows from (2′) and the symmetry of $\nabla^2\Pi^*$ that

$$(7)\quad \frac{\partial R}{\partial v_i} = \frac{\sum_{j=1}^{n} v_j \frac{\partial x_i}{\partial v_j}}{w}.$$

Hence, a sufficient condition for (7) to be negative is that all factors be complements (in the sense that $\Pi_{ij} > 0$). Yet, to invert the relationship in (4) and obtain a unique sign for dv, it was assumed that all goods are substitutes. Multiplying both sides of (7) by $\frac{1}{x_i} > 0$ and rewriting in elasticity form yields

$$(7')\quad \frac{\partial R}{\partial v_i} \frac{1}{x_i} = \frac{\sum_{j=1}^{n} \epsilon_{ij}}{w}.$$

So, given a world of substitutes and that

$$\frac{\partial x_i}{\partial v_i} < 0,$$

a necessary condition for $\frac{\partial R}{\partial v_i}$ to be negative is that $|\epsilon_{ii}| > \left| \sum_{j \neq i}^{n} \epsilon_{ij} \right|$, i.e., the sum of the cross-price elasticities be less than the own-price elasticity in the absolute value. These results establish:

PROPOSITION A: *Given the model specified above, all factor prices will be unit elastic with respect to* w *if factor supply is completely inelastic for all factors.*

PROPOSITION B: *In a world of substitutes, if each $S_{ii} > 0$ and for all factors the absolute value of the own-price elasticity exceeds the absolute value of the sum of the cross-price elasticities all factor prices will rise if* w *rises.*

Before we proceed further, it is worthwhile to examine just what type of behavior one would expect from such a cartel is substitutability is assumed. Substitutability implies that if the price of the ith input rises, then demand for all other inputs will rise as the cartel substitutes out of the now relatively more expensive input. This may seem quite intuitive, but it ignores the peculiar character of the cartel under discussion. Among the inputs to the processing function $[F(\mathbf{x})]$, a key ingredient is

unprocessed wheat. If the price of unprocessed wheat rises, one should not expect the cartel to substitute all other inputs. Rather, one expects unprocessed wheat to be a complement with at least some of the other inputs into the F process.[3]

The preceding arguments demonstrate some sufficient conditions for the solution (**dv**) to (4) to assume an unambiguous sign. However, the very restrictive nature of the assumptions, zero elasticity in the one case and everywhere substitutability in the other, suggests that it is unlikely that **dv** in (4) will ever assume, a priori, a unique sign. If this is so, then in general one cannot a priori prèsume that any element of **dv** will be positive. Hence, we have not been able to establish that an increase in w which does lead to higher cartel profits will also lead to higher farmgate prices for wheat. By the same token, precious little information is available for determining the effect on other input prices of an increase in w. Cartelizing, therefore, may not insure that farmers or the owners of these factors will reap higher returns for their wheat if the cartel attempts to maximize joint profits.

Turning to the effect on cartel price of an increase in w and thus, to some extent, to the linkage between the cartel price and the price of wheat to farmer,[4] differentiate the optimal cartel price $p^* = wD[F(\mathbf{x}^*)]$, where $\mathbf{x}^* = [-\Pi^*_1, \ldots, -\Pi^*_n]'$ with respect to w to obtain

$$(8)\quad \frac{\partial p^*}{\partial w} = D + w\frac{\partial D}{\partial F}\left[\sum_{j=1}^{n}\frac{\partial F}{\partial \mathbf{x}^*_j}\frac{\partial \mathbf{x}^*_j}{\partial w}\right] = D - w\frac{\partial D}{\partial F}\left[\sum_{j=1}^{n}\frac{\partial F}{\partial \mathbf{x}^*_j}\frac{\partial R}{\partial \mathbf{v}_j}\right].$$

The second equality follows from the symmetry of $\nabla^2\Pi^*$, which implies that $\frac{\partial \mathbf{x}^*_i}{\partial w} = -\frac{\partial R}{\partial \mathbf{v}_i}$. If it is assumed that $\frac{\partial R}{\partial v_j} < 0$ for all j, then the sign of (8) is a priori indeterminate. This forces the conclusion that one cannot always establish a unique relationship between the price farmers receive for their wheat and the cartel price because, as demonstrated above, a sufficient condition for the farmgate price to increase is that all $\frac{\partial R}{\partial \mathbf{v}_j} < 0$. For example, suppose that all factors are indeed substitutes and, further, that the own-price elasticity dominates the cross-price elasticities in all cases. As demonstrated above, this assures that **dv** in (4) will be unambiguously positive, i.e., an increase in w will lead to higher returns for each factor. Now return to (8). Since the price the cartel will charge, *ceteris paribus*, is a decreasing function of its sales and marginal product is always positive, then the second term after the second equality necessarily will be negative when $\frac{\partial R}{\partial \mathbf{v}_j} < 0$, for all j. The first term, however, is positive and a priori there is no way to determine whether the absolute value of the first term dominates that of the second or vice-versa. If the second (first) dominates the first (second), then (8) is negative (positive).

To recapitulate, it has been established that an increase in w, reflecting, say, a shortfall in world production, leads to higher cartel profits and possibly higher farm level and cartel prices. In fact, if one retreats to a one input model (with a downward sloping factor demand curve) one can unambiguously conclude that the farm level wheat price would rise. This, however, is not the general result, and it remains a possibility that an increase in w actually could lead to a lower price for wheat at the farm level. Intuitively, one might suspect that the price of wheat at the farm level will rise while, say, the price of storage would fall as less storage is demanded, but the possibility of a paradox still remains. One policy recommendation is to insure that increased demand does lead to higher returns for wheat farmers by levying a proportional tax on the cartel and distributing the tax revenues among the factors.

Cartel Stability

One of the most important problems facing any cartel is the problem of cartel stability since a cartel has to survive to be of any long-run consequence. Some of the major barriers to stability are external competition, sharing of cartel revenues, locating the contract surface, and detecting and deterring cheating by members. To some extent we have already investigated via w the response of the cartel to external competition.

---

[3] Of course, more care, that is, more usage of other factors, will allow the processor to extract more processed wheat from a given amount of unprocessed wheat and there is a possibility for some local substitution. However, this effect is limited and there is definitely a point beyond which unprocessed wheat cannot be substituted for.

[4] We would like to thank an anonymous reviewer for suggesting this area of research.

Cheating, however, is perhaps the most important problem any cartel faces. For a cartel to be effective, it is necessary that all firms cooperate and not exceed the optimal level of sales, or cartel profits will fall. Extensive, sustained cheating will almost certainly break a cartel because cheating by one or more members leads to lower profits for all other members of the cartel; thus, there is little incentive for these members to cooperate in cartel arrangements. However, all firms participating in this type of cartel have the incentive to cheat. This is a well-known result which is easily explained. Suppose that the cost function of the ith cartel member can be represented as $C_i(Q_i)$. Profit maximization for the cartel requires

$$(9) \qquad w\left[D + Q\frac{\partial D}{\partial Q}\right] = \frac{\partial C_i}{\partial Q_i}.$$

Now, if each firm were to maximize its own profits (assuming that the pricing structure does not change), it would act in such a manner that

$$(10) \qquad w\left[D + Q_i\frac{\partial D}{\partial Q}\right] = \frac{\partial C_i}{\partial Q_i}.$$

Hence, profit maximization for the cartel requires each firm to equate its marginal cost to the marginal revenue of the cartel as whole; whereas, in maximizing its own profits, the firm equates its marginal cost to its marginal revenue. Evaluating (9) and (10) at the optimal cartel output Q^* obtains

$$(11) \qquad \frac{\partial C_i(Q^*_i)}{\partial Q_i} = w\left[D + Q^*\frac{\partial D(Q^*)}{\partial Q}\right] \leq w\left[D + Q^*_i\frac{\partial D(Q^*)}{\partial Q}\right],$$

since $Q^*_i \leq Q^*$ by definition. Thus, each firm's marginal revenue is greater than or equal to its marginal cost at the cartel point. Consequently, each firm has an incentive to expand its output. However, an expansion of output by even one firm would lead to a fall in cartel profits. This problem can be represented graphically using the isoprofit contours for each firm. The contract curve of possible cartel solutions is the locus of tangencies between the isoprofit curves of the n firms (e.g., $\Pi_j{}^i$), i.e., points which are Pareto optimal in the sense that movement away from them signals a decline in profits for at least one member of the cartel. Therefore, in the two-firm case we can represent the contract curve as DD in figure 1, where superscripts represent decreasing levels of profit and subscripts represent firms (e.g., $\Pi_1{}^2 > \Pi_1{}^1$).

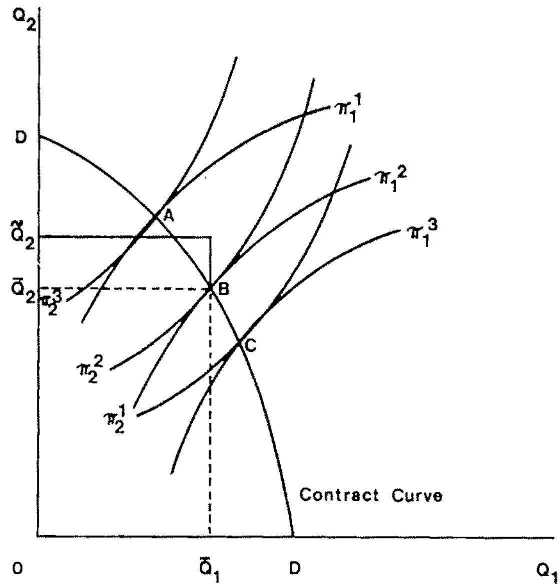

Figure 1. The optimal cartel solution

Once the cartel locates the contract curve and chooses a cartel point, say B, suppose the second member of the cartel decides to cheat by increasing exports from the cartel amount $\bar{Q}_2$ to $\tilde{Q}_2$ in figure 1. While this increases profits above profit level $\Pi_2{}^2$, the profits of the other cartel member falls below $\Pi_1{}^2$, which in turn is an incentive for the loyal member to diverge from the cartel solution. In game-theoretic terms, the cartel faces a prisoner's dilemma, where as a whole the cartel is better off if no one cheats but each individual has an incentive to cheat.

However, it is easy to demonstrate that the objective function of the above cartel will allow the application of the quota rule established and discussed in Osborne (1976, 1978) and Holahan to deter cheating. We define

$$S_i = \frac{\bar{Q}_i}{\sum_{j=1}^{n} \bar{Q}_j}$$

as the ith firm's market share at the cartel point $[\bar{Q} = (\bar{Q}_1, \bar{Q}_2, \ldots, \bar{Q}_n)']$. Osborne's quota rule for the ith member of the cartel is to process and sell

$$\text{Max}\left[\bar{Q}_i, \bar{Q}_i + S_i \frac{\sum_{k\epsilon K}\Delta Q_k}{\sum_{k\epsilon K} S_k}\right],$$

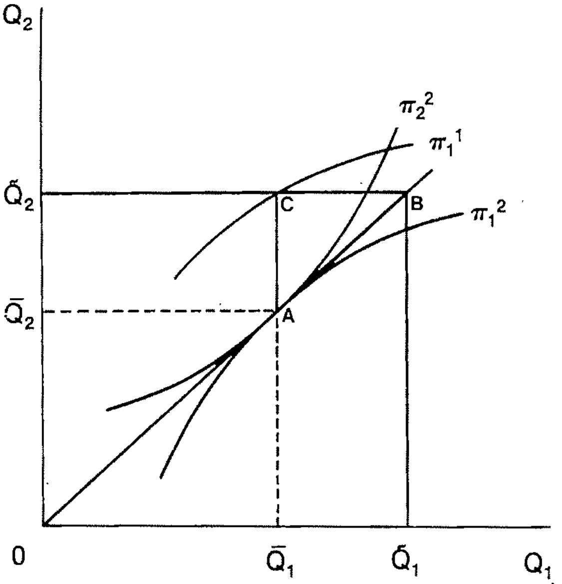

Figure 2. The ray property and cheating

where ΔQ_k is the amount by which the kth member of the cartel cheats and K represents the group of cheaters. In other words, to prevent cheating, each firm maintains a constant market share. In the case of a two-member cartel, this decision rule is demonstrated in figure 2. Let A represent the cartel point. If the second member decides to cheat by exporting $\tilde{Q}_2$ instead of $\bar{Q}_2$, the first firm's response under the quota rule would be to sell $\tilde{Q}_1$, which is the amount necessary to maintain the same share as at the cartel point. If firm 2 expects firm 1 to react in this fashion it will not usually cheat because at B, its profit is lower than at A. Furthermore, in most cases firm 1 will have the incentive to move to B, because it loses less profit than if it remained at C without retaliating. Osborne demonstrates that maintaining market share is effective in preventing cheating only if the hyperplanes tangent to each member's isoprofit surface intersect in a line which is ray from the origin.[5] If the cartel point satisfies this condition, it is said to have the "ray property." Holahan demonstrates that cartels of the type discussed above have the critical "ray property" that makes Osborne's quota rule an effective method of deterring cheating in many instances.

Given that there appears to be a feasible deterrence program that the cartel could enact to limit cheating, we turn to the problem of discovering cheating. Deterrence is only effective if cheating is discovered. For the case of the international wheat market, it could be argued that there would be a time lag between cheating and discovery. All of the major grain companies maintain highly sophisticated information networks, as do the governments of the major exporters, with various methods including inspection programs. Hence, although there may be a time lag involved in the discovery process, it should be relatively short and probably could be compensated for by following Osborne's suggestion and adjusting the quota rule so as to keep the expected vector of sales on the ray from the origin.

The final problem facing the cartel, therefore, is the sharing of cartel revenue. Basically stated, a firm will not participate in the cartel if it can expect to achieve a higher return by acting outside the cartel or by buying out the other members of the cartel and acting as a pure monopolist.[6] The latter point may not be particularly relevant for members of an international cartel that may include some government-owned corporations (such as the Canadian Wheat Board), but it should be considered for completeness' sake. That the firms can earn more in a cartel that rigorously enforces the market share rule suggested by Osborne is obvious from previous discussion. Osborne (1976, pp. 840–1) demonstrates that any solution to the cartel problem which has the "ray property" also insures that a member can be no better off by buying out the other cartel members. Therefore, maintenance of market share will provide a feasible means for sharing the cartel revenues while it simultaneously deters cheating. In this respect, the solution to the sharing problem is very similar to that detailed for a triopoly model suggested in Alaouze, Watson, and Sturgess.

Concluding Remarks

Much discussion in the popular press has centered on the feasibility of major grain ex-

[5] Holahan has noted that in the case of extremely antisymmetrical cost structures it may not pay firm 1 to move to a point on the ray from the origin. However, we agree with Osborne's (1978) reply that this seems to be fairly unimportant in practice. The reader will also note that there have been other proposals that rely on maintenance of market share to prevent cheating. For example, Alaouze, Watson, and Sturgess have constructed a triopoly model of wheat pricing that explicitly assumes a bounded price leader-follower relationship. Within the price bounds, it is assumed that members maintain a constant market share and respond to cheating in a manner that will preserve this share. Recall, however, that the triopoly model of Alaouze, Sturgess, and Watson does not have the same objective function as the present cartel, and hence, the arguments above about the applicability of Osborne's rule to the problem at hand are not necessarily equivalent to those necessary for their model.

[6] Here again, it is assumed that firms are profit maximizers (see footnote 1). If some members of the cartel are government-owned corporations with a different objective function, say revenue maximization, these arguments must be modified somewhat.

porters forming a cartel to exploit potential monopoly profits that might exist in the international grain market. The present paper has analyzed the impacts of the formation of such a cartel with the explicit objective of joint profit maximization. It has been demonstrated that without some fairly strong assumptions, e.g., substitutability, fluctuations in international demand might evoke different responses on the part of the cartel profits and the farm level price for wheat. Furthermore, if substitutability in factor demand is assumed, then one can show that an increase in international demand could lead to a drop in cartel price and a rise in the price of wheat as paid to the farmer. The restrictive nature of these assumptions, however, illustrates the difficulty of establishing what appears to be a fairly intuitive result. More specifically, it has been demonstrated that if all factor supplies are completely inelastic, the response of factor prices to an increase in w will be positive and unit elastic. Further, if substitutability in factor demand and own-price dominance of cross-price effects is assumed, then an increase in w will lead to an increase in all factor prices. An increase in w will always lead to an increase in cartel profits but, a priori, will be associated unambiguously with a rise in cartel price if the differential effect $\frac{\partial R}{\partial \mathbf{v}_j}$ is positive for all j.

Thus, it has been demonstrated that even if cartel profits rise, there is no reason to expect that the price of wheat at the farm level necessarily will rise. Hence, the economic surplus captured by forming a cartel may not filter down to the farm level. Politically, of course, this would be hard to justify. However, among several alternatives, it is always possible to levy a straight percentage tax on profits to capture some of this surplus and redistribute it to farmers. The feasibility of such a policy action is, of course, another question. The track record of past efforts at this type of taxation is not encouraging. Consequently, it may be necessary for the governments involved to intervene more directly in the marketing and production process if a portion of this economic surplus is to be captured for the factors. The obvious implication of this result is that there may well be cases where government-operated export cartels, which consider consumer and producer returns in addition to the level of cartel profits, would be appropriate. This, of course, is a normative question and remains outside the framework of this analysis. Further research, both theoretical and empirical, along these lines is needed.

Because a cartel must survive to be of any long-run consequence, some time also has been spent showing that the cartel under analysis is capable of overcoming some of the divisive factors that ordinarily might lead to a breakdown of the cartel. In the main, these results follow directly from Osborne's quota solution to cartel problems.

The discussion of Osborne's quota rule and its application to the problem at hand, however, raises an interesting issue. If Osborne's quota rule is used to impose a solution on the members of the cartel, i.e., specify a particular level of sales for each firm, it follows that each firm will not necessarily face a differentiable demand relationship. This is important because it implies that if the cartel in question is itself a "firm" that is operating in a larger cartel (say, a national grain-exporting company in a multicountry cartel) then there will not necessarily exist a differentiable relationship between price and quantity for this minicartel if the larger cartel is implementing Osborne's quota rule. Hence, some of the specific results of the preceding analysis may be valid only where the cartel in question does not participate in a larger cartel.[7] This, however, does not change the general conclusion that formation of a wheat-exporting cartel need not lead to higher farmgate prices and a positive correlation between cartel profits and the farmgate price of wheat. Obviously, the above model serves as a counter-example to such a conclusion.

Although it has not been discussed explicitly, there is the definite possibility that a good part of the potential monopoly profits could be erased by monopsony power on the part of the importers. Indeed, this is the gist of the recent paper by Carter and Schmitz, who demonstrate that importers may be exploiting their monopsony situation. If correct, the Carter-Schmitz result is really a further argument for the formation of some type of cartel or cooperative export arrangement, since not cartelizing leaves the exporters in the rather uncomfortable position of knowing that they are being exploited while not doing anything about it. Forming a cartel at least would help to counteract some of the bargaining power of the importers. Of course, this leads to a bilat-

[7] We would like to thank Chris M. Alaouze for bringing this point to our attention.

eral monopoly situation which is outside the scope of the present paper but should be the topic of further research, perhaps along the lines suggested by McCalla (1977).

Academic Freedom and Peer Reviews of Research Proposals and Papers

R. L. Berry

Academic freedom—the freedom of professional persons to present unpopular views—can exist only when there is freedom from severe sanctions such as censorship of research proposals and papers. Peer reviews are invaluable to researchers struggling to improve their work. They are also invaluable to administrators who must allocate limited funds and journal pages among competing researchers. However, evidence indicates that some administrators use peer criticisms to justify the suppression in whole or part of unpopular proposals and papers. Such prior restraint is censorship unless the administrators can prove that it is justified because of gross incompetence or financial exigency.

Key words: academic freedom, censorship, peer reviews, research papers, research proposals, responsibilities.

For excellence in teaching and research, two things are needed: excellent professional workers and excellent working conditions. Of the working conditions, one of the most difficult to achieve and maintain is academic freedom—also sometimes called intellectual, individual, or scientific freedom. But what is academic freedom? What are its limits? If there are limits, how can they be set? By whom?

Special interests—powerful persons or groups on or off the campus—often limit academic freedom. They may limit by their mere presence, but sometimes they take direct action to intimidate administrators who, in turn, limit academic freedom. Political scientist Charles Hardin found that special interests often set such limits in the U.S. Department of Agriculture (USDA) and the State Agricultural Experiment Stations (SAES) between 1930 and 1955. In 1972 a Committee on Research, created by the National Research Council of the National Academy of Science, found in both USDA and SAES a "shocking amount of low quality research," which it held was due largely to heavy-handed bureaucratic administration that was reducing "individual freedom, motivation and creativity" (p. 15).

The Committee recommended increased use of peer review committees for proposed research similar to those used for awarding research contracts or grants and the review of journal papers. Partially in response to this criticism, the USDA through its Scientific and Educational Administration-Cooperative Research (SEA-CR) has asked all SAES to arrange peer reviews for all research proposals to be submitted to it for some of the federal research funds which it administers. Because the peer reviews are to be similar to those used for the review of research papers, they may be discussed together.

Granted that a peer review is a valuable research tool, is it not a two-edged sword? Is it not possible that peer criticism may be used by timid or fearful administrators to suppress certain kinds of research and suppress in whole or in part research reports or papers? If so, what safeguards are needed to make sure that peer reviews increase rather than decrease academic freedom? My purpose is to answer these questions by critically reviewing the literature concerning (*a*) the limits of academic freedom, (*b*) some legitimate uses of peer review committees, and (*c*) the dangers to academic freedom when peer reviewers are asked to evaluate critically in-house research proposals or papers.

Russell L. Berry is an associate professor of economics, South Dakota State University and Agricultural Experiment Station.

Valuable suggestions for improving this paper were made by Thomas E. Daves, Thomas L. Dobbs, and Richard C. Shane. T. W. Schultz, Don Paarlberg, and an anonymous reviewer also provided helpful suggestions. The author accepts full responsibility for the views expressed.

Academic Freedom: What Are Its Limits?

The word freedom means without limits bounds. But what is academic freedom? It is considerably more than what is usually meant by intellectual freedom. It gives scholars and scientists freedom to seek and report the truth as they see it to students and the public in both oral and written form and is made possible by freedom from sanctions which may be imposed by powerful persons or groups on or off the campus. This definition is a restatement of definitions by others. Because of their importance, these definitions also are given here.

Philosopher Arthur Lovejoy declares that "academic freedom is the freedom of the teacher or research worker in higher institutions of learning to investigate and discuss the problems of his science and to express his conclusion whether through publication or in the instruction of students without interference from political or ecclesiastical authority, or from the administrative officials of the institution in which he is employed unless his methods are found by qualified bodies in his own profession to be clearly incompetent or contrary to professional ethics" (p. 384).

Economist Fritz Machlup declares academic freedom exists when there is "protection from" powerful persons or groups on or off the campus who would use restraints, pressures, or sanctions to create in the minds of researchers, teachers, and students "fears and anxieties" that may inhibit their freedom to seek the truth and discuss, teach, or publish "whatever opinion they may have reached" (p. 178).

Philosopher Sidney Hook states that "academic freedom . . . is the freedom of professionally qualified persons to inquire, discover, publish and teach the truth as they see it in the fields of their competence." Hook makes clear that this "freedom . . . to" can exist only when there is freedom from administrative controls when he declares "it is subject to no control or authority except the control . . . of . . . rational methods" (p. 34). Hook also emphasizes that professionals must have the freedom to present the truth "as they see it"—not as others see it. Furthermore, he insists they have "the right to be wrong"—the right to be honestly mistaken; that without this right there can be no academic freedom (pp. 36–7).

In 1973 the Committee for Economic Development (CED) assembled a distinguished panel consisting of college administrators and business leaders who defined academic freedom as "the principle that individuals, both faculty and students, should not be inhibited or restrained by external forces or threat of censure in the search for knowledge and the presentation of information and ideas whether in the classroom, in publications, or through other means of communication" (p. 56).

Perhaps the most widely accepted definition of academic freedom is provided by the 1940 *Statement of Principles on Academic Freedom and Tenure* jointly developed by the Association of American Colleges and the American Association of University Professors (AAUP, 1977a), which has now been endorsed by 107 professional organizations. The 1940 *Statement* declares that "the teacher is entitled to full freedom in research and the publication of the results . . . freedom in the classroom in discussing his subject . . . [and] when he speaks or writes as a citizen he should be free of institutional censorship or discipline" (p. 2). There are some cautionary words: "He should be careful not to introduce into his teaching controversial matter which has no relation to his subject"; but a note declares that "the intent of this statement is not to discourage what is 'controversial.' Controversy is at the heart of the free academic inquiry which the entire statement is designed to foster" (p. 3). Still, to avoid unnecessary controversy "he should at all times be accurate, should exercise appropriate restraint, should show respect for the opinions of others and should make every effort to indicate that he is not an institutional spokesman" (p. 2).

The 1940 *Statement* declares that all faculty members, whether tenured or not, should have these freedoms and they should not be dismissed or sanctioned for exercising them. Furthermore, to help protect academic freedom, faculty members who have completed a probationary period should be granted permanent or continuous tenure which may be broken only for "adequate cause" in a due process hearing such as provided for in AAUP's RIR—"Recommended Institutional Regulations on Academic Freedom and Tenure" (AAUP 1977b). When tenure is granted, the burden of proof regarding professional competence shifts from the faculty member to the administration. When there is clear evidence of professional incompetence or unfitness, this burden is not heavy. Only when there is considerable doubt does it become heavy—as it must be if tenure is to protect academic freedom.

Unfortunately, academic freedom can be destroyed by lesser sanctions than summary dismissal. When nontenured professors present unpopular views, they may not be reappointed. Also they may be punished by denial of promotion or normal pay increases. Finally, their proposals and papers may be suppressed or censored. But, when the professor can show that a "motivating factor" for dismissal or other sanctions may be a violation of civil rights, then the U.S. Supreme Court (*Mount Healthy* v. *Doyle* 1977) has held that those responsible must show by a "preponderance of the evidence" that the action was justified for other lawful reasons (Rabban, pp. 4–6).

Freedom to present unpopular views is not a popular concept. CED's distinguished panel of college presidents and trustees declared that "among major distinctive problems . . . of colleges, none is more critical than the preservation of academic freedom" and hence called for "policies and practices that will protect responsible intellectual freedom" (p. 24). The word "responsible" suggests limits. What limits? One limit is serious misconduct which violates the 1940 *Statement*'s academic responsibility provisions quoted above. Even when the administration holds that such violation by a professor justifies dismissal, it must prove its case in a due process hearing if its assurance of academic freedom is to be trusted. This the University of Illinois failed to do in 1960 when a biology professor wrote a letter to the student newspaper condoning premarital sex. AAUP's Committee A held that institutions might apply sanctions for misconduct if shown by a due process procedure to be warranted. Unfortunately, the University did not provide a satisfactory hearing and hence was censured.

What kind of a violation would justify sanctions? Ralph F. Fuchs, law professor, and former General Secretary of AAUP followed the 1940 *Statement* when, in a comment on the Illinois case, he declared "A violation may consist of serious intemperateness of expression, intentional falsehood, incitement to misconduct or conceivably some other impropriety of circumstance. It may not lie, however, in the error or unpopularity, even though gross, of the ideas contained in an utterance" (pp. 41–2).

Freedom, Responsibility, and Neutrality

Academic freedom like any other freedom creates responsibilities. The AAUP Statement of Professional Ethics declares that the professor's "primary responsibility to his subject is to seek and state the truth as he sees it" (AAUP 1977d, p. 65). But when the professor's views are controversial or unpopular, administrators come under heavy pressure to dismiss or apply other sanctions which would violate academic freedom.

To avoid this situation some administrators hold that professors must be neutral—they must present only the issues and the facts and not their conclusions or opinions about their significance. Administrators who hold this view sometimes charge that professors who incur the wrath of powerful people or groups have failed to observe a second responsibility, which is "to exercise critical self-discipline and judgment in using, extending and transmitting knowledge" (AAUP 1977d, p. 65). In some cases this may be true, but the burden of proof of such a charge must be on the administration. Otherwise the freedom to present controversial conclusions, views, and opinions evaporates.

Some people believe that teachers and researchers can handle any controversial subject simply by presenting "issues" and "facts" and then leaving hearers or readers to draw their own conclusions. Unfortunately, both issues and facts are often matters of opinion. Hence this does not resolve the difficulty. Furthermore, the refusal of an expert to take a stand is an acceptable position only when he is genuinely uncertain about what should be done. To do otherwise is to raise the question as to his professional integrity. Moreover, when academic freedom exists he must use it or lose it.

Sometimes, of course, there is nothing to lose. Some administrators limit freedom to popular conclusions, views, and opinions—a freedom that exists in the most repressive nations and institutions, for example, prisons.

Thus, institutional neutrality is essential if the teacher or researcher is to have academic freedom. This means that the faculty, its committees, and its administrators and editors, despite strong feelings and opinions they may have about the issues, must be officially neutral. If they are not officially neutral, academic freedom is impossible. As Solberg has emphasized, "the norm of neutrality is an essential safeguard of academic freedom" (p. 13).

In 1934, A. Lawrence Lowell, professor of law and then president of Harvard University, wrote, "If the university or a college censors

what its professors may say, if it restrains them from uttering something it does not approve, it thereby assumes responsibility for that which it permits them to say. This . . . is a responsibility which an institution of learning would be very unwise in assuming." He concludes that because "there is no middle ground," the university should be neutral (Taylor p. 396).

But can the university really be neutral? Some critics have pointed out that neutrality is also a position. Indeed it is, but it is the only position that permits full academic freedom and avoids censorship. Recently Harvard University has been urged to sell its stock in corporations doing business in South Africa because of its racial policies. President Derek Bok has been criticized for his refusal to do so, but it should be remembered that the university consists of all of its scholars and scientists. If they value academic freedom, they should not attempt to judge such issues by the ballot box nor permit their administrators to take action pro or con in their name. Either way, academic freedom in this area would be destroyed. Unpopular positions would be beyond the pale.

It is also argued that the university cannot afford to be neutral—cannot afford full or unlimited freedom for fear that professors will publish errors that will destroy not only their own reputations but also that of their colleagues, their department, college, and institution. Hence it is argued that peer reviewers should not only help the author avoid errors of omission or commission but also should be able to suppress the work in whole or part until it meets with their approval. Because this is the central issue of this paper, further discussion will be delayed until the legitimate functions of peer review committees have been critically examined.

Peer Review Committees: Their Legitimate Uses

The word peer means equal, not superior. Yet, some peers also are made superiors. For example, college administrators often are chosen for their excellence as peers and they do not lose their professional competence the moment they are appointed administrative superiors. In like manner, peer review committees also may become superiors when they are given certain administrative duties. Why should they be given such duties? First, because they are the most competent people available to make recommendations concerning teaching, research, and other educational matters. Second, because they must cooperate if administrative decisions are to be carried out. Third, because this cooperation is more likely to be secured when decisions are jointly made.

These reasons support the principle of "shared authority" found in the "Statement on Government of Colleges and Universities," which would give the faculty the major voice "in such fundamental areas as curriculum, subject matter and methods of instruction, research, faculty status and those aspects of student life which relate to the educational process" (AAUP 1977c, p. 43). For example, peer review committees should be asked to make recommendations when decisions must be made to appoint, reappoint, promote, grant tenure, or dismiss faculty members. Furthermore, administrators should reject peer recommendations "only in exceptional circumstances, and for reasons communicated to the faculty" (p. 43). Even then, when possible, the review committee should be given an opportunity to reconsider before a final decision is made. Thus, faculty or peer committees may be used legitimately whenever administrative decisions must be made about the allocation of educational resources.

Research Grants and Journal Space

Thus, when institutions make grants of research funds or journal space, they may properly use peer review committees to referee the competition. Because funds and pages are limited, it often happens that some research proposals and papers must be rejected. While both can be rejected for reasons that violate academic freedom, this does not necessarily follow peer review. Indeed, peer reviewers can do much to protect academic freedom. Because of their expertise, they are better qualified to recognize innovative or creative research and should support it.

Unfortunately, the best qualified peers may also be the researcher's competitors. Hence prejudice and jealousy may lead to rejection and violation of academic freedom (AAAS p. 8). Here the rule should be this: If a researcher alleges that his proposal or paper was rejected for reasons that violate academic freedom, he should be responsible for stating the reasons and the evidence that supports them. If he

makes a *prima facie* case, those responsible for rejecting the paper should then be required to show by a preponderance of the evidence that the rejection was for other valid reasons (AAUP RIR Rule 10, p. 21, and Rabban, pp. 4–6). This rule places a heavy burden on any researcher who believes that he was denied a research grant or journal space for reasons that violate academic freedom. While this burden is heavy, it must be heavy if administrators, with or without the aid of peer reviewers, are to have freedom to achieve excellence in research and publication.

To summarize, peer committees may legitimately be used to assist administrators in their efforts to manage wisely the limited resources at their disposal but this does not include their use to suppress or censor unpopular or controversial views and opinions.

Peer Reviews of In-House Research

What are the legitimate uses of peer review committees when there is in-house research and in-house publishing facilities? This is the crucial issue. Both the USDA and the land-grant institutions have funds to conduct in-house research and publish the results. Peer review committees can be used legitimately to help choose the areas of research and to assign them to researchers just as they can be used legitimately to decide what subjects shall be taught and who shall teach them.

The task of the administrator is to allocate wisely the available resources for teaching and research, and he may legitimately use peers to help make these decisions. However such decisions are made, it would be a gross misallocation of research funds to secure competent research workers, provide them with research facilities, all at great cost and then not publish the results. Such action would be comparable to assigning a teacher to lecture to a class but then barring him from the classroom. Publication is one way of communication and a lecture is another.

Thus, research institutions may appoint researchers and assign research projects, but their administrators should not interfere with research methodology or censor the findings and conclusions. They will be concerned about the quality of research and it would not be improper to ask the researcher to submit his procedures and papers to peer reviewers for whatever help they can provide. But it would be most improper for administrators to insist that researchers accept the reviewer's criticism before the project is funded or the paper is published. Such prior restraint is censorship—and therefore a violation of academic freedom—unless the institution can show that such action is justified by gross incompetence or an extraordinary financial exigency. In either case the burden of proof should be on the administration, and peers not previously involved should be asked to evaluate the evidence (AAUP RIR Rule 10, p. 21, and Rabban, pp. 4–6).

After an administrator, with or without peer assistance, has made a teaching or research assignment, his responsibility ends and the professor's begins. The professor is the administrator of his classroom and his research project. As administrators, professors also may seek the advice of peer reviewers. While peers should have full freedom to evaluate critically and make recommendations, the author also should have full freedom to accept or reject them. If he does not, there is a violation of his academic freedom.

Administrators have reasons for their reluctance to grant researchers full freedom as to methodology because it may lead to unpopular findings, conclusions, views, and opinions. As a result, special interests may be offended and public funds reduced. Funds must be secured to finance the institution. To secure additional funds, people need to be assured that present funds are being spent wisely. Senator William Proxmire appeals to taxpayers when he makes his "golden fleece" award for research which he believes is fleecing the public. While he may hit the mark, there is danger that his attacks may destroy more than it conserves. Academic freedom to do innovative or creative research may be chilled. But the Senator is not alone. Every state has special interest groups who wail in anguish whenever their golden sheep are threatened by research proposals or papers. Hence, administrators are under heavy pressure to suppress both.

Peer and Public Pressures

In large private universities the greatest threat to academic freedom may originate with peers. For example economist George Stigler, University of Chicago, has said that "academic freedom in its true meaning—the freedom to say unpopular things—is in its present low estate because we professors . . . [exercise] strong sanctions against the hiring and

promotion of holders of unpopular views" (last page). Hence many professors are afraid to express such views, especially in writing.

Kingman Brewster, Jr., former president of Yale University, agrees: "In strong universities assuring freedom from intellectual conformity coerced *within* the institution is even more a concern than is the protection of freedom from external interference" (his emphasis). Tenure, he points out, provides some protection, but even so "fear of failure in the eyes of the peerage inhibits some . . . . Too many seek the safe road of detailed elaboration of accepted truth rather than the riskier paths of true exploration which might defy conventional assumptions" (p. 382).

But in public universities and research institutions, the professor's academic freedom is under heavy pressure primarily from off-campus special interest groups. Perhaps the best-known example is the 1943 butter-margarine controversy at Iowa State College, now Iowa State University. This controversy reveals not only the pressures which special interests can exert on academic freedom but also the misuse of review committees to justify censorship (Hardin, Weir).

In 1943 Iowa State was forced by Iowa dairy interests and the Iowa Farm Bureau to withdraw its Pamphlet Number 5, "Putting Dairying on a War Footing." In this pamphlet its author, agricultural economist O. H. Brownlee, had stated that properly fortified margarine "compared favorably" with butter. The president of Iowa State, after making a defense of academic freedom, agreed that if there were errors, they should be corrected. But who was to determine what errors existed? This task was assigned to a committee of six dairy leaders and six professors. Three of the professors were agricultural economists (T. W. Schultz, G. S. Shepherd, and W. G. Murray). The committee found what it believed to be some errors, ambiguities, and lack of adequate documentation. Hence, it recommended that the pamphlet be retracted and completely revised under the direction of a committee composed of dairy and farm leaders. In the meantime, the president had had the pamphlet reviewed by the director of agricultural relations and by professors of dairy husbandry, dairy industry, animal husbandry, and home economics. This committee was also critical of the pamphlet.

As a result, the president retracted the pamphlet and announced that it would be revised in cooperation with the dairy interests. Then T. W. Schultz, head of the economics and sociology department, in a letter of resignation, charged that the administration was violating academic freedom not only in the margarine controversy but by its (*a*) refusal to publish an article on the feed grain situation in the *Iowa Farm Economist,* (*b*) refusal to approve publication of a manuscript on wartime farm food policies by John Vieg and William H. Nicholls, (*c*) abrupt termination of a radio program by a social science staff member, Bryce Ryan, and (*d*) refusal to permit the department to use any further funds from a $10,000 research grant made by Rockefeller Foundation (Hardin, pp. 115–20; Russell, Sect. 4, p. 1; Weir, pp. 98–105). When the president was asked about these charges he replied, "I have never questioned the right of the staff member to write and publish whatever he pleases but I do reserve the right of decision of the propriety of having publication under the college signature" (Russell, Sect. 4, p. 1).

Within a week the president issued a policy statement which included these points: "[1] that over the past 25 years wise and effective procedures and controls have been developed. . . . [2] that those controls provide every reasonable freedom within the accepted limits of our activities [3] that those controls have proved to be entirely sound and constructive [4] that they have served as safeguards to members of the staff and to the many groups . . . with whom we have worked and will continue to work." The statement concluded by declaring that "the fundamental right of the college staff to publish on his own responsibility has never been in question. But at the same time the college has the right and obligation to see that all publications issued under the official sponsorship and signature of the college have been submitted to the approved methods of review and criticism" (*Des Moines Tribune,* 25 Sept. 1943, p. 1).

Thus the president, by both his actions and words, made it abundantly clear that, in his view, academic freedom does not require institutional neutrality, that the institution must provide not only for peer but also nonpeer reviews, and that these reviews may be used to justify the suppression in whole or part of research proposals and papers. This is, of course, censorship; and censorship is a violation of the widely accepted meaning of academic freedom. Given the president's limited

view of academic freedom and the power of pressure groups, it is not surprising that Iowa's state board of control found "after thorough and intensive consideration . . . that the charge of the violation of the fundamentals of academic freedom in all particulars is without foundation in fact" (*Des Moines Tribune*, 5 Nov. 1943, p. 1; Hardin, p. 121). Hardin concluded that what happened at Iowa State was "by no means unique." He found administrators at other institutions in fairly general agreement that the butter-margarine issue was "too hot to handle," and hence their research and extension workers were induced to keep hands off. By doing this, they were violating academic freedom. Under these circumstances it is not surprising that most elements in these institutions lined up with the dairy interests.

Only when administrators are neutral do professors have full freedom to seek and report the truth as they see it (Solberg, Taylor, Friedland). But such neutrality is difficult to maintain when powerful persons or groups have vested interests. These interests are almost always found when federal or state funds are being allocated but they also exist for private funds. "Patrons of university activities are not renowned for their neutrality when it comes to economic research," says Schultz in a recent unpublished paper (p. 2). He notes that "the now fashionable concepts of targeted and mission-oriented research are as a rule subterfuges for intrusion. Peer review of economic research proposals . . . is a convenient device of obtaining sufficient differences in evaluations to give the administrator . . . a free hand in deciding whether or not to approve the proposal" (p. 12). Also, administrators are under heavy pressure to use peer reviews of research papers to justify the suppression in whole or part of findings and conclusions with which they or other powerful persons or groups may disagree.

Administrators may agree with Lowell's view quoted above, that once they accept responsibility for what professors may not say, they also accept responsibility for what they do say. However, this presents them with no serious problem. They can use peer reviews to assist in the suppression in whole or part of unpopular research proposals and papers and they are eager to accept credit for any noncontroversial or popular conclusions of their "team." These popular "products" make it easier for administrators to secure support for more research and helps them achieve professional advancement. In some cases this may even maximize the public interest just as some monopolies do. But as noted, a NRC-NAS Committee found that there was much low quality research in both USDA and the SAES which appeared to be due to heavy-handed administration that was reducing "individual freedom." The Committee proposed that this situation be corrected by peer reviews of research proposals.

Perhaps as a result of this criticism, USDA has made some changes. SEA-CR has requested all SAES to make peer reviews of all new research proposals to be funded through its office. By 1978, SEA-CR had "cleared" the peer review systems of forty SAES (SEA-CR Exp. Sta. Letter, 1448, 7 Apr. 1978). The South Dakota station's system, entitled "Peer Review of Research Proposals," requires that proposals be approved by two or more peer reviewers before administrative approval and submission to SEA-CR. The reviewers are required to report their criticisms in writing and sign their statements. Then the researcher must respond to the reviewers recommendation and submit both to the administrator along with the comprehensive project proposal. Thus, peer reviewers' criticisms are available to justify censorship.

An alternative which avoids censorship would be to require the researcher to attach a statement to his project proposal or paper attesting that an earlier draft had been critically reviewed and the criticisms had been carefully considered in preparing the present draft. This alternative would allow peers full freedom to criticize and suggest changes and the researcher full freedom to accept or reject them—just as he must accept or reject any other information.

To avoid censorship, funds should be available to publish the results of in-house research; but if they are not, the researchers should be informed before starting the research that publication must be secured elsewhere. Generally, it is a gross misallocation of resources to fund research but not publication of the results. Quality of research and research papers can be maintained by appointing competent researchers, by peer reviews, and by editorial services.

Summary and Conclusion

Excellence in teaching and research can be achieved by appointing the most competent

persons available and by giving them good working conditions. Of these conditions the most important is academic or scientific freedom to seek and to report what they believe to be true, made possible by freedom from dismissal or other severe sanctions that may be urged by powerful persons or groups on or off the campus.

Administrators may legitimately use peer review committees to help them wisely allocate available resources, including the refereeing of competitive research proposals and papers for limited funds or journal pages. When funds or pages are limited, peer review committees can provide invaluable help in selecting the best for acceptance. The choice should be made on the excellence of the proposals or papers—on their contribution to knowledge. But there is the ever-present danger that proposals and papers may be rejected because they are unpopular with reviewers whose golden sheep are being sheared or because the proposals and papers are likely to be controversial or unpopular with powerful persons or groups.

Administrators of in-house research and publishing facilities such as USDA and the State Agricultural Experiment Stations also may insist that their professionals submit their research proposals and papers to peer reviewers before they are funded or published. Peers should exercise full academic freedom in making their reviews but their suggestions and criticisms should go directly to the researcher. If they also go to the administrator, he may be tempted to reject the proposal or paper until at least a majority of the reviewers approve. When this happens the peer review committee has become, perhaps without its knowledge or consent, a board of censors—a means of suppressing unpopular or controversial research proposals and papers, a means of violating academic freedom so necessary for creative and innovative research and teaching.

Social Costs and Benefits from Component Pricing of Soybeans in the United States

Nelson J. Updaw

The recent development of near-infrared reflectance instruments allows grain traders to measure chemical composition when grain is sold. This study provides estimates of the social benefits and costs of such measurements to be used in the pricing of soybeans. The economic model integrates a production possibilities frontier with the demand for two chemical characteristics, oil and protein content. The results indicate that it is unlikely that the benefits of pricing soybeans on the basis of component measurement would have exceeded measurement costs.

Key words: component pricing, consumers' surplus, elasticity of transformation.

Agronomic practices which are expected to maximize profits for producers tend to vary among regions of the United States. Locational differences in the employment of factors of production, combined with differences in the marginal productivity of inputs used at every location, ensure that the product characteristics of most commodities will vary. For those commodities in which variation of product characteristics is of major concern, market traders have developed grading standards that define product "quality." Each grade specifies for selected characteristics a bound which cannot be exceeded, thereby providing market participants an indication of the utility to be obtained through the consumption of any unit. Established standards are intended to segregate each commodity so that there exists an identifiable relationship between each unit's grade assignment and the value of its characteristics. Price differentials among grades reflect differences in the market-clearing prices for highly substitutable goods.

Because grades provide information to market participants, they may be viewed as an input to the marketing process (Kihlstrom). Unless grading procedures are prescribed by law, each characteristic observed in the grading process must be expected to provide marginal benefits to traders that exceed or equal marginal measurement cost.

Some characteristics included in the official grading standards may go unmeasured; in addition, those characteristics observed need not include the characteristic(s) of greatest interest to certain traders. If a particular characteristic (or set of characteristics) determines the marginal value product of an agricultural commodity but is extremely costly (or impossible) to observe at the time of sale, then it is conceivable that alternative characteristics known to be correlated with the characteristic of interest will be substituted for it in the grading standards. Unless the correlation is perfect, a grade assignment based upon the proxy characteristics may provide an imperfect assessment of the value of the unit to the purchaser.

Some observers have criticized grading procedures used in the United States because those characteristics measured frequently provide an inaccurate estimate of marginal value product (e.g., Graf). Furthermore, the size of the divergence between estimated marginal value product and market price can be sizeable; for example, Ladd and Martin have demonstrated that corn graded as low as standard may have characteristics valued more highly by some purchasers than those of corn which meet the requirements for U.S. No. 1. It has been suggested that price determination based upon grades be replaced by a system in which the price of every commodity be set in accordance with the sum of the value of its

separate components. This may be referred to as component pricing (Perrin). This concept is a logical refinement of grade determinant pricing; rather than establish a price on the basis of measurements that fall into specified ranges, the price of an unprocessed commodity would be set according to point estimates of the values of all measured characteristics. Proponents claim that society would benefit from component pricing because (*a*) there would be a reduction in, or perhaps the elimination of, the risk now borne by commodity buyers of paying a price which exceeds marginal value product; and (*b*) producers would be provided an incentive to produce commodities the characteristics of which possess marginal social benefits that exceed or equal marginal social costs.

Because market traders are free to establish grading schemes for most commodities, component pricing will not replace pricing by grades until market participants are convinced that component pricing is the more profitable practice. This may occur through a reduction in the cost of component pricing, an increase in its expected benefits, or a combination of the two. The recent introduction of near-infrared reflectance (NIR) instruments may represent a technological change that will reduce the cost of component measurement sufficiently so that many grains may be priced according to measured chemical characteristics.

The purpose of this study is to estimate the social costs and benefits of the component pricing of soybeans. This crop was chosen because (*a*) there is a strong association between marginal value product and soybean oil and protein content (Updaw, Bullock, Nichols); and (*b*) representatives of grain companies have indicated that they have not included chemical content measurements in determining offer prices for various deliveries of soybeans.[1]

Approach of the Study

It will be assumed in this study that the only characteristics of interest to soybean traders are oil content and protein content and that the component pricing of soybeans will create an environment in which the price of each bushel of soybeans equals the value of the two processed commodities obtained from each bushel less a constant crushing margin. In addition, it will be assumed that the introduction of component pricing of soybeans will have no effect upon international trade or the year-to-year carry-over of the crop.

Rinne et al. have documented that NIR measurements of soybean oil content and protein content are highly correlated with those obtained through conventional laboratory tests when the NIR measurements are made by trained operators in a controlled environment. Therefore, the social cost of the component pricing of soybeans will be defined as the additional cost incurred by traders who measure soybean content, or the ownership and operating costs of the machines. It will be assumed that competition among buyers will prevent the occurrence of systematic misreadings of soybean composition and that all domestic transactions will be made on the basis of component pricing.

If component pricing is economically feasible, those soybean buyers who first employ the practice can increase profits in the short run by restricting their soybean purchases to those beans that possess above-average levels of desired characteristics. Those buyers who do not practice component pricing will face a reduction in the quality of soybeans made available to them and, consequently, a reduction in profits. However, in the long run the rate of return on investment for NIR instruments should be consistent with zero economic profits. Therefore, it will be assumed that the component pricing of soybeans will confer no lasting benefits upon grain traders and soybean processors. The social benefits of component pricing will be reaped by soybean producers and the consumers of soybean oil and protein.

Gross social benefits of component pricing will be measured as the sum of the estimated change of producers' surplus for soybean producers and the estimated change of consumers' surplus for domestic consumers of soybean oil and meal. It will be assumed that welfare losses borne by any group will be exactly compensated by gainers. Social costs will be subtracted from this sum to arrive at a conclusion of the desirability of component pricing of soybeans in the United States. If gross social benefits exceed estimated measurement costs, it will be concluded that component pricing would have improved social welfare; if the difference is negative, it will be

[1] Personal correspondence with author. It should be mentioned that each individual contacted expressed reservations concerning the use of NIR instruments, citing measurement costs and machine reliability as problems.

concluded that social welfare would have been reduced. Any inference regarding the effect of component pricing in the future must be tentative in nature, but estimates based upon recent experience ought to provide a reasonable indication of the magnitude and direction of welfare changes.

Economic Model

The model to be used in this study is that of perfectly competitive markets for the two characteristics (Perrin). Given a fixed set of resources to be applied in the annual production of soybean oil and protein and no externalities in production or consumption, the maximization of social welfare occurs when society is located on its production possibilities frontier and the marginal rate of substitution in consumption equals the marginal rate of transformation in production (Nicholson, p. 534). This is equivalent to the requirement that the price of protein relative to oil paid by consumers be equal to that received by producers.

If no attempt is made to price soybeans according to chemical composition, the implicit prices received by soybean producers for oil and protein are equal. The wholesale price of soybean oil paid by consumers, however, has tended to exceed the wholesale price of protein, as shown in table 1.[2]

The producer price of protein (P_1^p) and oil (P_2^p) are calculated as the sum of the average price received by farmers for soybeans and the average crushing margin earned by processors, divided by 31.6 pounds of useful product (10.8 pounds of oil and 20.8 pounds of protein). The consumer price of oil (P_2^c) represents the average annual wholesale price of crude soybean oil at midwestern mills. The consumer price of protein (P_1^c) is calculated as the average annual wholesale price of 44% protein meal at midwestern mills, divided by 0.44. These data suggest that the equilibrium which has persisted each year is similar to that depicted in figure 1.

[2] Oilseed buyers are known to record the chemical composition of soybeans purchased in various regions of the United States. This information should affect regional demands and may force prices to reflect the average chemical composition of soybeans in each region. The extent to which this practice affects the average national oil content and protein content is uncertain.

Table 1. Average Wholesale Prices of Soybean Oil and Protein in the United States, in Cents per Pound, 1961–75

Time Period	$P_1^p = P_2^{p\,a}$	P_1^c	P_2^c	P_1^c/P_2^c
1971–1975	18.26	16.93	20.84	.812
1966–1970	9.26	8.79	10.12	.869
1961–1966	8.79	8.17	9.96	.820

[a] P_1^p is producer price of protein; P_2^p, producer price of oil; P_1^c, consumer price of protein; P_2^c, consumer price of oil.

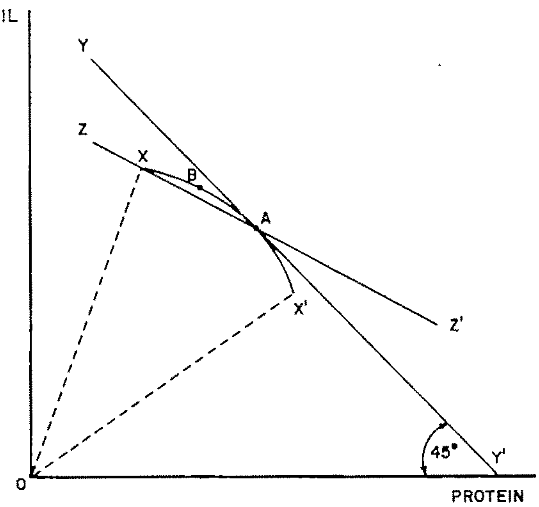

Figure 1. Market equilibrium

Let the function labelled OXX' represent the production possibilities frontier of soybean oil to protein, YY' the relative price ratio of protein to oil for the producing sector, ZZ' the relative price ratio for consumers and Point A the equilibrium quantities of oil and protein that are produced and consumed each year. Since oil and protein are produced jointly within each bushel of soybeans, it is impossible to specialize in the production of one good to the exclusion of the other; hence, the function OXX' does not span the entire quadrant (Heady, pp. 216–17).

With a constant, unitary relative price of protein to oil received by the producing sector, the point at which producers maximize profits is that combination of output at which the marginal rate of product transformation equals -1.0 (point A). Assuming that the transformation function is homogenous of degree one, proportional changes in the application of factors of production will shift OXX' but not change the ratio of oil to protein.

The implementation of component pricing is expected to alter the chemical composition of soybeans as producers respond to a change in the relative price ratio paid to them. Because the slope of ZZ' represents the relative price

of protein to oil paid by consumers, theory indicates that soybean producers can be expected to increase oil production and decrease protein production, *ceteris paribus*. If producer prices mirror those faced recently by consumers, annual output would rotate to point B of figure 1. However, as protein production declines relative to oil production, the relative price of protein to oil for consumers would rise. Equilibrium output would lie along OXX' between points A and B. A comparison of this point with point A provides an indication of the change in annual production and consumption attributable to the introduction of component pricing.

It is not possible to state a priori that the producing sector would experience an increase or decrease in welfare from the introduction of component pricing. If resource application is fixed, as assumed in this model, changes in total revenue will represent identical changes in producers' surplus. Because total revenue changes are determined by the demand for oil and protein, knowledge of these functions as well as the new equilibrium quantities is required to assess the benefits of component pricing to the producing sector.

Similarly, it is not possible to determine whether consumer welfare would increase or decrease from the introduction of component pricing. The direction of expected adjustment by producers indicates that oil consumers should benefit while consumers of protein should experience a decline in consumers' surplus. Whether the increase in consumers' surplus for oil consumers exceeds the decline in consumers' surplus in the protein market is an empirical question that cannot be answered without an estimate of the demand for the two goods and an estimate of the new equilibrium quantities.

The economic model, then, consists of a production possibilities frontier, the demand for oil and the demand for protein. By enforcing the restriction that the production frontier exhibit constant elasticity of transformation and the demand curves constant elasticity of demand, the model may be presented in the following six equations.

(1) production possibilities frontier:
$$X_2^{\phi_0} + \phi_1 X_1^{\phi_0} = K_0,$$

(2) profit maximization:
$$dX_2/dX_1 = -P_1^p/P_2^p,$$

(3) demand for protein:
$$X_1 = \epsilon_0 \, (P_1^c)^{\epsilon_1},$$

(4) demand for oil:
$$X_2 = \gamma_0 \, (P_2^c)^{\gamma_1},$$

(5) protein market equilibrium:
$$P_1^p = P_1^c, \text{ and}$$

(6) oil market equilibrium:
$$P_2^p = P_2^c,$$

where X_1 is quantity of protein produced and consumed each year; X_2, quantity of oil produced and consumed each year; P_1^p, real price of protein received by producers; P_2^p, real price of oil received by producers; P_1^c, real price of protein paid by consumers; P_2^c, real price of oil paid by consumers; and K_0, ϕ_0, ϕ_1, γ_0, γ_1, ϵ_0, and ϵ_1 are parameters to be estimated.

A solution of all six equations simultaneously provides a unique set of quantities and prices which corresponds to the equilibrium described by the neoclassical competitive model for a two-good economy. Through a series of successive substitutions, the six equations may be reduced to one nonlinear equation in which the equilibrium quantity of either good is determined by the parameters of the demand curves and the production possibilities frontier. Solving for protein (Updaw, pp. 28–29):

$$(7) \quad X_1 = (K_0 - \phi_1 X_1^{\phi_0})^{\left(\frac{\phi_0 - 1 - 1/\gamma_1}{\phi_0 D}\right)} (\phi_1)^{\frac{-1}{D}} (\gamma_0)^{\frac{1}{\gamma_1 D}} (\epsilon_0)^{\frac{-1}{\epsilon_1 D}},$$

where $D = (\phi_0 - 1 - 1/\epsilon_1)$.

Inserting X_1 in equation (1) provides the equilibrium quantity of soybean oil, X_2. X_1 and X_2 may then be inserted in their respective demand equations to obtain equilibrium prices for soybean protein and oil. Therefore, knowledge of the parameters of equations (1), (3), and (4) is necessary and sufficient to determine the equilibrium quantities and prices that would prevail if soybeans were priced in accordance with the value of their components. This solution may be compared with an observed equilibrium to determine the gross social benefits and costs of component pricing.

Demand for Oil and Protein

Because the mathematical specification of each demand curve is log-linear, observed average quantity demanded and real price over 1971–75 may be used with estimated price elasticity to derive the appropriate value of the constant term which precedes price in

each equation. Recent studies of the demand for oil and meal provide a rather wide range of estimated elasticities for the domestic demand for oil and meal (Updaw). Therefore, it became necessary to include the estimation of these elasticities in the study.

The demand models employed have been drawn from earlier studies (Vandenborre; Houck and Mann; Houck, Ryan, Subotnik). To allow comparisons to be made with these earlier studies, the quantity demanded, rather than price, was chosen as the endogenous variable in each equation. Exogenous variables included in the domestic demand for oil were the size of the domestic food-consuming population, real per capita income, and the annual quantities demanded of cottonseed oil, butter, and lard. In the case of the demand for protein, the exogenous variables were livestock population and the annual quantity demanded of substitutable feed (Updaw).[3] The results, corrected for positive serial correlation (Kmenta, pp. 278–82), are given in table 2.

The estimated elasticity of demand for protein is similar to those found earlier for soybean meal (Houck, Ryan, Subotnik). The elasticity estimate for oil, however, is significantly more inelastic than earlier estimates at the 95% level of probability. This may be attributed to the nonlinear specification of the demand curve as well as differences in the samples used in each study.

Incorporating these estimates with observed average quantities demanded and real prices over 1971–75 gives

[3] The formula used for converting substitutable feed to soybean meal equivalent is given in Houck and Mann, p. 46.

Table 2. Estimated Domestic Demand for U.S. Soybean Oil and Protein, 1947–1975

$$\ln X_{2t} = \underset{(4.36)^{a}}{-11.5035} - \underset{(0.06)}{0.0507} \ln P_{2t} \underset{(0.06)}{-0.0451} \ln(Q_{cotton}) \underset{(0.23)}{-0.0293} \ln(Q_{B\&L}) + \underset{(0.41)}{1.0951} \ln(real\ y) + \underset{(0.56)}{2.2365} \ln(pop) \qquad R^2 = .98$$

$$\ln X_{1t} = \underset{(17.80)}{-42.8448} - \underset{(0.17)}{0.3077} \ln P_{1t} \underset{(0.68)}{-0.2827} \ln(Q_{sub}) + \underset{(1.71)}{4.8360} \ln(pop) \qquad R^2 = .33$$

[a] Estimated standard errors in parentheses.

$$(8) \qquad X_1 = (27{,}065.225)\, P_1^{-.31},$$

$$(9) \qquad X_2 = (7{,}769.357)\, P_2^{-.05}.$$

Production Possibilities Frontier

Given the joint nature of the production of soybean oil and protein, the most appropriate mathematical specification of the production possibilities frontier is that of a cone (Fare and Jansson):

$$(10) \quad F = \{(X_2 - \delta_0 X_1)^{\delta_3} + \delta_1 (X_1 - \delta_2 X_2)^{\delta_3}\}^{1/\delta_3} - K_0 = 0,$$

for $\delta_0 \leq X_2/X_1 \leq 1/\delta_2$, and F being unspecified otherwise.

This equation represents a family of functions of which equation (1) of the economic model is a member (with $\delta_0 = \delta_2 = 0$); δ_3 is the parameter of elasticity corresponding to ϕ_0 of equation (1); and δ_0 and δ_2 establish rays which emanate from the origin to restrict the range of transformation. Given an estimate of δ_3 plus observed quantities of oil and protein, ϕ_1 may be derived from equation (2) if both δ_0 and δ_2 are zero. Insertion of ϕ_0 and ϕ_1 in equation (1) provides a solution of K_0, thereby completing the set of parameters required for solution of the model.

If it is assumed that component pricing of soybeans has not taken place in the past, predictions of the values of $\delta_0, \ldots, \delta_3$ may not be based upon observed annual production of soybean oil and protein. With no change in the relative prices of protein to oil paid to producers, any fluctuation in the average oil/protein content of American soybeans should be random. To obtain data which can identify the range of production possibilities available to producers once component pricing is introduced, observations have been drawn from the recorded results of breeding efforts conducted by agronomists at experiment station sites (Uniform Soybean Tests, 1972–76). The quantities of oil/acre and protein/acre for twenty seed varieties grown at seventy locations have been calculated (Updaw).

The agronomists who have recorded the results of these experiments have not consistently reported the quantities of inputs employed each year. Those factors of production which have been found to influence the chemical composition of soybeans include nitrogen (Ham et al.), lime, phosphorus and potassium (Lutz and Jones), and seed variety (Nichols, Clapp, Perrin). Without observations of factor

use, calculated observations of oil per acre and protein per acre are not amenable to the direct estimation of a production possibilities frontier; however, variation in component production may be attributed to the effects of locational differences, differences among years, and variety effects, if these are independently distributed. By identifying that variation attributable to changes in variety, a production frontier may be estimated. This may be achieved through an analysis of variance in which production of each component is determined by location, year, and variety:

$$(11)\quad X_{1ijk} = \mu_1 + V_{1i} + L_{1j} + R_{1k} + \epsilon_{1ijk},$$

$$(12)\quad X_{2ijk} = \mu_2 + V_{2i} + L_{2j} + R_{2k} + \epsilon_{2ijk},$$

where X_{1ijk} is observed production of protein per acre of variety i at location j during year k, in pounds; X_{2ijk}, observed production of oil per acre of variety i at location j during year k, in pounds; V_{1i}, fixed varietal effect on protein per acre of variety i; V_{2i}, fixed varietal effect on oil per acre of variety i; L_{1j}, fixed location effect on protein per acre for location j; L_{2j}, fixed location effect on oil per acre for location j; R_{1k}, fixed year effect on protein per acre for year k; R_{2k}, fixed year effect on oil per acre for year k; ϵ_{1ijk}, random protein effect for variety i, location j, year k; and ϵ_{2ijk}, random oil effect for variety i, location j, year k.

The estimated variety effects provide the basis for the data required for the production possibilities frontier:

$$(13)\quad X'_{1i} = \mu_1 + V_{1i},$$

$$(14)\quad X'_{2i} = \mu_2 + V_{2i},$$

where X'_{1i} is estimated protein production for variety i, and X'_{2i} is estimated oil production for variety i.

With the members of the sample determined, all that remains is to estimate the elasticity coefficient of the production possibilities frontier. This is achieved through the use of nonlinear regression (Gallant, Schmidt). While the small sample properties of this procedure remain undocumented, it is known that the estimators are asymptotically unbiased, efficient, and consistent (Gallant). With 635 observations in the sample, it will be assumed that the estimators possess the asymptotic properties.

The results of the nonlinear regression are presented in table 3. The point estimate of the parameter of transformation, δ_3, is so close to unity that the elasticity of transformation approximates infinity. Furthermore, the slope of the function is positive throughout the transformation range. This implies that the economically relevant frontier consists of a single point. Therefore, the effective value of the elasticity of transformation is zero. If this conclusion is correct, the national production of oil and protein could not have been expected to change had the component pricing of soybeans been in effect.

K_0	410.7642	380.1349

Social Costs and Benefits

With no expected change in the chemical composition of soybeans, there can be no social benefits for consumers of soybean oil and protein from the introduction of component pricing. With no change in the supply of these goods, equilibrium quantities and prices for consumers remain constant. The only effect would be to force the ratio of producer prices to equal that for consumers, thereby redistributing income among producers without changing total revenue. With no change in consumers' surplus or producers' surplus, gross benefits are predicted to be zero.

Niernberger's estimates of ownership and operating costs of NIR instruments provide a basis upon which to determine the social cost of component pricing. Measurement cost is calculated as a weighted average of these estimates, where the weights represent the fraction of American processing mills which have annual operating capacity in the ranges outlined by Niernberger. In the construction of weighted-average screening cost, it is assumed that Niernberger's high estimates apply and that all mills with estimated annual operating capacity exceeding 5.0 million bushels will incur a measurement cost of 0.5¢ per bushel

processed (Updaw). On this basis, the social cost of component pricing is estimated to be 0.81¢ per bushel processed per year if components are measured only once before processing.

It is not likely that soybean components would be measured only at the market where the processor purchases soybeans. Traders at country points or subterminal elevators should be unwilling to bear the risk of being assessed the relatively large discounts that would be associated with component pricing (Updaw, Bullock, Nichols). Components might be measured two or three times, on the average, before soybeans are crushed. Therefore, it is assumed that component measurement would occur 2.5 times as soybeans progress through domestic marketing channels. For the average year during 1971–75, this would imply an annual social cost of $12,585,375.

With estimated social benefits of zero, the study indicates that the component pricing of soybeans would have reduced social welfare in the United States over the period 1971–75 by $12,585,375 per year.

Sensitivity Analysis

The estimated social costs and benefits of component pricing are derived from the estimated parameters of the domestic demand for soybean oil, the domestic demand for soybean protein, and the production possibilities frontier. Because the values of these parameters are never known with certainty, it may be worthwhile to recompute social costs and benefits using different values of the parameters of the economic model.

As a first step, assume that the production possibilities frontier possesses some range of transformation. Nichols, Clapp, and Perrin determined an approximately linear trade-off between the oil content and protein content of different soybean varieties that is 1:1. This is not inconsistent with the nonlinear regression results of this study, since the estimated frontier of this study includes the effect of differences among varieties in yield. However, let us impose an elasticity of transformation of -1.0 and $-\infty$ on the model, ensuring that the marginal rate of transformation is -1.0 at the average value of oil and protein production over 1971–75. The results are presented in the second and third rows of table 4.

In each case, the predicted equilibrium output of oil/protein lies within the rays of the estimated cone of table 3. In the iteration in which the elasticity of transformation equals -1.0, predicted oil production for the average year during 1971–75 increases by 49.08 million pounds and predicted protein production decreases by 49.36 million pounds, compared to the quantities actually observed. This corresponds to an estimated decline in the real consumer price of oil of 2.53¢ per pound and an

Table 4. Results of Sensitivity Analysis

	Predicted Change in:					
Model Assumptions	Oil Production	Protein Production	Oil Surplus	Protein Surplus	Producer Surplus	Net Social Welfare
	--(million pounds)--		($ million)

$\lambda = -\infty$ $\gamma_1 = -.5$ $\epsilon_1 = -.31$	172.64*	−172.64*	62.71	−89.85	30.73	−9.0

[a] λ is elasticity of transformation; all other variables are as defined earlier.
[b] Asterisk denotes a corner solution.

estimated increase in the real consumer price of protein of 0.22¢ per pound. Calculated changes in consumers' surplus and producers' surplus sum to $708,000, far less than the cost of measuring soybean components.

With the elasticity of transformation made infinitely elastic, the quantity response is greater, as would be expected. A predicted increase in the annual production of oil by 52.87 million pounds leads to a predicted decrease in the annual production of protein by 52.87 million pounds. Equilibrium prices for consumers are estimated to fall by 2.71¢ per pound for oil and rise by 0.24¢ per pound for protein. Estimated gross social benefits become $756,000 per year, which is exceeded by measurement costs. Again, it is predicted that the component pricing of soybeans would have reduced social welfare over the period 1971–75. Even if soybean producers face perfectly elastic transformation frontiers, the model predicts that the increased consumer surplus in the oil market would not have been large enough to compensate protein consumers and soybean producers as well as cover the cost of screening.

An additional parameter of the model to be changed might be the elasticity of demand for soybean oil (γ_1). The estimate reported in this study is much less elastic than those published in recent years; therefore, it might be suspect. To determine the effect of this parameter on the results of the study, the elasticity of demand for oil has been changed to $-.5$ and solutions to the model have been obtained for an elasticity of transformation of -1.0 and $-\infty$. The results are presented in the fourth and fifth rows of table 4.

In each of these iterations, the equilibrium solution lay beyond the range of transformation outlined by the rays of the predicted frontier. Therefore, the solution obtained was located at the corner of a ray and the transformation surface. In these cases, the predicted price ratio for consumers does not equal that for the producing sector; however, the divergence between the two is less than that which existed without component pricing. The corner solution represents an equilibrium in which oil production is lower and protein production higher than that which would be predicted for an unconstrained case.

Two effects of increasing the elasticity of demand for soybean oil are to raise predicted annual oil production and to lower the predicted gain in consumers' surplus for oil consumers. These, in turn, lead to predicted increases in producers' surplus and a decline in total consumer welfare. In both cases, the gain in welfare for soybean producers and oil consumers is not great enough to compensate the loss of consumers' surplus in the protein market and to cover the social cost of screening soybeans. In these cases, as well as the others, the predicted net effect of the component pricing of soybeans over the period 1971–75 would be to reduce social welfare in the United States.

Summary

The purpose of this study has been to predict the social costs and benefits of the component pricing of soybeans in the United States. A model consisting of the demand for soybean oil and soybean protein and a production possibilities frontier was developed so that changes in equilibrium quantities and prices might be estimated. The salient parameters of the model were estimated for the average year during the period 1971–75, so that conclusions might be drawn from predictions based upon recent experience.

The result of the empirical work was that there would have been no change in the quantities of oil and protein produced and consumed in the United States had soybeans been priced in accordance with component value. Because component pricing can be achieved only at some additional cost, it was concluded that component pricing would have reduced social welfare over 1971–75.

Next, certain parameters of the model were changed and social benefits recomputed to assess the sensitivity of the conclusion to different parameter values. In every case examined, the expected social cost of the component pricing of soybeans exceeded its predicted social benefits. While changes in producers' and consumers' surplus were predicted to be sizeable, the gain to one group tended to be nearly completely offset by losses to others.

In comparison with the annual expenditure on soybean oil and protein in the United States, predicted marginal social costs and benefits are extremely small. For example, if the net social cost of component pricing had been $12,585,375 per year and had this cost been borne proportionally by consumers of oil and protein, the average real price of each good over 1971–75 would have risen by less than .075¢ per pound. Nevertheless, the sensitivity

analysis indicates that net social benefits were not likely to be positive, even if the elasticity of product transformation is perfectly elastic. On the basis of these results, it appears that the component pricing of soybeans should not raise social welfare if implemented in the near future.

Multiple Exchange Rate Changes and U.S. Agricultural Commodity Prices

Keith J. Collins, William H. Meyers, and Maury E. Bredahl

A model was developed to assess recent effects of exchange rate changes, inflation, and price insulation policies on real U.S. commodity prices. Exchange rate effects are defined so that they can occur and be significant under either fixed or floating rate regimes. The results indicate exchange rate effects on real U.S. commodity prices are smallest under free trade and real commodity price insulation policies but rise substantially as nominal price insulation policies become more prevalent.

Key words: exchange rates, inflation, price insulation policies.

The coincidence of the depreciation of the dollar against many foreign currencies with the rapid expansion of U.S. agricultural exports in the seventies has suggested to some economists that a strong relationship exists between exchange rates and agricultural trade (Schuh). By implication, a relationship is hypothesized between the domestic prices of agricultural commodities and the relative value of the dollar. Empirical results, although subject to valid criticism of specification and theoretical constructs, have provided support for an exchange rate effect but have differed with respect to its magnitude (Fletcher, Just, Schmitz; Chambers and Just; Johnson, Grennes, Thursby; Yandle). Our purpose is to assess the size and nature of such a relationship by developing a framework for examining the effects of recent changes in the value of the dollar.

A change in purchasing power is the ultimate source of a trade response to changes in the value of the dollar. In the early 1900s Cassel originated the purchasing power parity (PPP) theorm, which holds that a bilateral exchange rate reflects the relative domestic purchasing power of the currencies. While not without criticism, PPP has been accepted in empirical work to mean that changes in bilateral floating exchange rates are a function of divergent rates of inflation. The PPP hypothesis suggests that real trade flows may be induced if movements in the exchange rate and relative inflation rates diverge. This situation can occur under either floating or fixed exchange rate regimes. Suppose a country experiences an internal rate of inflation which exceeds that of potential import suppliers. If the exchange rate is fixed, the import prices (reflecting inflation in other countries) do not increase as rapidly as domestically produced import substitutes. The divergent rates of inflation, given a fixed exchange rate, should induce an expansion of the country's imports. This situation, of course, cannot continue indefinitely because foreign exchange shortages resulting from balance-of-trade deficits ultimately will force a devaluation of that currency. If the adjustments in an exchange rate simply reflect divergent rates of inflation, little response in trade flows would be expected.

The above logic argues that exchange rate effects can occur in the absence of exchange rate changes. Thus an understanding of the relationship between exchange rates and commodity prices should profit from an analysis which incorporates relative rates of inflation and exchange rate changes. With commodity producers and consumers having to adapt their behavior to the global inflation of the seventies, some recent empirical trade studies (Bale and Greenshields; Johnson, Grennes, Thursby; Konandreas, Bushnell, Green) have benefited from the use of general price level variables. This analysis is con-

cerned with exchange rate effects that include relative inflation rates as an intrinsic part of an exchange rate effect.

Exchange rate analyses relying on theoretical models limited to free trade or two countries are misleading. Although studies such as those of Abbott and Hillman have recognized barriers to free trade, measurement of the extent to which trade barriers constrain or enhance exchange rate impacts has received little attention. In addition, the dollar has depreciated against the currencies of many developed countries while appreciating against those of many less developed countries. The developed countries primarily import soybeans and corn, while the less developed countries import more wheat and cotton. Hence, one would not expect a single measure (such as the SDR) to serve very well for all commodities. An analytical model that considers multilateral exchange rate changes is essential.

The impact of multilateral exchange rate changes on U.S. prices of major agricultural commodities is analyzed by developing a simple analytical method which incorporates multiple exchange rate changes, rates of inflation, and trade restrictions. The first section of the paper presents the theoretical foundation for the analysis by developing an expression for short-run U.S. commodity price changes caused by both nominal exchange rate changes and exchange rate changes adjusted for differential inflation rates. The second section presents calculated annual changes in U.S. prices of wheat, corn, soybeans, and cotton attributed to exchange rate changes and inflation rates of major noncommunist nations during the period 1971 to 1977. These changes are compared with the observed changes in prices in order to determine where, in the range from small to large, exchange rate impacts on U.S. agriculture may be placed.

Analytical Method

The theoretical approach is developed by specifying a world market equilibrium system for each commodity. Such a system consists of (*a*) a domestic demand and (*b*) a supply relation for each country engaged in trade, (*c*) a market clearing world equilibrium condition, (*d*) currency linkages based on a numeraire currency, and (*e*) price linkage equations based on a numeraire country. This system is totally differentiated, yielding an expression for the percent change in the numeraire price that is associated with multiple exchange rate changes (Ridler and Yandle; Bredahl, Meyers, Collins). The United States is used as the numeraire country in the study with the U.S. dollar as the numeraire currency.

Model

Consider the following simple spatial model for a particular commodity. We abstract only partially from demand and supply shifters and express a country's domestic demand, D_i, as a function of own price, P_i, and an alternative price, OP_i, which represents all other items or the general level of output prices (a deflator). Domestic supply, S_i, depends on the lagged values of own price and the same alternative price. The alternative price represents substitutes in both demand and supply. All prices are defined in the domestic currency of each country. We assume that demand and supply are homogenous of degree zero in prices. Demand and supply for the *i*th country may then be written as

(1) $D_i = D_i(P_i/OP_i) = D_i(RP_i)$, and

(2) $S_i = S_i[(P_i/OP_i)_{-1}] = S_i[(RP_i)_{-1}]$,

where RP_i indicates real price and the subscript, minus one, a one-year lag. An increase in the price term would be expected to reduce current quantity demanded and increase quantity supplied in the following year. In this formulation, the alternative price is exogenous to the model and unaffected by exchange rate changes, implying a price heavily weighted by nontraded goods. Further, a change in the exchange rate of the country is assumed to have no effect on the real income term in the demand equation; hence, it is not included in equation (1).

The analysis is partial equilibrium. Our interest is in each country's demand and supply curves in the real price/quantity plane. Inflation and exchange rate changes are restricted to movements along a curve. We will explain changes in U.S. commodity prices due to monetary variables (exchange rates and inflation), rather than to curve shifters such as real income, weather, and others. This means working on the demand side with a compensated demand curve. The percent change in U.S. prices explained by exchange rates and inflation will, as a result, be a partial effect. The effects of other demand and supply factors would be required to explain the actual

commodity price movement, or total effect.

The world equilibrium condition simply states the sum of all demands equals the sum of all supplies. Denoting the demand and supply of the United States, D_{us} and S_{us}, this condition is expressed as U.S. export supply equals the demand for U.S. exports,

$$(3) \qquad S_{us} - D_{us} = \Sigma_i(D_i - S_i).$$

The summation operator here, and subsequently, excludes the United States. The nominal internal price in each country is linked to the numeraire price, P_{us}, by the relation

$$(4) \qquad P_i = g_i(e_iP_{us}),$$

where e_i is the value of the ith country's currency per U.S. dollar. The functional specification, g_i, represents the price transmission mechanism and implicitly subsumes direct factors such as transportation costs and less direct factors such as trade restrictions and price intervention policies.

Total differentials of equations (1)–(4) are

$$(5) \qquad dD_i = D'_idRP_i = D'_i[(OP_idP_i - P_idOP_i)/OP_i^2],$$

$$(6) \qquad dS_i = S'_id(RP_i)_{-1},$$

$$(7) \qquad dS_{us} - dD_{us} = \Sigma_i(dD_i - dS_i), \text{ and}$$

$$(8) \qquad dP_i = g'_i(e_idP_{us} + P_{us}de_i).$$

Equations (5), (6), and (8) may be substituted into equation (7) to yield

$$(9) \qquad \frac{dRP_{us}}{RP_{us}} = \left[\Sigma_iD_iN_i\frac{dZ_i}{Z_i} - {}_iS_iE_i\left[\left(\frac{dZ_i}{Z_i}\right)_{-1} + EP_i\left(\frac{dRP_{us}}{RP_{us}}\right)_{-1}\right] - S_{us}E_{us}\left(\frac{dRP_{us}}{RP_{us}}\right)_{-1}\right]\Big/ - (D_{us}N_{us} + \Sigma_iD_iN_iEP_i),$$

where

$$(10) \qquad \frac{dZ_i}{Z_i} = EP_i\frac{de_i}{e_i} + EP_i\frac{dOP_{us}}{OP_{us}} - \frac{dOP_i}{OP_i},$$

$$(11) \qquad EP_i = g'_i\frac{e_iP_{us}}{P_i}.$$

In equation (9), N_i and E_i are elasticities of domestic demand and supply in the ith region with respect to real domestic price. EP_i is the elasticity of nominal price transmission. When $EP_i = 1$, equation (10) defines an inflation-adjusted (or purchasing power parity) exchange rate change.

Equations (9) and (10) reveal the economic forces at work. The percent change in the current real U.S. commodity price depends on (a) the changes in general price levels and exchange rates in the current period and (b) the supply effect due to price and exchange rate changes in the previous period.

Demand and Supply Effects

The current period changes in exchange rates and alternative prices operate through the demand side only. This demand effect is measured by the first term of equation (9). For a nonzero EP_i, an increase in the bilateral exchange rate (appreciation of the dollar) or in the U.S. general price level reduces the current real U.S. commodity price.

The demand effect of alternative prices in other countries reflects the substitution with other commodities. An increase (decrease) in foreign general price levels increases (reduces) foreign demand and current U.S. price.

The supply side, by assumption, is affected only by the lagged values of prices and exchange rates. The lagged effects of all previous exchange rate and alternative price changes are captured by the two supply terms of equation (9). The first supply term measures the foreign supply effect. The second supply term measures the U.S. supply effect.

The bracketed expression in the first supply term is the percent change in the lagged real domestic price in the ith country. This lagged real price change determines current period supply. For a nonzero EP_i, an increase in the lagged bilateral exchange rate or in the lagged nominal U.S. commodity price (due to past inflation and exchange rate changes) tends to increase foreign supply, reducing current real U.S. commodity price. An increase in lagged foreign alternative prices tends to decrease the foreign supply effect, increasing current U.S. commodity price. (Note that from the foreign supply viewpoint, the effects of changes in alternative U.S. prices net to zero.)

An increase in lagged real U.S. commodity price will increase current U.S. supply and tend to reduce current price. If the level of U.S. supply is large relative to total world demand, the U.S. supply term will tend to

dominate the expression for the total supply effect.

Inflation and Exchange Rate Effects

Although we are interested primarily in combined, or inflation-adjusted exchange rate effects, the separate effects of inflation and bilateral exchange rate changes can be determined. To determine the impact of inflation, independent of exchange rate effects, all exchange rate changes are set equal to zero, and the time path of real price changes, due to general price level changes, is calculated. Alternatively, setting all price changes equal to zero and tracing exchange rate changes determines the real price effects due to exchange rates independent of other price changes.

Price Insulation Policies

The linkage of internal and world market prices is an essential factor in determining the impacts of exchange rates on U.S. commodity prices. We consider a free trade policy and two types of price insulation policies.

Free Trade. We use free trade policy to describe the situation where the nominal price transmission elasticity is near one. For simplicity we assume the nominal price transmission is perfect, $EP_i = 1$, under free trade. Equation (10) then gives

$$(12) \quad \frac{dZ_i}{Z_i} = \frac{de_i}{e_i} + \frac{dOP_{us}}{OP_{us}} - \frac{dOP_i}{OP_i}.$$

The change in current U.S. price depends on the change in the bilateral exchange rate relative to the divergent rates of inflation. If exchange rate changes reflect PPP theory, the sum of these terms will be zero.[1] In this case, there would be no current price effects, hence, no subsequent supply effects in later periods. Exchange rate effects would emanate only from movements of disequilibrium rates to equilibrium and from equilibrium rates to disequilibrium.

Nominal Price Insulation Policies. If the EP_i is less than one, exchange rate changes that reflect PPP theory would result in a divergence between changes in real commodity prices in the United States and those in foreign countries. Trade and price effects in the United States would be created. The closer EP_i is to zero, or to perfect domestic nominal price insulation, the more dominant the foreign inflation rate becomes in determining supply and demand changes.

The perfect insulation of domestic nominal prices reduces the price linkage equation (10) to a single term,

$$(13) \quad \frac{dZ_i}{Z_i} = -\frac{dOP_i}{OP_i}.$$

Thus, current foreign demand is influenced only by the current change in other prices. Similarly, foreign supply is influenced only by the lagged value of other prices. Foreign demand would be increased by foreign inflation tending to increase U.S. commodity prices. Supply would be decreased by inflation, also tending to increase U.S. prices.

A nominal price insulation policy, with inflation, would result in a declining real consumer and producer price of a commodity. Such a situation has been noted for the real Japanese consumer price of wheat over relatively long periods (Gallagher, Lancaster, Bredahl). Nominal price insulation also may be descriptive of cotton prices in many less developed countries.

Real Price Insulation Policies. If consumption levels and/or farm income parity are policy goals, rather than nominal prices, the nominal price transmission specified in equation (4) may not obtain. Real price may be the policy target. Nominal prices would be adjusted to mitigate the effects of domestic inflation. For this case, the model is modified to reflect a real price insulation specification.[2] Equation (9) remains the same, but equation (10) becomes

$$(14) \quad \frac{dZ_i}{Z_i} = EP^*_i \left(\frac{de_i}{e_i} + \frac{dOP_{us}}{OP_{us}} - \frac{dOP_i}{OP_i}\right).$$

For a country with perfect domestic real price insulation, $EP^*_i = 0$, intertemporal demand and supply changes would be zero.

In this case, divergence of the exchange rate from that suggested by the PPP theory will not induce demand or supply changes. One would suspect that this type of price insulation policy most likely would be followed in countries with high rates of inflation.

[1] See Officer for a review of PPP. He labels this short-run interpretation of PPP an extreme view.

[2] This may be derived using equations (1)–(3), and $RP_i = h_i(R_iRP_{us})$, where the inflation-adjusted exchange rate, R_i, is defined as $R_i = e_i \dfrac{OP_{us}}{OP_i}$. Defining EP^*_i as the real price transmission elasticity, $dZ_i/Z_i = (EP^*_i)\, dR_i/R_i$.

The existence of price insulation policies has a potentially significant impact on the effect of bilateral exchange rate changes and rates of inflation. The nominal price insulation case acts as an upper bound on the price effects under restricted trade, because of the demand and supply changes caused by foreign inflation. The real price insulation case represents a lower bound under restricted trade, as governments attempt to insulate real domestic market forces.

Data and Assumptions

Historical values of exchange rates and general prices are used to compute both their combined (inflation-adjusted exchange rate) effects and separate, or decomposed, effects on U.S. commodity prices. The analysis is replicated under free trade and restricted trade assumptions, using both nominal and real price insulation alternatives. Both current demand and lagged supply effects are isolated.

The necessary data include (*a*) demand and supply elasticities, quantities demanded and supplied, and inflation rates for all countries; (*b*) percent changes in foreign currency values of the U.S. dollar; and (*c*) elasticities of price transmission for all countries. The requirements are large but not restrictive. Trade data and exchange rates are widely reported. Numerous estimates of demand and supply elasticities are available for many countries. Trade policies are well-documented providing information for determining the price transmission elasticities.

Thirty-seven foreign countries were selected to provide breadth in coverage of total consumption, production, and trade in market economies for the four commodities of interest. Central plan countries were excluded from consideration due to the inability to obtain appropriate data and acceptance of the hypothesis that price movements along internal demand and supply curves have not been principal inducements to agricultural trade.[3] Of the market economies during 1970 to 1977, the countries used in the calculations accounted for 70% of wheat, 77% of corn, 95% of soybean, and 85% of cotton consumption. Their shares in production were 83% for wheat, 75% for corn, 96% for soybeans, and 81% for cotton.

[3] This is equivalent to the real-price transmission case with $EP^*_i = 0$ for central plan countries.

For consistency across commodities, changes in exchange rates and general price levels are computed for a compromise September/August crop year. The exchange rate series selected as most appropriate is a period-average trade conversion rate, the International Monetary Fund's (IMF) "rf" series.

There are many possibilities for the alternative price, or deflator, used in the internal demand and supply equations. Any broad-based measure of general price levels that has a small imported good component (candidates are the GNP deflator, consumer or producer price indexes, index of unit labor costs, etc.) is reasonable, since changes in exchange rates are assumed to have little or no impact on the deflator. The producer price index (PPI) is used here because the agricultural product supply is a primary commodity supply and the demand is a derived demand. The PPI may better reflect available substitution opportunities in supply and demand because decision variables would include prices of inputs, other primary commodities, or semimanufactured and manufactured products not yet at the final production state.

For a given commodity, the same internal short-run domestic demand and supply elasticities are used for each country. The demand and supply elasticities (identical to those used in previous analyses by Johnson, and Bredahl, Meyers, Collins) are −.2 and .2 for wheat and cotton and −.4 and .2 for corn and soybeans.

Procedures and Results

Results of the analysis are reported in three sections. First, we compare the impacts of exchange rate changes in a world characterized by free trade, nominal-price insulation policies, and real-price insulation policies. Second, the computed change in real wheat price is decomposed into demand, supply, exchange rate, and inflation effects. Finally, the time path of actual real-price changes of the major commodities for the 1971/72 to 1977/78 crop years are compared with the computed results.

Under free trade, price transmission is perfect; thus, the differences in results due to nominal and real price insulation can arise in the restricted cases only. The nominal-price insulation case assumes that price-insulating countries do not adjust commodity prices in

response to internal inflation. The real-price insulation case assumes commodity prices in insulating countries are pegged to general price levels as measured by the PPI.

In the restricted trade cases, the elasticity of price transmission is set equal to zero for countries that exhibited significant market insulation policies during part or all of the seventies, and it is set equal to 1 for the remaining countries. Although these polar cases are unlikely to hold rigorously over time for each country, their use obviates the selection of an intermediate point. The free trade case assumes the elasticity of price transmission is 1 for all countries. Consideration of the free trade and restricted trade cases permits flexibility; it provides a measure of the sensitivity of exchange rate effects to different levels of effectiveness of price insulation policies of major trading nations.

Supply effects of previous exchange rate changes in the initial period of analysis, 1970/71–1971/72, are assumed to be zero.[4] For subsequent periods, inflation-adjusted exchange rate effects are determined using the current period data and the previous period's computed exchange rate effect.

[4] Our interest is in the exchange and inflation rates of the 1970s, so we desire a base year (the year preceding the first year analyzed) that closely precedes the seventies. Inflation-adjusted exchange rate effects in the base year should be minimal so that little bias is introduced by assuming no lagged supply effects in the first year of analysis. To the extent that a real-price-increasing (decreasing) supply effect exists in the first year of analysis, the results understate (overstate) the exchange rate effects.

Impact of Price Insulation Policies

The impact of exchange rate changes and inflation on real U.S. commodity prices depends critically on the nature of the price insulation policies of foreign countries. In most cases, the magnitude of real price effects is least under real-price insulation prices, somewhat larger under free trade, and largest under nominal-price insulation policies (table 1).

Price insulating policies do not mitigate the impact of exchange rate changes and foreign inflation. Almost without exception, the impact is largest under nominal-price insulation policies. In a few comparisons, even the real-price insulation case results in larger changes than the free trade case.

It is not surprising that the results for the real linkage case are generally similar in sign and magnitude to the free trade case, since the real linkage case is, analytically, the free trade case applied to a smaller world. These results imply that if countries practicing price insulation attempted to hold real prices fixed during the seventies, the inflation-adjusted exchange rate impact on U.S. prices would not have been much different than if they had engaged in free trade.

Foreign inflation explains why the nominal linkage case shows much larger inflation-adjusted exchange rate impacts than under the real-price insulation case or free trade.[5] The

[5] Brazil, Argentina, and Chile have been omitted from the analysis for wheat, corn, and cotton. Argentina and Chile were omit-

Real price insulation		3.0	0.4	0.3	−1.7	−3.8	−2.1	−0.3
Free trade		0.4	−2.6	7.3	−4.1	−0.3	−0.5	4.8
Nominal price insulation		6.6	10.3	22.2	7.5	4.8	6.7	11.3

Note: The nominal-price insulation case assumes trade-restricting countries fix domestic nominal commodity prices. The real-price insulation case assumes nominal commodity prices are insulated from world market prices but pegged to a general price level.

principal reasons for this disparity would be the demand-increasing effects of rising prices of substitutes and supply-reducing effects of increased foreign production costs.

A similarity of the results for wheat and cotton, under all cases, should be noted. A similar correspondence exists for corn and soybeans. These results reflect the importance (supply and demand weights) of major producing and consuming countries. The results for corn and soybeans are dominated by developed countries (European Community and Japan). These countries have experienced moderate rates of inflation; thus, smaller commodity price changes were computed under the nominal-price insulation case. The results for the free trade and real-price insulation cases indicate exchange rate changes have almost completely compensated for divergent rates of inflation.

Wheat and cotton are produced and consumed primarily in less developed countries (LDCs). Characteristically, these countries have experienced large rates of inflation which account for the relatively large impacts under the nominal-price insulation case. However, if these countries attempted to adjust agricultural commodity prices to the domestic rate of inflation, the impact of inflation-adjusted exchange rate changes on U.S. commodity prices would be much smaller. These results underlie the need to take account of domestic price policies and inflation rates in empirical trade research.

ted for soybeans. The principal result of including these countries is larger inflation-adjusted exchange rate effects under nominal linkage, from 1974/75 on. This is due to their extremely large domestic inflation rates.

Decomposing Wheat Price Effects

In order to illustrate the factors contributing to the computed inflation-adjusted exchange rate effects, the restricted-trade wheat results are broken into separate exchange rate, inflation, demand, and supply effects (table 2).[6] Wheat policies are checkered with restrictions that result in numerous trade barriers. Barriers vary from the fixed import price of the European Community to the fixed Japanese consumer price; therefore, free trade is not descriptive of the effect of global wheat policies.

The separate exchange rate effects are, by derivation, identical under the two price insulation policies. We conclude that the magnitude of exchange rate impacts in the seventies depends decisively on whether an exchange rate impact is defined as that which was caused by changes in exchange rates alone or that which was caused by inflation-adjusted exchange rates. The computed change in real U.S. wheat price due to exchange rates alone is negative in five of seven years. This reflects the currency depreciations against the dollar of a number of wheat importers. Many countries, primarily LDCs, have pegged their currencies to the dollar.

[6] Decompositions of price effects for free trade and for the other commodities and the policy assumptions used are available from the authors on request.

Inflation	6.3	8.7	25.5	4.6	11.3	7.6	15.3

[a] The nominal-price insulation case assumes trade-restricting countries fix domestic nominal commodity prices. The real-price insulation case assumes nominal commodity prices are insulated from world market prices but pegged to a general price level.
[b] The total supply effect is the sum of the foreign and U.S. supply effects.

Computed inflation effects account for the differences in the restricted trade results for wheat. In the real-price insulation case, the maximum increase in real wheat price due to inflation alone is 9.4%, for nominal price insulation the maximum jumps to 25.5%. Under real price insulation, downward commodity price pressure is indicated after 1973/74. Inflation effects under nominal price insulation, however, imply upward pressure on wheat prices throughout the entire period.

The decomposition of the restricted-trade, real-commodity price effects into their demand and supply contributions permits further insights. We conclude that exchange rate impacts during the 1970s depended on both current and past exchange rate changes and that the economic impact of these changes in any one year have often been offsetting. A current period U.S. dollar depreciation, coupled with foreign inflation, increases U.S. export demand inducing U.S. commodity price increases. This feeds into the next year as a supply-increasing incentive which puts downward pressure on U.S. prices in that period. The effect on wheat price from U.S. supply changes due to inflation-adjusted exchange rate changes was primarily negative, while the foreign supply effect was positive, offsetting the U.S. effect in almost every year.[7]

Offsetting demand and supply factors explain part of the small, separate exchange rate effect for wheat. For example, during 1972/73, the dollar depreciated about 10% against major Western Europe currencies and the yen. Decomposing the computed separate exchange rate effect of these depreciations into demand and supply effects for wheat reveals that the developed countries' demand effect on U.S. wheat price was about 4%. Offsetting supply effects and the demand effect of LDCs resulted in a net exchange rate effect of −0.1% (table 2). This is evidence of the inappropriateness of using simple exchange rate measures (often heavily weighted by developed countries) to infer exchange rate impacts for individual commodities.

Comparison with Actual Price Changes

The approach used measures the impact of inflation-adjusted exchange rates in isolation of other factors. This approach facilitates disentangling the effects of the factors affecting exports, hence commodity prices, during the seventies. A comparison of actual changes in real U.S. commodity prices with the computed price changes indicates the importance of exchange rates and inflation relative to the changes related to other factors.

To make the comparison, the "best" de-

[7] The assumed cobweb supply response causes the U.S. supply effect to be opposite in sign to the previous period's real price effect. The sign of the foreign supply effect, and thus the total supply effect, may agree or disagree in sign with last period's price effect, depending on foreign inflation and exchange rate changes of the previous period. The magnitude of the total supply effect is, of course, a result of the assumed cobweb model. Alternative lag patterns could be used to distribute the supply effect over several periods.

Table 3. Comparison of the Computed Real Price Changes, under Selected Price-Insulation Policies, with Actual U.S. Commodity Price Changes

[c] Results based on nominal-price insulation policies.

scription of the price insulation policies for each commodity was selected. We judged real-price insulation policies for wheat and corn, free trade for soybeans, and nominal price insulation for cotton to be representative of most of the seventies.[8] The strength of the implications is, of course, conditioned on the reasonableness of these selections.

Comparing price effects under the selected policies with actual price changes suggests inflation-adjusted exchange rates had a minor role in the large increases in commodity prices of wheat, corn, and soybeans during the early 1970s (table 3). For example, the real U.S. price of wheat increased almost 108% from 1972/73 to 1973/74. An increase of about 7% would be attributed to exchange rates and inflation. The comparison of actual and simulated corn and soybean prices leads to a similar conclusion.

By contrast, the real price of cotton increased almost 50% from 1972/73 to 1973/74. An increase of about 22% would be forthcoming from the effects of exchange rates and inflation. Note, however, the following year real cotton prices fell over 50%, illustrating the importance of factors other than exchange rates and inflation.

It has been suggested that the depreciation of the U.S. dollar has been a driving force behind trade and price increases during the seventies. Our results indicate much of the variability in commodity prices is attributable to other factors. However, to the extent that nominal-price insulation policies were pursued, domestic and foreign inflation emerge as important price-increasing forces for individual commodities.

Conclusions

The model and the application naturally have limitations. They abstract from many, possibly significant, factors. The partial-equilibrium elasticity approach admits no endogenous cross-price effects or absorption approach feedbacks. Choice of the reported exchange rates, price deflator, and assumed elasticities may raise issues of suitability. Expectations and lags (other than the one-year supply response lag) are not considered. Further, the computed exchange rate effects are not empirically validated and must be accepted with confidence proportionate to that one has in the assumptions of the model.

Limitations, however, should be only the sustenance, not the substance, of economic analysis. The computed exchange rate effects on U.S. commodity prices, despite abstractions, consider many factors heretofore ignored by researchers. The strength of the model lies in the simultaneous consideration of prices, consumption and production levels, and exchange rates for a nearly exhaustive set of major trading nations. The advantage of integrating alternative prices and intervention policies moves distinctly toward realism.

The strength of the empirical application, the tracing of exchange rate effects during much of the 1970s, lies in the diversity of results. The alluring simplicity of being able to announce exchange rate impacts on trade, hence prices, as simply large or small is rejected. Their size depends on the crop, the year, the countries considered, the degree of government influence on markets, the underlying elasticities, the price variable that is measured, whether real or nominal, the alternative prices considered, and importantly, the definition of an exchange rate effect.

This analysis does not limit the exchange rate effect on current U.S. price to the price change that occurs when a current period dollar revaluation alters demand. It goes beyond this: the price effect from a change in current supply, induced by past exchange rate changes, is part of the effect. The inclusion of the supply side moderated the overall exchange rate impacts. Differential inflation rates are also part of the effect.

If exchange rate changes reflect only differential rates of inflation, then under free trade, nominal commodity prices change but demand and supply do not. In contrast, if exchange rates are fixed, differential inflation rates cause demand and supply changes. An effect on real prices is induced.

Understanding exchange rate effects during the 1970s requires consideration of world inflation and price insulation policies. As the pervasiveness of nominal-price insulation policies increases, the impact of inflation and exchange rate changes on U.S. export demand and real commodity prices increases significantly.

[*Received November 1979; revision accepted May 1980.*]

[8] The policy assigned to each country for each commodity was assumed to remain in effect over the 1971–77 period. An alternative approach would be to vary the assignments year by year.

Aggregated Personalistic Beliefs on Yields of Selected Crops Estimated Using ARIMA Processes

David A. Bessler

This study investigates the empirical relationships between the aggregated elicited probability distributions from individual farmers on yields of three 1977 California field crops and their data-based representations. The comparison suggests that for expected values, the ARIMA representations agree with the aggregated elicited distributions. However, for higher moments, the ARIMA processes do much poorer in representing the elicited distributions.

Key words: crop yields, stochastic processes, subjective probability.

The personalistic theory of probability is now well accepted in the literature on decision analysis. This theory differs from others (logical or frequency) by not attempting to specify a correct assessment. Any coherent assessment is admissable as long as it adequately reflects an individual's state of ignorance concerning an uncertain event. For instance, nothing obliges a decision maker to choose his probabilities according to relative frequency or some other a priori specified pattern. As the amount of information each person possesses varies, so too might his personalistic probabilities. This apparent lack of restrictions on probabilities presents no logical difficulty when the decisions of the individual are the object of analysis. Indeed, the theory only requires the decision maker adhere to a rather weak condition: probabilities should be evaluated such that it is not possible to bet with an individual and be guaranteed a priori of a gain or a loss.

The picture is somewhat muddied when we study the aggregate decisions of groups of individuals. For instance, the analysis of farmers' acreage response to price and other information variables is often given theoretical justification by referring to theories of individual firm behavior; a similar relationship is then argued to hold by analogy among macroinformation variables at the aggregate level. Where the individual behavior is thought to depend on personalistic probabilities, it is not obvious which particular personal probability (or combination of probabilities) ought to be used. In addition, even if one is able to arrive at a meaningful aggregate personalistic distribution using a notion of, say, the representative individual, it is likely that the observations on such will be difficult (or expensive) to obtain. For example, this might require that the analyst elicit personalistic probability distributions from a random sample of farmers every year and use their average distribution in an aggregate model.

An alternative procedure is to argue that individual and aggregated (representative) probabilities are closely related to their data-based representations. That is, one might argue that the personalistic distributions of individual agents are systematically related to the quantitative observations on one or more information variables. This is the procedure followed by Just in his analysis of California acreage supply response. Although he argued that individual production decisions were dependent upon personalistic (subjective) distributions of the individual decision makers, in the final analysis he had to relate these distributions to observations on quantitative data observed over time. He did not use elicited personalistic distributions of individual deci-

Journal Paper No. 8024, Purdue University Agricultural Experiment Station.

The author wishes to acknowledge helpful discussions on this topic with Richard Howitt and Quirino Paris. The time-series data were obtained from Richard Green. Specific comments, which improved the readability of the paper, were made by Otto Doering and an anonymous referee.

sion makers in his final supply response estimation. Indeed, a time series of such observations would have been all but impossible for him to obtain.

Fortunately, this intuitive notion on the relationship between subjective probabilities and observed data has been worked out for a number of cases. For example, de Finetti (1937) in his seminal paper on probability, was able to show a relationship between exchangeable data and personalistic probability. In particular, he showed that for observations on exchangeable data—data for which the order of observation makes no difference to a decision maker—an evaluation of probability close to relative frequency follows in a coherent manner from an initial judgment. In language commonly used by Bayesian probabilists, we can restate de Finetti's point more intuitively by saying that as one observes more and more exchangeable observations, his prior distribution is swamped by the data. The case for nonexchangeable observations is similar conceptually—although there are numerous practical difficulties in arriving at a final distribution. Here the influence of order of observation on the probabilities must be considered. That is, for example, if the data tend to follow some pattern in the sequence of observation, one will want to take this into account in forming his probabilities. We can use de Finetti's (1937) own words to make the argument for nonexchangeable observations:

> The influence of the order on the evaluation of the probabilties . . . does not modify, indeed, the way in which the problem is posed and answered according to the subjectivistic conception; one will only be led, in the general case, to take account of the circumstances which in the case of exchangeability are (by definition) neglected. One can indeed take account not only of the observed frequency, but also of regularities or tendencies toward regularities which the observations can reveal. (p. 145)

The fact that analysts are able to work out a natural evolution of personalistic probabilities based on the sequential observation of data does not necessarily imply that decision makers follow or hold these derived probabilities. Such derivations are normative in the sense that if the analyst has identified the set of information deemed relevant by the decision maker and if the decision maker is rational, then he should form his probabilities close to the normative benchmark. However, there is nothing in such derivations which suggest that agents must or will formulate their probabilities according to any prespecified rule (de Finetti).

The purpose of this paper is to investigate the empirical relationship between personalistic probabilities and their data-based representations on 1977 yields of certain California field crops. The study could be carried out at the individual or microlevel. That is, the relationship between historical observations on yields received by individual farmers and their personalistic distributions on future yields could be studied and would generally be of interest to decision analysts. However, individual records on historical yields were not available for the sample of farmers in this study. Such data were available at higher levels of aggregation—county, region, and state. Because much of the work in economic modeling is at these higher levels of aggregation, a study of the relationship between aggregated personalistic distributions and their data-based representations also is of general interest.

Considerations on Aggregation

Because the analysis is made at the aggregate level, discrepancies between the data-based representations and the aggregated personalistic distributions can arise from numerous sources. To illustrate these, note figure 1, adapted from Ijiri. The micro or individual relations of interest ($f_{i,x}$) are between individual observations on historical data, ($x_{i,1}$, $x_{i,2}$, . . . , $x_{i,\tau}$), and individual, personalistic distributions on data in period $\tau + 1[\pi_i(x_{i,\tau+1})]$. Here we follow de Finetti's theory and allow this relationship to vary across each of the N individuals in the sample. Because we were not able to observe individual observations on the $x_{i,\tau}$'s of these microrelations, we focus on the relationship (F_X) between aggregates of historical data, (X_1, X_2, . . . , X_τ), and aggregates of individual personalistic distributions on data in $\tau + 1[\Pi(X_{\tau+1})]$. That is, we observe the relationship between the data and probabilities in the bottom line of figure 1.

$$\begin{tikzcd}(x_{i,1}, x_{i,2}, \ldots, x_{i,\tau}) \arrow[r, "f_{i,x}", "i=1,2,\ldots,N"'] \arrow[d, "\phi"'] & \pi_i(x_{i,\tau+1}) \arrow[d, "\psi"] \\ (X_1, X_2, \ldots, X_\tau) \arrow[r, "F_X"] & \Pi(X_{\tau+1})\end{tikzcd}$$

Figure 1. A general representation of an aggregation

Clearly, the function f can vary from individual to individual and from random variable to random variable. For instance, the relationship between exchangeable data and personalistic distributions is expected (de Finetti 1937) to be different from the relationship between nonexchangeable data and personalistic distributions. Thus, the particular function f must be allowed to be dependent on both the individual decision maker and the particular set of data which he brings to the assessment task. Analogously, the aggregate relation F is written such that it is dependent upon the data X (we could also write F such that it is dependent upon the group of individuals studied).

The aggregators ϕ and ψ take the microdata and microprobabilities into macrodata and macro (or aggregate) probabilities. The function ϕ, for instance, may be a simple convex combination with weights of $1/n$ assigned to each set of microdata. Similarly, ψ might be a convex combination of each microprobability.

Using the structure in figure 1, we can then restate the focus of our study as the relationships $(f_{i,x})$ which exist between observed data and personalistic probabilities. However, since we are not able to obtain long series of observations on microdata, we somewhat pragmatically study the relationship (F_X) between aggregate data and aggregated personalistic probabilities. Specifically, we describe a relation (F_X) between aggregate data and aggregate probabilities; we then investigate its reasonableness by comparing modeled aggregate probabilities based on aggregate data and actual aggregated probabilities, $\Pi(X_{\tau+1})$.

Modeling Time-Series Data

The class of models we investigate focuses on the probability structure itself. Procedures for doing this have been available for some time from numerous sources—probably the best known being the three-step procedure of Box and Jenkins.

A general univariate representation of the process Y_t (yield in period t) which we investigate is given as

$$(1) \quad \phi(B)(1-B)^d(Y_t-\mu)=\theta(B)a_t,$$

where the term $\phi(B)$ is an autoregressive operator of order p, given as

$$\phi(B)=(1-\phi_1B^1-\phi_2B^2-\ldots-\phi_pB^p),$$

$\theta(B)$ is a moving average operator of order q,

$$\theta(B)=(1-\theta_1B^1-\theta_2B^2-\ldots-\theta_qB^q),$$

where μ is the mean of the series Y_t, B is the lag operator $(B^iY_t=Y_{t-i})$, and a_t is a random error. Some suggest it useful to view a_t as an innovation that drives the series through time (Granger and Newbold 1975). The integer d is usually of low order 0, 1, or 2 (Granger and Newbold 1974). Writing equation (1) for the stationary series $y_t=(1-B)^d(Y_t-\mu)$, we can characterize the conditional probability distribution on y_t by its first two moments:

$$E(y_t|y_{t-1},y_{t-2},\ldots)=\phi(B)^{-1}\,\phi(B)E(a_t);$$

$$\mathrm{Var}\,(y_t|y_{t-1},y_{t-2},\ldots)=\sigma_{a_t}^2.$$

Note, for all periods preceding period t, $E(a_{t-i})$ will not, in general, equal zero. It will be given as a fixed, observable number which represents the unexplained portion of y_{t-i} in period $t-i$.

Box and Jenkins (p. 175) provide the following relations between the autocorrelations and partial autocorrelation functions of the series Y.

(*a*) For a nonstationary process the autocorrelation function tails off slowly.

(*b*) For a purely autoregressive process of order p, the autocorrelation function tails off and the partial autocorrelation function (Durbin, p. 235) has a cutoff after lag p.

(*c*) For a purely moving average process of order q, the autocorrelation function has a cutoff after lag q and the partial autocorrelation function tails off.

(*d*) For a mixed autoregressive process of order p and a moving average process of order q, the autocorrelation function is a mixture of exponential and damped sine waves after the first $q-p$ lags and the partial autocorrelation function is dominated by a mixture of exponential and damped sine waves after the first $p-q$ lags.

Box and Jenkins suggest comparing the estimated autocorrelation and partial autocorrelation functions applied to a particular series with the above patterns. The identification of values p, d, and q can oftentimes result in two or more distinctly different models (values of p, d, and q) which give reasonable representations of the empirical series (Box and Jenkins, p. 192; Wallis, p. 1487; or Priestley, p. 153). In such cases, researchers must rely on one of the many simplifying choice principles handed down from more philosophical works. These

include Occam's Razor, Parsimony (Box and Jenkins), or a Simplicity Postulate (Jeffreys). The models identified, using the procedures outlined above, can be estimated using iterative methods or nonlinear least squares. The usual conditions on the estimated parameters are that the autoregressive operator defines a stationary process and that the moving average operator defines an invertible process. In other words, the restrictions on estimated values of the parameters are that $\hat{\phi}(B)$ defines a process which is nonexplosive and $\hat{\theta}(B)$ defines a process which allows us to recover (observe) past values of a_t.[1]

Time-series data on yields were obtained from each California county from which our personalistic elicitations were obtained. We formed a regional series on each crop as a convex combination of each county—where weights were given by the rate of sampling for our personalistic elicitations. For example, our aggregate distribution on central valley wheat included three Merced County growers and five San Joaquin County growers. We combined the historical data on Merced and San Joaquin Counties, using the same 3/8 and 5/8 weights.

The estimated autocorrelation and partial autocorrelation functions on each series are given in table 1 for 1946–76 data.[2] The standard errors associated with low lags are approximately .18. From these estimates and their standard errors, we can make a number of observations. First, the functions for wheat and barley suggest different stochastic processes underlying central valley production and central coast production. The autocorrelations for the central valley grains remain high at relatively long lags (five or six); while those for the central coast show no strength at high lags. Second, it is not clear that different processes are required to model central coast sugar beets and central valley sugar beets. The autocorrelations for both series look similar. Third, note that the partial autocorrelation functions of both sugar beet series and central valley wheat and barley cut off at lag one; suggesting that if these series are modeled as stationary in their original levels, a first-order autoregressive scheme should be considered.

Due to the tailing off pattern in the autocorrelations for both sugar beet series and the series on Central Valley wheat and barley, we have used a difference transformation. The estimated autocorrelation and partial autocorrelation functions of the differenced series are given in table 2. The standard errors of the autocorrelations for low lags are approximately .18. Notice that the autocorrelations of each differenced series cut off at lag one. This suggests these differences are not generated by an autoregressive scheme in their first differences. The partial autocorrelations on both sugar beet series and the barley series show some evidence of tailing off. Thus, these may be generated by a first-order moving average process in their first differences. The series on Central Valley wheat exhibits no recognizable

[1] Hats (ˆ) refer to estimated values of the parameters included in the operator.

[2] The autocorrelation and partial autocorrelation functions are described in detail in Box and Jenkins, p. 64, and Durbin, p. 235.

barley	P	−.34	−.38	−.26	−.23	.04	.03	.34	−.11	−.15	−.26
Central valley	A	−.52	.01	.21	−.16	−.16	.33	−.18	−.01	.21	−.19
sugar beets	P	−.52	−.35	.05	.01	−.31	.05	.09	.04	.14	.03
Central coast	A	−.51	.09	−.29	.34	−.03	−.10	−.04	−.01	.20	−.13
sugar beets	P	−.51	−.23	−.51	−.17	.07	−.11	−.06	−.19	−.01	.02

Note: Autocorrelations for each commodity are given by the row labeled A; partial autocorrelations are given by row labeled P. Standard errors at low lags are approximately .18.

pattern. However, a first-order moving average process applied to its first differences ought to give us a parsimonious representation.

The models estimated for each commodity are given in table 3. As a check of the appropriateness of the estimated models, we have calculated the autocorrelations of the observed residuals—formed as the difference between the observed yield in any particular year and the yield predicted with our estimated model. These, along with the Q statistic (see Box and Pierce) are presented in table 4. The standard errors associated with the first two autocorrelations are approximately .18. In all models, the autocorrelations of the residuals are not significantly different from zero. Also, the Q statistics are below the critical chi-squared values—leading us not to suspect the adequacy of these representations. The time-series models summarized in table 3 are used as parsimonious representations for yields of the commodities studied.

Table. 3. Estimated Time-Series Models for 1946–76

Commodity	Model	Residual Standard Error
Central valley wheat	$(1 - B)Y_t = a_t - .33a_{t-1}$	.27
Central coast wheat	$Y_t = .43 + .35Y_{t-1} + a_t$	.13
Central valley barley	$(1 - B)Y_t = a_t - .38a_{t-1}$	.24
Central coast barley	$Y_t = .78 + .05Y_{t-1} + a_t$	.13
Central valley sugar beets	$(1 - B)Y_t = a_t - .48a_{t-1}$	2.56
Central coast sugar beets	$(1 - B)Y_t = a_t - .66a_{t-1}$	3.20

Note: All time-series models were estimated in terms of tons per acre. The forecasts on wheat and barley must be transformed to hundredweights per acre for comparisons with the subjective distributions in tables 6 and 7.

The Elicitation Experiment

Thirty farmers were selected from the files of the county farm advisors in ten California counties. These counties are in the large central valleys of California (San Joaquin and Sacramento valleys) and the central coast region. The elicitations took place in the fall of 1976 on the distributions of 1977 yield on barley, wheat, and sugar beets. Each elicitation took about one hour. The elicitations followed the procedure outlined in de Finetti (1965). We constructed a proper scoring rule and asked each assessor to distribute ten discrete probability units over the predetermined intervals given in table 5 (Stael von Holstein). The rule expressed potential payoffs to the assessor depending on the distribution of the discrete assessments and the average yield actually experienced by each farmer for the 1977 crop year. We allowed each farmer to modify this discrete distribution by shifting weight among intervals.

The individual elicited distributions are, in fact, distributions on separate random variables. That is, the yield from delta wheat land is not the same as Merced County wheat land. Soil, climate, managerial, varietal, and other differences exist among farming operations. Thus, each farmer responds to uncertainty inherent in his own operation. There is no reason to believe, a priori, that any agreement at all should exist among these individual distributions. Following the discussion of aggre-

gation given above, a more promising comparison can be made between the aggregated personalistic distributions and the statistical distributions based on aggregate historical data. We formed the aggregated personalistic distributions as a simple average of the individual distributions.

Comparison of Time-Series and the Elicited Distributions

The comparison statistical tests used here are ad hoc in nature. The classical theory of hypothesis testing is strictly couched in a frequency concept of probability. Thus, in testing the difference between two distributions (or their means), one makes inferences dependent on closeness relative to the number of observations or frequencies behind each distribution. Clearly, we cannot follow this line. The personalistic distributions are not frequency-based. In examining a similar problem, Winkler proposed using a quasi frequency-based test (in particular the Komogorov-Smirnov test) as evidence of agreement or disagreement among two or more subjective distributions. Our situation differs slightly in that, in the comparison of interest, we have one frequency-based distribution and one personalistic distribution. If we treat the aggregated personalistic distributions as fixed (which of course they are not), then we can apply standard frequency-based tests. However, such tests should be viewed with caution.

The time-series and aggregated subjective distributions on each commodity are given in figures 2.a–4.b. The smooth representations are for the time-series distributions obtained from table 3. The step functions represent the aggregated personalistic assessments on the yields of the same commodities.

The means of the times-series distributions and the personalistic distributions are given in table 6. Note the time-series distributions underpredict the mean yield in four of the six cases. Nevertheless, the ratio of the difference between the time-series mean and the aggregated personalistic mean to the standard error of the time-series mean (what is labeled t in table 6) is rather small in all cases. That is, the aggregated personalistic means fall within usually acceptable intervals around the time-series means.

An analysis of how well the entire aggregated personalistic distributions are modeled by the time-series distributions can be made using a quasi-Komogorov-Smirnov test. Winkler applies the procedure as one of his indica-

Table. 5. Subdivision of Yield Half-Line for Subjective Probability Assessments

Commodity	Number of Assessments	Unit of Measurement	Intervals for Assessment
Barley			
Coast	5	cwt./acre	$0 \leq Y_1 < 2.5 \leq Y_2 < \ldots < 100. \leq Y_{41} < \infty$
Valley	4	cwt./acre	$0 \leq Y_1 < 2.5 \leq Y_2 < \ldots < 100. \leq Y_{41} < \infty$
Wheat			
Coast	2	cwt./acre	$0 \leq Y_1 < 2.5 \leq Y_2 < \ldots < 100. \leq Y_{41} < \infty$

Sugar beets			
Coast	5	tons/acre	$0 \leq Y_1 < 2.0 \leq Y_2 < \ldots < 50. \leq Y_{28} < \infty$
Valley	6	tons/acre	$0 \leq Y_1 < 2.0 \leq Y_2 < \ldots < 50. \leq Y_{28} < \infty$

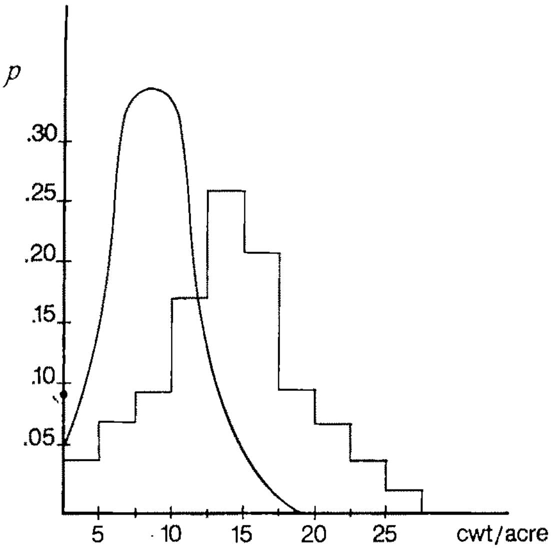

Figure 2a. Aggregate subjective and time-series distributions on 1977 California central coast wheat yield

tions of agreement among a group of subjective assessments. Other uses of the procedure include the work of Stael von Holstein. The procedure is analogous to the frequency-based Komogorov-Smirnov test of equality of two distributions. In table 7, we list the maximum vertical distance between the time-series and the aggregated personalistic cumulative distributions on each crop with the appropriate quasi-Komogorov-Smirnov test statistic.

The test summarized in table 7 suggests disagreement among the two distributions. That

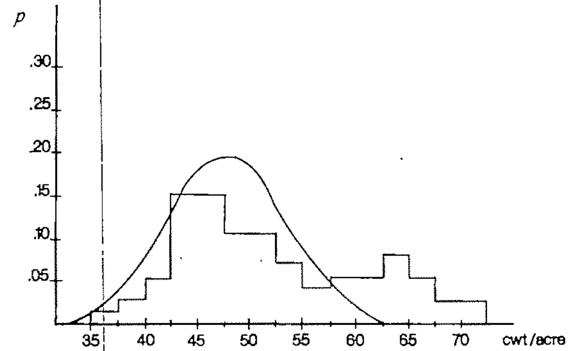

Figure 2b. Aggregate subjective and time-series distributions on 1977 California central valley wheat yield

is, treating the aggregated personalistic distributions as fixed, the chance that time-series distributions were generated by a process similar to the personalistic distributions is small.

Discussion

The analysis presented above should be qualified with a few comments. First, the time-series models used to represent the data assume the process generating the errors is normal. This presents at least two difficulties. First, the time-series distributions can suggest significant negative yields. That is, as in figure 2.a, it is possible for significant density to be nonzero at negative yields. In figure 2.a, we have accumulated all negative density and "stacked" it over zero. This seemed reasonable, yet it makes for an odd looking density function. In addition, the normality assumption does not allow the analyst to represent

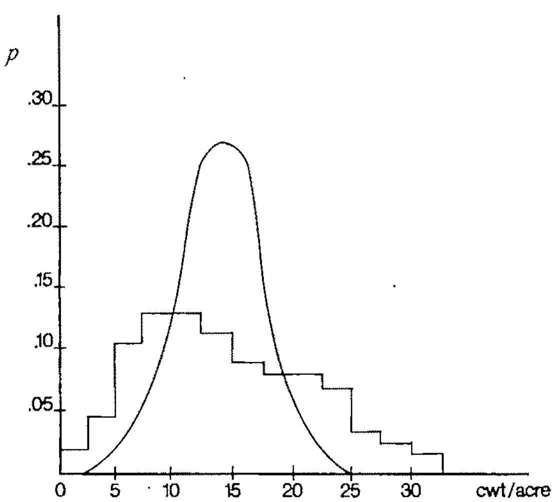

Figure 3a. Aggregate subjective and time-series distributions on 1977 California central coast barley yield

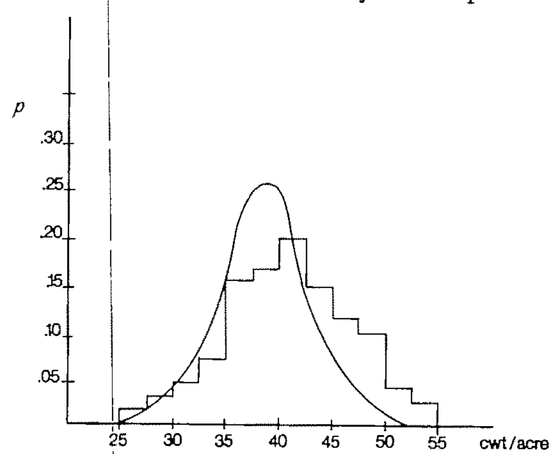

Figure 3b. Aggregate subjective and time-series distributions on 1977 California central valley barley yield

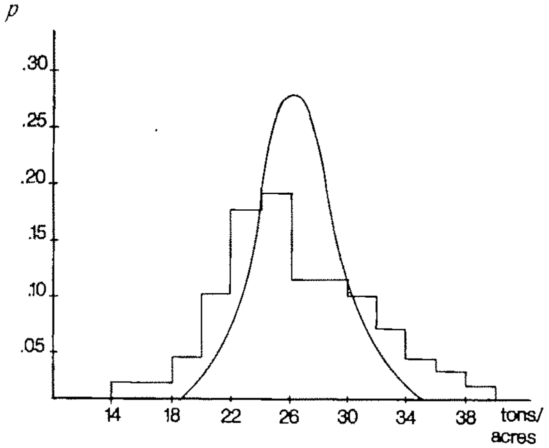

Figure 4a. Aggregate subjective and time-series distributions on 1977 California central valley sugar beet yield

skewed distributions. This point comes across in the figures and contributes to the large quasi-Kolmogorov-Smirnov statistics. Clearly, the aggregated personalistic distributions possess nonzero higher moments.

A second point which ought to be brought out is the static nature of our comparison. The analysis provides a "snapshot" of personalistic distributions at one particular point in time. A more complete and therefore preferred study would test the evolution of personalistic distributions through time, an important area for further study.

It is generally hoped that the aggregate representations of the macro variables "look something like" their micro counterparts. From the results of our study, we feel reasonably confident of using the ARIMA representations for the mean yield. Therefore, a suggestion similar to that made by Nerlove, that we model expectations using optimal statistical predictors (similar to our time series models) is not too disturbing. However, no such confidence can be expressed for modeling higher moments of the yield distribution. Of course the results presented here apply only to our particular commodities and to the set of thirty farmers interviewed.

Estimation and Optimal Control of an Uncertain Production Process

C. Robert Taylor and Jean-Paul Chavas

Three alternative decision rules for estimation and control of an uncertain production process are examined. One is a certainty equivalence strategy whereby an optimal rate based on current estimates of production parameters is used throughout the planning horizon. A second is updated certainty equivalence, a passively adaptive strategy. Third is an actively adaptive control formulation. Monte-Carlo simulation results show that the passively adaptive strategy outperforms the others. For the cases simulated, the actively adaptive approximation to the information state for a dual control problem is not good enough to establish superiority of this sophisticated strategy for all problems.

Key words: dual control, uncertain production processes.

Farm level recommendations regarding economically optimal input rates often are based on response functions estimated with data obtained from carefully controlled experimental plots. While optimal rates estimated with experimental data may be best for experimental plots, they often appear suboptimal for actual farm conditions (Taylor and Swanson). A response function for an experimental plot can diverge from a response function experienced under field conditions for a variety of reasons, including soil type differences, different topsoil thickness, micronutrient availability, precision of control over other inputs, and timing of field operations. Further decision complications arise when a new technology, such as a plant variety or tillage system or a whole production system, is introduced. In these cases, little if any experimental data are available on which to base optimal input rate recommendations.

Divergence of experimental fertilizer response data from actual farmer experiences and the lack of data for new production technologies suggest that individual farmers have to rely on their own experience in choosing optimal input rates. In this context, any input decision may have two roles. First, it is used to control the mean and higher moments of profit. Second, it will influence the generation of new observations which will allow the farmer to learn about his particular production technology and thus make better decisions in the future.

Recent articles by Feldstein, and Just and Pope examined economic implications of uncertain production technology. However, they did not introduce learning and adaptive optimization into the decision framework. The objective of this paper is to investigate alternative decision rules for estimation and optimal control of an uncertain process. Three strategies that could be used for making recommendations to a farmer about optimal input use are examined. All strategies involve using the same input rate for the whole field in a given crop year.

The first strategy considered is a certainty equivalence (CE) strategy whereby an optimal rate based on current estimates of the parameters of the response function is used throughout the planning horizon. With this strategy, there is no updating of parameter estimates as new observations become available. The second strategy examined is updated certainty equivalence (UCE), which differs from a CE strategy only in that parameter estimates are updated and optimal rates revised accordingly each time a new observation becomes available. UCE is a passively adaptive control strategy in the sense that current decisions are made without recognizing how they will influence learning. It belongs to the class of open-loop feedback controls. An actively adaptive control formulation (TBM) advanced by Tse, Bar-Shalom, and Meier is the third

C. Robert Taylor and Jean-Paul Chavas are associate professor and assistant professor, respectively, Department of Agricultural Economics, Texas A&M University. Seniority of authorship is equally shared.

strategy considered. This "wide-sense" adaptive model explicitly recognizes how current decisions will influence future knowledge. This strategy is dual in nature because the input level is chosen for both control and estimation of the model.

Organization of the remainder of the paper is as follows: section two presents the response model, while theoretical aspects of alternative control strategies are discussed in section three. Monte-Carlo simulation results, which provide the basis for the evaluation and comparison of each strategy, are presented in section four. Concluding remarks and suggestions for further research into adaptive optimization are given in the final section.

The Model and Alternative Control Strategies

We assume a quadratic response function that can give a local second degree approximation to any production function at time k:

$$(1) \quad y_k = b_1 + b_2 x_k + b_3 x_k^2 + e_k,$$

where y_k is per acre yield obtained in season k; x_k is per acre input rate in season k; b_1, b_2, b_3 are parameters characterizing the response function with $b_2 > 0$ and $b_3 < 0$; and e_k is normally and independently distributed noise in the response function attributed to weather variability or any random factor.[1] The error is assumed to be distributed with mean zero and variance

$$E(e_k, e_{k'}) = \begin{cases} \sigma^2 \text{ for } k = k' \\ 0 \text{ for } k \neq k' \end{cases}.$$

For the problem at hand, it is assumed that the form of the response function is known with certainty; however, there is incomplete knowledge about the parameters b_1, b_2, b_3. It is further assumed that the producer has available prior information (mean vector and covariance matrix) on the parameters b_1, b_2, b_3, and on the noise e_k. This information can be based objectively on previous observations on the field to which function (1) applies. Alternatively, the information can be of a subjective nature. Let the prior information on the parameters (b_1, b_2, b_3) at time k be denoted by $B(k) = [b_1(k), b_2(k), b_3(k)]'$, with prior covariance matrix Σ_k. Moreover, let s_k^2 be an unbiased estimate of the variance, σ^2, at time k.

[1] Process noises could also be included. However, we will assume no process noise throughout the paper.

Assuming risk neutrality, the performance measure is the present value of expected per acre profits:

$$(2) \quad E(\Pi) = \sum_{k=1}^{N} \left(\frac{1}{1+i}\right)^k E(Py_k - Rx_k),$$

where i is the interest rate, N is the planning horizon, and P and R are output and input prices, respectively. The parameters i, N, P, and R are assumed fixed (nonrandom). Thus the only uncertainty in the model is about the vector of production parameters (b_1, b_2, b_3). Thus the problem under consideration is one of uncertain technology with random parameters.

Certainty Equivalent Strategy (CE)

Letting the current decision period be $k = 1$, the CE strategy is to compute the optimal input rate for all future periods as

$$(3) \quad x^*_k = \frac{R/P - b_2(0)}{2b_3(0)},$$

where P is per unit price of the output, and R is per unit price of the input. Obviously this is a naive strategy that does not allow for any time of learning over time. It is included here primarily to show how the other strategies perform in comparison.

Updated Certainty Equivalent Strategy (UCE)

UCE differs from a CE strategy in that parameter estimates are updated each time a new observation on output y_k becomes available. Thus,

$$(4) \quad x^*_{k+1} = \frac{R/P - b_2(k)}{2b_3(k)}.$$

For this problem, the Kalman filter can be used to update the parameter estimates at time k based on the prior information $B(k-1)$, Σ_{k-1}, and on the observations for period k.

$$(5) \quad B(k) = B(k-1) + \Sigma_{k-1} X'_k(X_k \Sigma_{k-1} X'_k + s_{k-1}^2 I)^{-1}[Y_k - X_k B(k-1)],$$

where $X_k = (1, x_k, x_k^2)$. If the prior information represented by $B(k-1)$ and Σ_{k-1} is estimated by ordinary least squares (OLS) from sample information obtained before time k, the Kalman filter estimator, equation (5), is equivalent to an OLS estimator at time k and is an unbiased, minimum variance estimator of the population parameters (Chow 1975).

The UCE strategy does learn over time, but learning is of a passive nature since anticipation of learning is not used in calculating the current input rate.

Wide-Sense Actively Adaptive Strategy (TBM)

Various active adaptive schemes have been proposed in the literature (MacRae 1972, 1975; Chow 1975, 1976a,b; Tse, Bar-Shalom, and Meier; Bar-Shalom and Tse). Such schemes are intuitively appealing because they explicitly recognize the need for learning (Rausser, p. 483). Current decisions consider both control and estimation of the model. Current and future uncertainty are introduced in the decision rules, thus increasing information for improved performance in the future. Because of the closed-loop nature of actively adaptive strategies, the dimensionality (usually infinite) of the control problem is such that solution for an optimal strategy is computationally prohibitive. Consequently, workable active adaptive schemes are only approximations.

As noted by Rausser, the most widely publicised actively adaptive scheme is based on the work of Tse, Bar-Shalom, and Meier. Reasoning behind the TBM approach is too lengthy to reiterate in this paper. But, Rausser has provided a concise summary:

> In essence, the wide-sense dual control procedure advanced by these authors . . . decomposes the complete adaptive control problem into three components (*a*) current control, (*b*) future deterministic control, and (*c*) a future perturbation control. The perturbation, or experimental control component, is partitioned into a caution and probing term. The caution term reflects the effects of uncertainty at time *k* and subsequent system noise on the criterion function. The probing term summarizes the effect of uncertainties when subsequent decisions are made. (p. 483)

To avoid the infinite dimensionality associated with maintaining all features of the information state for adaptive control, the TBM approach approximates this state by maintaining only the updated estimates of the means and covariances of the parameters. Estimates can be updated with the Kalman filter (Chow 1975), given by equation (5). In the TBM approach, the optimal future benefit or cost-to-go is approximated up to the end of the planning period. Since the control of a linear quadratic Gaussian problem is easy to solve, the nonlinear joint control estimation problem is accordingly modified. TBM associates with each control at present time (k) a future fictitious nominal control sequence. For each nominal control trajectory, there is a corresponding nominal state trajectory and approximate trajectory of variances and covariances. Perturbation analysis carried out around these nominals from which approximate costs-to-go are obtained that explicitly reflects future learning and control performance.

In our case, the future nominal trajectory is chosen as the certainty equivalence (CE) solution. The objective function is to maximize the present value of net returns, which for the TBM model is the sum of three terms: the deterministic part, the caution term, and the probing term. The deterministic part is comprised of current expected profit and the discounted future profit along the nominal path. Because discounted future profits along the nominal path is not dependent on the current input rate, the deterministic component of the TBM objective function differs from the CE objective function only by a constant. The probing term is a weighted sum of the future elements of the covariance $\Sigma_{0,k+1}, \ldots, \Sigma_{0,N}$ along the nominal. In the maximization case, it can be shown that the probing term is always negative. Thus, added uncertainty tends to decrease the value of the objective function. Current control that decreases future uncertainty therefore makes the firm better off, which corresponds to the probing effect. The caution term always has the opposite sign of the probing term. In the absence of measurement noise, it is a weighted sum of the elements of the updated covariance matrix of the parameter estimates for the decision period k, Σ_k. The caution term is necessarily positive in a maximization framework, and thus tends to increase the value of the objective function and balance the probing effect. Thus, current uncertainty tends to imply more "cautious" decisions.

The input level that maximizes the three-part objective function is the optimal solution of the TBM dual control approximation. An illustration of the shape of the TBM objective function as well as shapes of the terms which comprise the function are given in figure 1. Note in figure 1 that the TBM objective function has three peaks, at input rates of approximately 50, 75, and 100. Two of these peaks are outside the range of prior information, while the third peak is at the upper limit of prior values of X. Although not always the

case, two peaks outside the range of prior information is rather typical for the problem considered here when prior information is sparse. Thus, with sparse information, the TBM approach typically leads to experimentation in the sense of selecting values outside the range of prior information. As information increases, the TBM objective function approaches the CE objective function, and both approach true profit.[2]

It is interesting to compare the functions shown in figure 1 to the illustration given by Bar-Shalom and Tse (p. 331) for a different problem. They showed all functions as being monotonic, while for our problem some of the terms have ranges of both increasing and decreasing values.

Monte-Carlo Simulation Results

Because the objective function for any strategy is approximated, the optimal control never can be exactly obtained. In order to evaluate the performance of each strategy, a Monte-Carlo simulation was carried out. Previous simulation experiments using various static and dynamic systems have not clearly demonstrated that the more sophisticated control strategies are always superior to the other strategies (Bar-Shalom and Tse, and Rausser). In this section, we examine the comparative performance of the three strategies discussed previously for a response function that appears to reflect fairly accurately dryland grain sorghum response to nitrogen fertilization in the Texas Blackland Prairies. The assumed true response function is

$$y = 2600 + 33x - .15x^2 + e, \tag{6}$$

where e is assumed to be normally distributed with mean zero, y is yield in pounds per acre, and x is nitrogen fertilizer application rate in pounds per acre. Assumed prices were \$.04 per pound of grain and \$.20 per pound of fertilizer. For the above parameters, the optimal fertilization rate is 93.3 pounds per acre. A maximum of 110 pounds and a zero minimum were assumed as constraints on the fertilization rate.

Since the profit function based on production function (6) is rather flat—suggesting that different input rates may have a small impact on the profit level and that experimentation may not be profitable—the following hypothetical production function which has a more peaked profit function was also examined:

$$y = -4300 + 185x - x^2 + e. \tag{7}$$

For the simulations, the amount of prior information and the standard error of e were varied to examine how they influenced performance of the various strategies. Standard errors of 150 pounds and 450 pounds, and prior information uniformly distributed over the ranges 40–85 and 67–85 were considered for production function (6). For function (7) both standard errors were evaluated, but only with prior information over the range 67–85. In all cases, it was assumed that ten prior observations on x were available.

For each simulation, standard normal deviates were generated to yield observations on y, first for the ten prior observations and then for each year in the twenty-five-year simulation period. The same sets of deviates were used for all strategies evaluated.

Because of several local peaks for the objective functions (see figure 1) for the actively adaptive strategy (TBM), a grid search in five-pound increments was used to locate the neighborhood of the global maximum. Then, a finer grid search in one-pound increments was used. A finer grid search was not used for the

[2] A paper that gives a derivation of the TBM wide-sense dual control approximation, specialized for the problem considered in this study, is available from the authors.

whole range of x values because of the high cost of solving for the TBM strategy.

The present value of profit averaged over twenty simulations is given in table 1 for each strategy for the cases considered. Surprisingly, UCE resulted in higher profits than any of the other strategies in all cases simulated. For the relatively flat production function (6), CE resulted in higher profits than TBM in all four cases. However, TBM outperformed CE in one of two cases using the more peaked production function (7).

For a few simulations where the prior estimate of b_3 was positive, the UCE strategy tended to lock in to the maximum permissible rate of 110 pounds. If the UCE strategy was modified so that there would be a variable maximum rate over time, learning would occur and profits undoubtedly would be higher. Or, a restricted estimator could be used to prevent positive b_3 coefficients. But a restriction of this type does not appear reasonable for some problems as the farmer does not know a priori that he is not in stage one of production. If no upper limit of any kind is placed on x, then UCE or TBM will blow up when a positive b_3 is encountered.

Concluding Remarks

This paper has investigated alternative ways of taking into consideration the value of information obtained from experimenting about a static nitrogen fertilizer response on dryland grain sorghum. As expected, results show that greater uncertainty tends to lower expected profit, indicating that more information (less uncertainty) improves welfare. Unexpectedly, the passively adaptive strategy (UCE) performed better than the sophisticated actively adaptive strategy (TBM) in all cases considered, including cases for a profit function that is more peaked than one would expect for the problem considered. Because the TBM objective function is higher than the UCE objective function, one might conclude that TBM will always outperform UCE. However, the approximated objective function obtained from theoretical considerations is not the profit function realized by applying a TBM strategy. Because the performance of TBM was slightly worse than UCE, we conclude that the TBM approximation to the information state for a dual control problem of the type considered here is not good enough to establish superiority of TBM for all problems. Two reasons may be advanced to explain the surprisingly poor performance of the more sophisticated algorithm, TBM. First, the choice of the certainty equivalent solution for the nominal path may not be appropriate. Second, the quadratic approximation along the nominal may disregard some information that would be relevant. Thus the TBM approach, while purporting to measure the value of information, does not seem to give a good approximation to the control problem.

A limit of this study is that it relies on the use of the least squares estimation method. Recently, Klein et al. have argued that it is inappropriate to use maximum likelihood estimates to make decisions because the loss function of the statistical estimation is usually different from the utility function of the decision maker. Although this paper has considered learning about the production uncer-

tainty, the implication of the estimation technique has not been investigated and is left for further research.

Perfect Aggregation and Disaggregation of Complementarity Problems

Quirino Paris

Perfect aggregation of linear complementarity problems is possible under the notion of constrained consistency. This notion—which also can be interpreted as a disaggregation rule—requires restrictions on the domain of the microvariables to be aggregated. The linear complementarity problem includes symmetric and asymmetric quadratic programming, linear programming, and two-person, nonzero-sum games. Hence, all these mathematical programming structures admit consistent aggregation and disaggregation of their primal and dual variables.

Key words: constrained consistency, linear complementarity problem, perfect aggregation, symmetric quadratic programming.

The problem of finding consistent procedures for aggregating economic models remains a pressing issue of methodological and empirical analyses. In the area of economic models specified within the framework of mathematical programming, the discussion of aggregation procedures has been limited essentially to linear programming (LP), with the contributions of Day, Miller, Lee, Paris and Rausser, Guccione and Oguchi. Only recently Oguchi and Guccione presented a brief treatment of the aggregation problem in asymmetric quadratic programming models.

This paper attempts to expand the discussion of consistent aggregation and disaggregation methods to all the mathematical programming models from the class of linear complementarity problems. Such a class is vast and includes (among others) symmetric and asymmetric quadratic programming, linear programming, and two-person, nonzero-sum game problems.

The linear complementarity (LC) problem consists in finding nonnegative vectors $\mathbf{z}$ and $\mathbf{w}$, such that

(1) $$-\mathbf{q} = -\mathbf{w} + M\mathbf{z}, \text{ and}$$

(2) $$\mathbf{w}'\mathbf{z} = \mathbf{0},$$

where $\mathbf{q}$ is an $r \times 1$ vector and M is a given $r \times r$ real matrix. The linearity of the problem is expressed by (1), while its complementarity feature is exhibited by (2). For a thorough discussion of the LC problem, one may consult Lemke (1968). Interest in the general complementarity structure is based on the fact that any proposition established about the LC problem is valid also for the mathematical programming models which are special cases of it.

All the microsystems in previous discussions of the aggregation problem within the framework of programming models are special cases of the above formulation. Consider, in fact, Day's linear programming formulation as re-elaborated by Guccione and Oguchi. These authors discuss an aggregation problem where a microsystem of K firms exhibits identical technologies, $A_k \equiv A_a$, $k = 1, \ldots, K$, where inputs and outputs must be consolidated into a consistent aggregate LP model and where, furthermore, the microvectors of resource constraints, $\mathbf{b}_k$, and the microvectors of net revenue, $\mathbf{c}_k$, are proportional to the corresponding aggregate (macro) constraint and revenue vectors, $\mathbf{b}_a$ and $\mathbf{c}_a$. In other words, $\mathbf{b}_k = \lambda_k \mathbf{b}_a$ and $\mathbf{c}_k = \gamma_k \mathbf{c}_a$, with scalars $\lambda_k \geq 0$, $\gamma_k \geq 0$; $k = 1, \ldots, K$.

It is simple to accommodate the LP microproblem of Day and Guccione and Oguchi into the linear complementarity framework (1) and (2). First of all, the block-diagonal matrix A, defined as follows:

Quirino Paris is an associate professor of agricultural economics, University of California, Davis.
Giannini Foundation Paper No. 557.

$$A = \begin{bmatrix} A_1 \equiv A_a & 0 & \dots & 0 \\ 0 & A_2 \equiv A_a & \dots & 0 \\ \dots & \dots & \dots & \dots \\ 0 & 0 & \dots & A_k \equiv A_a \end{bmatrix},$$

represents the K firms' linear technologies which Day chose to be identical; the set of technologies in a microproblem. Similarly, the microresource vectors, $\mathbf{b}_k$, and the net revenue vectors, $\mathbf{c}_k$, are stacked to form the vectors $\mathbf{b}$ and $\mathbf{c}$, respectively; that is, $\mathbf{b}' = (b'_1, b'_2, \dots, b'_K)$, $\mathbf{c}' = (c'_1, c'_2, \dots, c'_K)$.

Now, the LP microproblem (or microsystem) of Day, Guccione and Oguchi, and others, can be stated compactly as in (1) and (2) by simply defining

$$\mathbf{q} = \begin{bmatrix} b \\ -c \end{bmatrix}, M = \begin{bmatrix} 0 & -A \\ A' & 0 \end{bmatrix},$$

$$\mathbf{z} = \begin{bmatrix} \mathbf{y} \\ \mathbf{x} \end{bmatrix}, w = \begin{bmatrix} \mathbf{v} \\ \mathbf{u} \end{bmatrix},$$

where $\mathbf{y}' = (y'_1, y'_2, \dots, y'_K)$, $\mathbf{x}' = (x'_1, x'_2, \dots, x'_K)$ are stacked solution vectors of the LP dual pair of microproblems, and $\mathbf{v}' = (v'_1, v'_2, \dots, v'_K)$, $\mathbf{u}' = (u'_1, u'_2, \dots, u'_K)$ are the stacked slack vectors of the dual and primal microconstraints, respectively.

It should be clear, therefore, (although the notation and the structure is slightly different) that we wish to deal also with the aggregation problems as discussed in the literature by Day, Miller, Lee, Paris and Rausser, Guccione and Oguchi, and Oguchi and Guccione. Indeed, the formulation is substantially more general than those previously proposed because it does not require a priori the identity of the firm technologies. The block-diagonal matrix A, in fact, can accommodate firm technologies, A_k, $k = 1, \dots, K$, which are completely different from one another. The difference involves both the technical coefficients and the dimensionality of the matrices A_k, $k = 1, \dots, K$, as subsequently illustrated.

Notice, finally, that the formulation specified in (1) and (2) encompasses also the aggregation problem with nondiagonal (full) matrices A, as in the case of input-output models, or of very large programming models of the economy, or the consolidation of two-person, nonzero-sum games.

In what follows, we first specify the aggregation problem for the linear complementarity problem following the conventional viewpoint of stating a micro and a macro (aggregate) system together with the aggregation relations. Except for the matrix notation, this specification is entirely similar to that encountered in the literature. As indicated by Guccione and Oguchi, the aggregation of mathematical programming models must be considered under some conditions of constrained consistency. We specify the constrained consistency in rather general terms. Next, we establish the fundamental aggregation and disaggregation theorem. Fourth, we apply the aggregation conditions so derived to symmetric and asymmetric quadratic programming and to linear programming. Finally, we demonstrate the feasibility of the procedure with a numerical example.

The Aggregation Problem

Consider problem (1) and (2) as the micro-linear complementarity model to be consolidated. In other words, instead of solving (1) and (2), the researcher wishes to solve a problem of the same structural form but of smaller dimensions. This aggregation problem occurs, for example, when a researcher seeks to represent the behavior of several microunits (a microsystem in Ijiri's terminology) by a single aggregate model (the macrosystem). Such an aggregate or macroproblem is that of finding nonnegative vectors $\mathbf{z}_a$ and $\mathbf{w}_a$, such that

(3) $$-\mathbf{q}_a = -\mathbf{w}_a + M_a\mathbf{z}_a, \text{ and}$$

(4) $$\mathbf{z}'_a\mathbf{w}_a = \mathbf{0},$$

where $\mathbf{q}_a$ is an $s \times 1$ vector considered to be arbitrary, M_a is a given $s \times s$ matrix and $s < r$.

Again, the aggregate LC problem (3) and (4) includes, as special cases, all the aggregate (macro) specifications discussed in the literature on aggregation of mathematical programming models.

The notion of constrained consistency with which aggregation of mathematical programming models must be associated was originally discussed by Ijiri. Very briefly, a one-to-one correspondence between the solution sets of the micro and of the aggregate problem does not exist. Hence, the researcher is left with the alternative of establishing a one-to-one correspondence between the solution set of the aggregate problem and a solution subset of the microproblem. How such a subset is to be selected is, in general, a matter of empirical interest. Obviously, a researcher would like to impose minimal restrictions on the solution set

of the microproblem, those strictly necessary to achieve perfect aggregation. The definition of constrained consistency adopted in this paper is now formulated.

Constrained Consistency

The domain of the vector $\mathbf{q}$ and variables $\mathbf{w}$ and $\mathbf{z}$ of the microproblem is restricted as follows:

$$\mathbf{q} = U\mathbf{q}_a, \tag{5}$$

$$\mathbf{w} = U\mathbf{w}_a, \tag{6}$$

$$\mathbf{z} = T\mathbf{z}_a, \tag{7}$$

where U and T are nonnegative matrices of full rank and of dimensions $r \times s$. It is obvious that conditions (5), (6), and (7) can be interpreted, alternatively, as a specification of perfect disaggregation.

The adopted definition of constrained consistency follows the same specification as that employed by all authors who discussed the aggregation problem in mathematical programming. Once again, consider, for example, the constrained consistency in the LP aggregation problem of Day with the notation of Guccione and Oguchi. The proportionality requirement between micro and macro vectors $\mathbf{b}_k = \lambda_k\mathbf{b}_a$, and $\mathbf{c}_k = \gamma_k\mathbf{c}_a$; $k = 1, \ldots, K$ is nothing more than condition (5) where the matrix U is defined as

$$U = \begin{bmatrix} \lambda_1 I & 0 \\ \lambda_2 I & 0 \\ \vdots & \vdots \\ \lambda_K I & 0 \\ 0 & \gamma_1 I \\ 0 & \gamma_2 I \\ \vdots & \vdots \\ 0 & \gamma_K I \end{bmatrix},$$

and $\mathbf{q}' = (\mathbf{b} - \mathbf{c})'$, $\mathbf{q}_a = (\mathbf{b}'_a - \mathbf{c}'_a)$.

Similarly, Day's and Guccione and Oguchi's discussions require that the primal and dual microsolutions be proportional to the corresponding macrosolutions $\mathbf{x}_a$ and $\mathbf{y}_a$. That is, $\mathbf{x}_k = \beta_k\mathbf{x}_a$, $\mathbf{y}_k = \alpha_k\mathbf{y}_a$, where α_k and β_k are nonnegative scalers. This specification is analogous to condition (7), where $\mathbf{z}' = (\mathbf{y}', \mathbf{x}')$, $\mathbf{z}'_a = (\mathbf{y}'_a, \mathbf{x}'_a)$, and the matrix T is defined as follows:

$$T = \begin{bmatrix} \alpha_1 I & 0 \\ \alpha_2 I & 0 \\ \vdots & \vdots \\ \alpha_K I & 0 \\ 0 & \beta_1 I \\ \vdots & \vdots \\ 0 & \beta_2 I \\ 0 & \beta_K I \end{bmatrix}.$$

Notice, furthermore, that condition (7) does not imply a priori knowledge of the aggregate solution. It simply states that, for achieving consistent aggregation, the micro and macro solutions must be related in the manner indicated above. Condition (6) relates the micro and macro slack vectors.

Perfect Aggregation under Constrained Consistency

Any set of microvariables ($\mathbf{q}$, $\mathbf{z}$, $\mathbf{w}$) which satisfies (5), (6), and (7), also must satisfy the following relations:

$$\mathbf{q}_a = T'\mathbf{q}, \tag{8}$$

$$\mathbf{w}_a = T'\mathbf{w}, \tag{9}$$

$$\mathbf{z}_a = U'\mathbf{z}. \tag{10}$$

Again, this specification of aggregation is the same as that of Day, Guccione and Oguchi, and others. The only difference with those treatments is that we have adopted matrix notation throughout. As indicated by these authors, the specification of exact aggregation chosen by them imposes stringent restrictions upon the structure of the micro and macro systems. For example, in their case, all the technology matrices in the microsystem must be identical and equal to the technology matrix in the macrosystem. This requirement is not necessary in this discussion.

All the same, the specification of perfect aggregation and disaggregation stated above implies definite restrictions for the structure of problems (1)–(2) and (3)–(4). Such restrictions are made explicit by the following aggregation:

THEOREM: *The necessary and sufficient conditions for perfect aggregation under constrained consistency are*

$$MT = UM_a, \tag{11}$$

$$T'U = I, \tag{12}$$

where I is an identity matrix.

Proof: (*Necessity*.) Premultiplying (3) by U and substituting (7) into (1), we obtain

$$(13) \qquad -U\mathbf{q}_a = -U\mathbf{w}_a + UM_a\mathbf{z}_a,$$

$$(14) \qquad -\mathbf{q} = -\mathbf{w} + MT\mathbf{z}_a.$$

Hence, in view of (5) and (6),

$$(15) \qquad MT\mathbf{z}_a = UM_a\mathbf{z}_a.$$

Since $\mathbf{q}_a$ can be chosen arbitrarily, let $\mathbf{q}_a = -M_{a,i}$, where $M_{a,i}$ is the ith column of M_a. Then, $\mathbf{z}_a = \mathbf{e}_i$ is a complementary solution to the aggregate system (3), where $\mathbf{e}_i$ is the ith column of I. It follows that (15) must hold for $\mathbf{z}_a = \mathbf{e}_i$. When this operation is repeated for each i, $i = 1, \ldots, s$, (15) yields (11). Condition (12) is obtained easily by premultiplying (5) by T', comparing the result to (8) and recalling that $\mathbf{q}_a$ is arbitrary.

(*Sufficiency*.) If (11) holds, any complementary solution ($\mathbf{z}$, $\mathbf{w}$) of the micro-LC problem (1) and (2) which also satisfies (5), (6), and (7), produces a complementary solution ($\mathbf{z}_a$, $\mathbf{w}_a$) for the aggregate problem (3) and (4). In fact, $\mathbf{w}_a = T'\mathbf{w} \geq \mathbf{0}$, and $\mathbf{z}_a = U'\mathbf{z} \geq \mathbf{0}$, since T and U are nonnegative matrices. Furthermore,

$$(16) \qquad \mathbf{z}'_a M'_a = \mathbf{z}' UM'_a = \mathbf{z}'M'T = (-\mathbf{q}' + \mathbf{w}')T = -\mathbf{q}'_a + \mathbf{w}'_a,$$

which establishes the feasibility of $\mathbf{z}_a$ and $\mathbf{w}_a$. To show that they constitute also a complementary solution, it is sufficient to recall that ($\mathbf{z}$, $\mathbf{w}$) is (by assumption) a complementary solution, and

$$(17) \qquad \mathbf{z}'_a\mathbf{w}_a = \mathbf{z}'UT'\mathbf{w} = \mathbf{z}'\mathbf{w} = \mathbf{0},$$

because $UT'\mathbf{w} = U\mathbf{w}_a = \mathbf{w}$, according to (6).

A few comments are in order. The condition that $T'U = I$, when both T and U are assumed to be nonnegative matrices, imposes stringent requirements upon their structure as well as upon that of the LC problems to be aggregated. In fact, each row of the matrix T must contain one and only one nonzero (positive) element in the same position as the corresponding nonzero element of each row of the matrix U.

These are essentially the restrictions imposed by Day and Guccione and Oguchi, upon their aggregation operators U and T which, in turn, require the micro and macro technology matrices to be identical. Their conclusion seems to be that for gaining in interpretability of the aggregation results the microproblems to be aggregated must exhibit proportionality of all components. This view of the aggregation possibilities of mathematical programming models is too pessimistic and can be improved within the present framework.

Under constrained consistency, in fact, there exist multiple sets of aggregation matrices. Indeed, any other matrix U^*, such that $MT = U^*M_a$ and $T'U^* = I$, can replace the matrix U as an aggregation operator. It is important to point out that also matrices with negative elements, properly qualified, can be admitted as perfect aggregation operators. The qualification can be established as follows: any matrix H, defined as $H = U - U^*$ and such that $T'H = 0$, establishes a variability limit for any aggregation matrix U^* from the matrix U, because only in this case we have that $T'H = T'U - T'U^* = 0$, or $T'U = T'U^* = I$. The matrix U^* is not unique and, in general, it contains some negative elements. Still, the relation $\mathbf{z}_a = U^{*\prime}\mathbf{z}$ remains nonnegative since $\mathbf{z}_a = (U' - H')\mathbf{z} = U'\mathbf{z} - \mathbf{H}'z$ and $\mathbf{H}'z = \mathbf{0}$ because, using (7) and $T'H = 0$, we have $H'\mathbf{z} = H'T\mathbf{z}_a = \mathbf{0}$. The relaxation of the restrictions upon the structure of the aggregation operator U is important because in this way it admits to perfect aggregation problems with nonproportional technologies. It is important also to point out immediately that the interpretability of the aggregate components of the problem is not necessarily lost with the introduction of matrices of the U^* type.

Perfect Aggregation of Quadratic and Linear Programs

The most general form of quadratic programming is the symmetric structure discussed by Cottle, Paris, and defined as follows:

$$(18) \qquad \textit{Primal} \max g = \mathbf{c}'\mathbf{x} - \mathbf{x}'Q\mathbf{x} - \mathbf{y}'E\mathbf{y}, \quad \text{subject to } A\mathbf{x} - 2E\mathbf{y} \leq \mathbf{b}, \quad \text{and } \mathbf{x} \geq \mathbf{0}, \mathbf{y} \geq \mathbf{0};$$

$$(19) \qquad \textit{Dual} \min p = \mathbf{b}'\mathbf{y} + \mathbf{x}'Q\mathbf{x} + \mathbf{y}'E\mathbf{y}, \quad \text{subject to } A'\mathbf{y} + 2Q\mathbf{x} \geq \mathbf{c}, \quad \text{and } \mathbf{x} \geq \mathbf{0}, \mathbf{y} \geq \mathbf{0},$$

where Q and E are known positive semidefinite matrices of order n and m, respectively, while $\mathbf{c}$ and $\mathbf{b}$ are given vectors of coefficients which admit parametric variations. The symmetric QP problem (18) and (19) may be restated as a linear complementarity problem (1) and (2) via the following correspondence:

$$\mathbf{q} = \begin{bmatrix} \mathbf{b} \\ -\mathbf{c} \end{bmatrix}, \ \mathbf{z} = \begin{bmatrix} \mathbf{y} \\ \mathbf{x} \end{bmatrix},$$

$$M = \begin{bmatrix} 2E & -A \\ A' & 2Q \end{bmatrix}, \ \mathbf{w} = \begin{bmatrix} \mathbf{v} \\ \mathbf{u} \end{bmatrix},$$

where $\mathbf{v}$ and $\mathbf{u}$ are slack vectors associated with the primal and dual constraints of (18) and (19), respectively.

The aggregation matrices T and U are specified as block-diagonal matrices:

$$T = \begin{bmatrix} W & 0 \\ 0 & D \end{bmatrix},$$

$$U = \begin{bmatrix} P & 0 \\ 0 & G \end{bmatrix},$$

with submatrices W and P of dimensions $m \times h$, while D and G are of dimensions $n \times k$, $h < m$, $k < n$. In explicit form, the aggregation condition (11) becomes

(20) $$EW = PE_a,$$

(21) $$A'W = GA'_a,$$

(22) $$AD = PA_a, \text{ and}$$

(23) $$QD = GQ_a,$$

where E_a and Q_a are positive semidefinite matrices of order h and k, respectively, defining the aggregate, symmetric, quadratic programming problem. The matrix A_a represents the aggregate technology.

The aggregation condition (12) corresponds to

(24) $$W'P = I_h,$$

(25) $$D'G = I_k,$$

where I_h and I_k are identity matrices of order h and k, respectively. Notice that if $E = 0$ and $E_a = 0$, conditions (21), (22), and (23) represent the necessary and sufficient conditions for aggregating the traditional asymmetric quadratic programming problem. If also $Q = 0$ and $Q_a = 0$, relations (21) and (22) constitute the conditions for perfect aggregation of linear programming models.

Finally, notice that premultiplying (11) by T', one obtains

(26) $$T'MT = M_a,$$

which defines the relationship between the micro and the aggregate matrices of the two LC problems. In terms of the symmetric quadratic programming model (18) and (19), relation (26) becomes

(27) $$W'EW = E_a,$$

(28) $$D'A'W = A'_a,$$

(29) $$W'AD = A_a,$$

(30) $$D'QD = Q_a.$$

We wish to reemphasize that the mathematical programming micro and macro structures specified in this section include, as special cases, the formulations of the aggregation problem stated by Day, Lee, Miller, Guccione and Oguchi, Oguchi and Guccione, and others. To see this, it is sufficient to adopt the structure of the block-diagonal matrix A previously defined. It is obvious that when one seeks to aggregate quadratic programming models of K individual firms, the matrices Q and E also exhibit a block-diagonal structure.

An Illustration of Perfect Aggregation and Disaggregation of QP Models

An asymmetric quadratic programming problem was chosen to illustrate the consistent aggregation procedures. Tables 1 and 2 contain all the relevant information. We hypothesize a block-diagonal matrix of the microtechnology A, with unequal submatrices on the diagonal. The submatrices A_1 and A_2 represent the technologies of two firms of unequal dimensions. Each firm produces a homogenous commodity by means of its first activity; and therefore its quantities can be aggregated in terms of their original units. This assumption is reflected in the components of the matrix G which are all ones and zeros. The first resource (land) of each firm is imperfectly homogenous. Yet, it is desirable to consolidate them into a unique class of resources. To accomplish this objective, it is necessary to transform the original measures of the resources into efficiency units. This is the reason why the nonzero weights of the W matrix are not unitary. The matrices Q_1 and Q_2 are positive definite and specify the quadratic forms in the objective functions of the two firms. They also form the blocks in the block-diagonal matrix Q.

The information in tables 1 and 2 can easily be used to form the micro and the macro quadratic programming problems and to verify that all their components and solutions satisfy the assumptions and the conditions of the aggregation theorem.

This example also offers an illustration of

Table 1. Aggregation of Quadratic Programs under Constrained Consistency

Set Number		Aggregate		Firm 1	Firm 2	
	A_k, $k = a,1,2$	2	3/2	49/36	49/10	12/5
		3	4	—	21/5	16/5
	Q_k, $k = a,1,2$	337/2800	3/40	359/3600	5/16	21/160
		3/40	1/10	—	21/160	1/10
1	$\mathbf{c}_k$, $k = a,1,2$	2	31/12	1/24	111/32	31/12
	$\mathbf{b}_k$, $k = a,1,2$	5	9	13/12	254/35	36/5

the existence of multiple sets of aggregation operators. Such alternative matrices can perform an important role in admitting great flexibility of the microtechnologies to be aggregated. Hence, $U^* = \left[\begin{array}{c|c} S & 0 \\ \hline 0 & R \end{array}\right]$ is an alternative aggregation operator fulfilling the condition $T'U^* = I$. Table 2 contains the aggregators employed in the numerical example. Table 1 exhibits the primal and dual solutions of the micro and macro problems obtained with three different sets of $\mathbf{b}$ and $\mathbf{c}$ vectors but the same operators as in table 2. The components of these vectors were selected to represent the

following cases: (a) boundary solution for firm 2 and interior solution for firm 1; (b) boundary solutions for both firms; (c) interior solutions for both firms. It can be verified easily that the aggregation is perfect in all three cases for both primal and dual variables. Indeed, notice that not only $\mathbf{x}_a = G'\mathbf{x}$ and $\mathbf{y}_a = P'\mathbf{y}$, but also $\mathbf{x}_a = R'\mathbf{x}$ and $\mathbf{y} = S'\mathbf{y}$, for all three numerical specifications. It should be clear that the same operators presented in table 2 can be used to perform perfect aggregation and disaggregation of all the micro and macro solutions in this numerical example obtained under a choice of the $\mathbf{b}$ and $\mathbf{c}$ vectors which satisfies relation (5). Hence, once a set of aggregation operators has been computed relative to some microtechnology, it can be used without need of revision in the consistent aggregation and disaggregation of the models, for an infinite number of $\mathbf{c}$ and $\mathbf{b}$ vectors satisfying (5).

The issue of interpretability of the aggregation results under the general specification of constrained consistency deserves some comments. As demonstrated by the numerical example, no problem arises in the interpretation of the macrosolutions $\mathbf{x}_a$ and $\mathbf{y}_a$. From the relation $\mathbf{x}_a = G'\mathbf{x}$, with the aggregation operator $\mathbf{G}$ specified as in table 2, each component of the vector $\mathbf{x}_a$ represents corresponding microvariables and possesses their same measurement units. Similarly, the dual macrovariables $\mathbf{y}_a$ satisfy the relation $\mathbf{y}_a = P'\mathbf{y}$,

with P as given in table 2, indicating that, also in this case, each macro dual variable represents corresponding micro dual variables. Of course, the nonzero elements of the P matrix are in general not unitary since they must aggregate "shadow prices."

The interpretability of the macrotechnology A_a, and of the matrix Q_a of macro demand slopes is also perfectly natural and meaningful. Notice that, from relation (28) or (29), the macrotechnology A_a is defined as $A_a = W'AD$. With the structure of the aggregation operators W and D given in table 2, it follows that each macro activity is defined in terms of the corresponding micro activities. In other words, if the first activity of each of the two firms represents tomatoes, the technical coefficients of the first macro activity are defined exclusively in terms of the land/tomato micro coefficients. The use of nonunitary weights of the aggregation matrixes W and D simply means that such macro coefficients are measured in efficiency units, rather than the natural units of their micro counterparts. But, as specified in the statement of the numerical example, the efficiency units were necessary to produce a unique measure of resources which were assumed to be imperfectly homogenous. Analogously, since $Q_a = D'QD$, the coefficients of the aggregate matrix Q_a are defined exclusively in terms of corresponding microcomponents and their interpretation is, thus, straightforward.

Finally, observe that under the aggregation specification used, no problem arises in the perfect aggregation of dual variables in quadratic programming models. This is in contrast with proposition 2 of Oguchi and Guccione. A careful examination of the assumptions and restrictions involved in the two specifications indicates that the source of discrepancy lies with the way the aggregate matrix Q_a (C_o in Oguchi and Guccione's paper) is related to the corresponding micro quadratic form matrix Q. Oguchi and Guccione chose to define a priori the macro quadratic form matrix Q_a as $Q_a = \Sigma_k \alpha_k Q_k$, $\alpha_k \geq 0$, $\Sigma_k \alpha_k = 1$, $k = 1, \ldots, K$. In this paper, however, the relation between these micro and macro matrices was a result (not an a priori assumption) of the analysis. Notice that from condition (30), $Q_a = D'QD$. It can be shown, therefore, that if the definition of the macro quadratic form in Oguchi and Guccione's paper were given as $Q_a = \Sigma_k \alpha_k^2 Q_k$, exact aggregation of the dual variables would be possible. To illustrate this point according to the stringent assumptions of Oguchi and Guccione, suppose there are only two firms with microtechnologies equal to each other's and to the aggregate technology, $A_1 = A_2 = A_a$; the micro quadratic form matrices also are equal, $Q_1 = Q_2 = Q^*$ and the aggregate quadratic form is defined as $Q_a = \Sigma_k \alpha_k^2 Q^*$, where $\alpha_1 = 1/4$ and $\alpha_2 = 3/4$. The microresource constraints $\mathbf{b}_1$ and $\mathbf{b}_2$ are proportional to the aggregate $\mathbf{b}_a$, and their sum corresponds to $\mathbf{b}_a = \mathbf{b}_1 + \mathbf{b}_2$. The vectors $\mathbf{c}_1$ and $\mathbf{c}_2$ in the micro-objective functions are identical and are aggregated with weights 1/4 and 3/4, respectively, to form the vector $\mathbf{c}_a$ in the macro-objective function; that is, $\mathbf{c}_a = \mathbf{c}_1/4 + 3\mathbf{c}_2/4$. Let

$$A_1 = A_2 = A_a = \begin{bmatrix} 2 & 3/2 \\ 3 & 4 \end{bmatrix},$$

$$Q_1 = Q_2 = \begin{bmatrix} 337/1750 & 3/25 \\ 3/25 & 4/25 \end{bmatrix}$$

$$\mathbf{c}'_1 = \mathbf{c}'_2 = [31/9 \quad 31/12],$$

$$\mathbf{b}'_1 = [7/4 \quad 3],\ \mathbf{b}'_2 = [21/4 \quad 9],$$

then, $Q_a = (1/16)Q_1 + (9/16)Q_2$

$$= \begin{bmatrix} 337/2800 & 3/40 \\ 3/40 & 1/10 \end{bmatrix}, \text{ and}$$

$$\mathbf{c}'_a = (1/4)\mathbf{c}'_1 + (3/4)\mathbf{c}'_2 = [31/9 \quad 31/12],$$
$$\mathbf{b}'_a = \mathbf{b}'_1 + \mathbf{b}'_2 = [7 \quad 12].$$

It can be verified that the solution of the aggregation problem is exact on both the primal and dual sides. In fact,

$$\mathbf{x}'_a = [20/7 \quad 6/7],\ \mathbf{x}'_1 = [5/7 \quad 3/14],$$
$$\mathbf{x}'_2 = [15/7 \quad 9/14],$$
$$\mathbf{y}'_a = [1.303563 \quad .006997],$$
$$\mathbf{y}'_1 = [1.554759 \quad .002799],$$
$$\mathbf{y}'_2 = [1.219832 \quad .008396].$$

Clearly, $\mathbf{x}_a = \mathbf{x}_1 + \mathbf{x}_2$ and $\mathbf{y}_a = (1/4)\mathbf{y}_1 + (3/4)\mathbf{y}_2$.

In summary: under the aggregation specification formulated in this paper, one obtains perfect aggregation of the primal and dual variables as well as of the primal and dual objective functions; whereas, with that of Oguchi and Guccione, the aggregation is not possible even for the primal micro-objective functions which do not involve dual variables.

Finally, when dealing with the aggregation of symmetric quadratic programming models, Oguchi and Guccione's proposition 2 leads to the following contradictory conclusion: if the dual variables in QP models cannot be perfectly

aggregated, it follows that in symmetric QP models the primal variables as well cannot be aggregated. This is so because in such models the dual variables enter also the primal constraints.

The conclusion seems inescapable: In aggregating QP models, the quadratic form matrix Q_a ought to be defined in terms of the square of the weights used to aggregate the microvectors $\mathbf{c}_k$.

Conclusions

We have shown that it is possible to achieve perfect aggregation for linear complementarity problems of considerable generality. The aggregation specification, however, must be qualified by the notion of constrained consistency. Although restricting the domain of the microvariables to be aggregated, the consequences of constrained consistency can be mitigated by the use of alternative sets of aggregation operators, one for the variables and one for the technologies.

The aggregation problem, it was seen, can be tackled in at least two ways. The first one is represented by the traditional approach of specifying all aggregation operators to be nonnegative with 0, 1 elements. As argued by Day, Guccione and Oguchi, and others, aggregation using these simple matrices requires the identity of the microtechnologies, and the proportionality of the resource and net revenue microvectors.

The second approach, presented here, is more flexible. It admits the perfect aggregation of microsystems without requiring the identity of the corresponding firms' technologies and the proportionality of resource and revenue microvectors.

In both cases, it is important to underline, the interpretation of the components of the aggregate structure is feasible and direct. In the second, more general, approach, aggregate components are likely to be measured and interpreted in efficiency units.

American Indian Farm Planning: An Analytical Approach to Tribal Decision Making

George W. Norton, K. William Easter, and Terry L. Roe

A multiyear linear programming model is used to assist an American Indian tribe develop agricultural plans for their tribal farm. Five-year crop, livestock, and investment plans are generated consistent with the tribal resource base, goals, and decision-making structure. The model has influenced the tribal farm decision-making process and provided the primary farming guide for 1979 and 1980. Frequent communication with the tribe was crucial in developing the model. Adequate updating procedures will be important in future farm planning.

Key words: American Indian, decision-making structure, farm, linear programming.

Many American Indian reservations are located in areas where agriculture is the primary source of income. For most Indian tribes on these reservations, agricultural land and labor are their primary resources. Few tribes, however, have been able to develop those resources to the point where agriculture contributes significantly to their economic and social well-being. Numerous hypotheses have been advanced to explain why Indian agricultural development has proceeded so slowly. Fractionated heirship lands, federal policies which have diminished the incentive to work, racial discrimination, certain aspects of Indian culture, a lack of formal education, and the absence of sufficient capital to make investments have all been mentioned as deterrents to agricultural development (Fitch, Dorner, Sorkin, Levitan and Johnston). Trosper has pointed out that Indian ranchers on the Northern Cheyenne Reservation own a small proportion of the land they graze and that this apparently has hindered access to capital.

In the 1970s there has been increased interest among Indian tribes in accelerating agricultural development. A few have established tribally owned farms. The Sisseton-Wahpeton Sioux Indians on the Lake Traverse Reservation in Northeastern South Dakota have established a tribal farming operation and sought planning assistance for that enterprise. This article describes the planning approach used to evaluate crop, livestock, and investment alternatives for the tribal farm. It begins with a description of the tribal resource base, agricultural goals, and decision-making structure. The planning model employed to reflect these factors is then described, followed by the resulting plans and a discussion of how closely they were followed. Procedures for updating the plans are presented and, finally, conclusions are drawn about the potential usefulness of this approach to other tribes.

Background

Approximately 3,900 members of the Sisseton-Wahpeton Sioux Tribe (SWST) reside on the Lake Traverse Reservation, representing 15% of the total reservation population. While agriculture is the primary industry in the area, less than 10% of the 1,100 Indian labor force is employed in agriculture. Per capita income is about $1,000 for Indians liv-

The authors would like to thank Yoav Kislev, Vernon Eidman, James Murray, Ron Trosper, and Delane Welsch for their helpful comments and suggestions without implicating them in any remaining errors or omissions.

Financial support for this project was provided by the Northwest Area Foundation, the Federal Reserve Bank of Minneapolis, Winrock International Livestock Research and Training Center, the Sisseton-Wahpeton Sioux Tribe, and the University of Minnesota computer center.

ing on the reservation and can be traced partly to the high unemployment rate. The major employer of Indians in the area is the tribe itself, through the various government programs for which it has contracted. Both the lack of job opportunities and the low education level of tribal members contribute to this situation. The education level of the Indians on the reservation has been rising, but approximately one-fifth of the Indians twenty-five years and older have not completed the eighth grade, compared to one-eighth of the non-Indian population.

The total land area of the reservation is 910,779 acres, of which approximately 91,000 acres are presently owned by individual Indians, 15,000 by the tribe itself, and the remaining 804,000 (88.3% of the total) by non-Indians. Usage of the Indian-held land is approximately 35% cropland, 56% pasture, and the remainder nonagriculture. These lands are spread out over the reservation in a checkerboard pattern. Most tribal members own small parts of several tracts of land and the vast majority of the tracts have multiple ownership by the heirs of the original allottee.[1] Each Indian enrolled in SWST has interest in an average of eight tracts and each tract of land has, on the average, thirteen Indian owners (U.S. Department of Interior, BIA). Most of the land is leased to non-Indian farm and ranch operators, although Indian operators lease some land.

A variety of small grains and row crops can be raised on the land owned by the tribe. The area has an average annual precipitation around 21 inches and a growing season of 135–140 days. There is little potential for irrigation from lakes and streams but some potential from groundwater sources. The most common livestock activity is a small cow-calf operation.

The Sisseton Reservation is an underdeveloped enclave within a more developed economy. Consequently, improved technologies specific to the area already exist. Part of what is needed is a mechanism to diffuse this knowledge in a manner consistent with the tribe's land, capital, and human endowment as well as the socioeconomic environment.

The Tribal Farm and Decision Making

The SWST began a land consolidation program in 1973 by purchasing from individual Indians tracts of land that had become fractionalized over time. Capital for these land purchases came from $4.25 million in Farmers Home Administration (FmHA) loans secured with money from land claim settlements with the federal government. The tribal farm was established on a small part of these lands in 1975 with financial assistance from the Economic Development Administration and technical assistance from the extension service. The tribal approach to farming was emphasized instead of individual ownership and management. Certain sources of capital were available to tribally controlled enterprises from both government and commercial sources that were not available to individual tribe members. Tribal leaders felt that cultural and managerial problems would be minimized by adopting a centralized decision-making structure.

After the first full year of farming (1976), tribal leaders requested assistance in developing short- and longer-range farm plans. They did so because they perceived that some of the problems experienced the first year resulted from a lack of an integrated plan. They wanted projections on the possible size and profitability of the farm after five years, analysis of the feasibility of irrigation, and information concerning the most profitable size of cattle operation, etc. Furthermore, they expressed a concern about the riskiness of activities because of outstanding FmHA loans on the tribal farm land.

One of the authors worked with the tribal leadership to develop a planning procedure and plans consistent with their decision-making structure and their resource endowments. At the beginning of the project, three months were spent in the tribal planning office collecting information and exchanging ideas. This contact was important in establishing channels of communication and gaining credibility. During the remainder of the two-year project, approximately twenty-five visits were made to the reservation to discuss ideas and results with the tribe.

[1] The allotment of lands to individual Indians occurred on the vast majority of Indian reservations following the passage of the Dawes Act in 1887. One of the provisions of the law provided for the federal government to hold land in trust for all heirs of deceased landowners rather than assigning it to one person. By the time Indians were allowed to sell their lands, an heirship problem which still plagues many reservations today was well-established. Some forty-acre plots now have as many as 150 heirs. Once lands were allotted to individual Indians on the Lake Traverse Reservation, non-Indians were allowed to homestead the rest, which placed most of it in the hands of non-Indians.

Discussions were held with tribal leaders and the planning director to help specify planning objectives. A written statement of objectives for the tribal farm(s) was provided by the tribe. It expressed a desire that the tribal farm(s) would (*a*) help strengthen the tribe's economic base in the event that the federal government continues to withdraw or terminates financial support of Indian tribes, (*b*) provide income, employment, and training opportunities for individual tribal members, and (*c*) generate revenue to help the tribe maintain control over its land base. The Sisseton-Wahpeton Sioux hoped that the tribal farm would provide examples for individual tribe members. They also feel the need to establish a record of success in an economic endeavor to place themselves on a more equal footing with the non-Indian community. They see tribal farming as only one part of a larger development program, but one which will facilitate expansion into other activities.[2] Objectives for the tribal farm were discussed many times during the course of the project. The issue of short-term versus long-term objectives was raised. Tribal leaders expressed a willingness to forego withdrawal of any profits in the first years to facilitate farm expansion. There is not complete agreement on this, however, and it is still a topic of debate within the tribe. A concern also has been expressed that the plans not be too risky because a substantial loss by the tribal farm might result in pressure to abolish it without giving it an adequate chance.

The planning model for the farm was developed to reflect and obtain insights into the implications of these objectives. The model on which plans were to be based also needed to take into consideration the tribal decision-making structure. There are three levels of decision-making authority which are pyramidal in structure. The decisions at the first level focus on plans and policies whose implementation at lower levels allows for some discretionary authority.

Decision-making authority at the first level is held by the tribal council, but currently most of the decision-making responsibility at this level is delegated to the tribal chairman. The chairman will sometimes confer with the tribal secretary, treasurer, or the full council before making certain decisions. He has information provided by a planning staff and tribal accounting office, such as the lease status of tribally owned land tracks, cash in the tribal farm account, and the status of federal grant proposals. The chairman also uses information provided by sources outside the tribe including the extension service and the computer planning model.

The decision maker at the second level is the farm manager. He interacts with and implements the decisions of the tribal chairman making the necessary assignments of labor, machinery, etc. The farm manager is constrained by his ability and experience, weather, and the quality of the labor force. He, in turn, must interact with those at the third decision level, the farm workers. While the workers' authority is more circumscribed, their efficiency influences the economic performance of the tribal farm.

The planning model, described in this paper, gives and receives information to and from the first and second decision levels as well as the planning staff and accounting office. The usefulness of an analytical planning model lies in the ability to search efficiently among many alternatives for the best strategy for achieving tribal objectives, subject to policy, risk, and physical constraints. It also enables tribal leaders to assess the effects on their objectives of varying those constraints. The model should reflect decision variables and constraints at the highest level as well as certain constraints at lower levels. Consequently, information was collected on soils, climate, labor availability and skills, crop yields, input and output prices, water availability, land and machinery ownership, borrowing sources and limits, etc. Tribal lands were classified and mapped into capability classes and the lease status of these lands was reviewed.

The model which was constructed reflects the lack of experience of both the farm manager and the rest of the work force through limits on the types of farming activities permitted.[3] At the same time, the climate, topography, and location with respect to markets will enable a wider range of possible crop and livestock activities to be included in the future. In addition, the model generates plans which consider not only the complementarities between crop and livestock enterprises but also the level of risk to the tribe.

[2] Profits generated by tribal activities on Indian-owned land are nontaxable by federal, state, and local governments.

[3] For example, irrigated alfalfa and corn are permitted during the first five years but not irrigated vegetables. Alfalfa and corn are easier crops to irrigate than vegetables for an inexperienced irrigator.

Methodology

The basic analytical technique used in the planning process is a multiyear linear programming model (MLP). Its primary objective is to determine a set and level of activities for the tribal farm(s) which maximize ending net worth subject to risk constraints and to limits placed on the enterprises by the availability of land, labor, machinery, and credit. Maximization of ending net worth was chosen as the initial objective function because the tribe expressed a willingness to sacrifice short-term consumption to facilitate farm expansion. An alternative objective of maximizing the sum of annual consumption plus ending net worth discounted at 9% also was used in the analysis and the results presented to the tribal chairman for comparison.

Linear programming was used rather than quadratic because of the computational cost advantage. The model contains five one-year time periods with 896 columns and 696 rows.[4] Five-year planning prices were based on outlook projections made by agricultural economists at the University of Minnesota, adjusted to reflect the expected difference between the local and the Minneapolis price. The model's general specification is

Primal		*Dual*
Maximize $\mathbf{C}'\mathbf{X} - \lambda\mathbf{d}$,	=	minimize $\mathbf{B}'\mathbf{Y}$,
subject to $A\mathbf{X} \leq \mathbf{B}$,		subject to $A'Y$
$D\mathbf{X} + I\mathbf{d} \geq 0$,		$+ D'Q \geq \mathbf{C}$,
		$IQ \leq -\lambda$,
and $\mathbf{X}, \mathbf{d} \geq 0$,		and $\mathbf{Y}, Q \geq 0$,

where $\mathbf{C}$ is a vector of objective function coefficients, $\mathbf{X}$ is the activity vector, A is a matrix of technical input-output coefficients, $\mathbf{B}$ is a vector of resource availabilities, and D is a gross-margin deviation matrix (see Hazell, Brink and McCarl). The vector $\mathbf{d}$ represents yearly total negative deviations summed over all risky activities. I is an identity matrix, λ is a risk-aversion coefficient, $\mathbf{Y}$ is a vector of shadow prices on nonrisk constraints, and Q is the shadow price on each risk constraint.

The activities in the model fall basically into nine classes: (*a*) crop production, (*b*) livestock production, (*c*) renting in of labor, land, and machinery, (*d*) cattle and feed purchasing, (*e*) crop and livestock selling, (*f*) machinery, storage, and building purchasing, (*g*) borrowing, (*h*) crop, livestock, and money transfers, and (*i*) risk transfers. The constraints and row transfers can be grouped into seven classes: (*a*) resource constraints, (*b*) crop transfers, (*c*) livestock transfers, (*d*) nutrient transfers, (*e*) cash flow constraints, (*f*) credit constraints, and (*g*) risk constraints.

Table 1 presents an aggregated representation of the model. Most of the activities and rows shown represent numerous activities and rows in the model. For example, crop production includes activities for ten crops in the model, with land divided into four dryland and one irrigated class. Labor requirements, cash requirements, machinery requirements, and set-aside requirements for each crop were included. Crop production is transferred in the model to selling, feeding, or storing activities. All land is assumed to be rented from the tribe by the tribal farm at the current lease rates established by the tribe. This mirrors the current situation and ensures that land which would be more profitably rented out to someone else will not be farmed by the tribe.

Various beef cattle activities designed to reflect the prevailing alternatives in the area, as well as the experience of the tribal labor force, are included in the model. They are (*a*) a cow-calf operation, (*b*) summer grazing of heifers or steers of two weight classes, (*c*) winter feeding of heifer or steer calves, (*d*) finishing heifers or steers of two weight classes during the winter, (*e*) raising replacement heifers for the cow herd, and (*f*) keeping bulls.

Cattle can be produced internally or purchased. Calves from the cow-calf alternative can be sold at weaning time, overwintered and sold, or overwintered and summer grazed. The steers can then be sold or finished over the winter and the heifers sold or enter the herd as replacements. Calves also can be purchased in the spring and summer grazed and then sold or kept and finished over the winter. The model also determines the optimal feed mix for the selected livestock activities based on dry matter, digestible protein, and total digestible nutrient requirements and supplies.

Investment alternatives for various types of

[4] The main purpose for including years beyond the first is to help the tribal leaders make decisions in the first year which are consistent with their long-term objectives and resources. If parameters such as the terminal value of assets could be appropriately specified, a single-year model would yield a solution identical to the first year of a multiyear model. The shorter the planning horizon, the more mistakes made in estimating future income streams of terminal assets will compound one another. Therefore, the effect on the first-year solution will be greater. The tribe also requested at least a five-year projection of farm size and net worth. The model has not been extended beyond five years because this would require sacrificing detail in early years in order to keep the size of the model within a manageable limit.

machinery, buildings, and storage are included in the model. These activities supply hours of machinery use, animal housing capacity, and tons or bushels of storage space. The monetary value of each piece of machinery or other investment is depreciated on a straightline basis and equity is calculated at the end of the five-year plan for each item. This equity is the amount paid off minus depreciation.

To reflect tribal planning needs there are rows in the model to account for inflows and outflows of cash each month and activities to transfer it from one month to the next. Three borrowing activities are included which reflect the main sources of capital available to the tribe: (*a*) long-term borrowing for buildings and irrigation equipment from Farmers Home Administration, (*b*) intermediate-term borrowing from a bank for machinery and storage, and (*c*) short-term borrowing from a bank. Each type of borrowing has its own interest rate, down-payment requirements, payback period, and credit limit. A savings alternative is also included for each year to ensure that investments are not made which yield less than the minimum opportunity cost of their capital.

A series of risk constraints and activities are included to deal with price and yield uncertainty in the crop and livestock activities. While the tribal leaders feel the farm can absorb more risk than individually owned farms, they are concerned about the riskiness of the plans for reasons mentioned earlier. Certain yield risks can be reduced by such methods as spraying for weeds, following rotations, providing supplemental irrigation, and vaccinating animals. Certain price risks can be reduced by using mechanisms to transfer risk, such as crop insurance, hedging on the futures market, and forward-contracting for market quantities or price. The major defense against income variability due to price or yield risk, however, is to select activities with lower yield and price uncertainty and eliminate or reduce those with higher uncertainty. The risk constraints in the tribal farm model in effect do this.

The approach used in the tribal farm model is based on Hazell's mean absolute total deviation (MOTAD) formulation. The activity net revenues are assumed to follow a multivariate normal distribution so that total net revenue will tend to be normally distributed and utility can be evaluated in terms of only the first two moments of the distribution of total net revenue. Mean absolute total deviations (M) are assumed to approximate the second moment or the variance (V).[5]

The deviation matrix (D) was obtained by first calculating gross margins (price times yield minus variable cost) for each crop and livestock activity in the model for each year from 1965 to 1975. For cropping activities, this was done by multiplying the average county crop yield data by the price inflated to 1975 by the USDA Parity Index and subtracting the 1975 level of variable costs. For livestock activities, it required calculating for each class of livestock the difference between the value at the time of purchase and the value at the time of sale (inflated to 1975). The 1975 level of nonfeed variable costs and feed costs calculated for each year, inflated to 1975, were then subtracted. Once the matrix of gross margins was calculated, it was then necessary to calculate the yearly deviations from the means of those gross margins. Deviations from simple means would have been misleading because of the presence of trends and the cattle cycle. Deviations from linear trends would not pick up cyclical changes. Therefore, following Brink and McCarl, deviations from a moving average of the previous four years was chosen as the deviation from the expected gross margin. Following Hazell, only negative sums of deviations are transferred to the objective function so the model actually minimizes the total negative deviations.

The level of risk assumed in the model for each enterprise is therefore based on deviations from historical gross margins. The decision maker's subjective estimate of risk inevitably will differ from this to some degree. In fact, the level of risk of an enterprise also can vary with the skill and experience of a particular manager. The purpose of including risk in the model, however, is merely to provide the decision maker with additional information on which to select a plan. It is recognized that the solutions generated by varying the risk parameter only approximates the risk

[5] It can be shown that $M^2[\pi t/2(t-1)]$ is an unbiased estimate of the population variance where M is the mean absolute deviation of expected income, π is the mathematical constant 22/7, and t is the number of observations or yearly risk constraints in this case when total gross margin distributions are approximately normal (Hazell). Thomsen and Hazell show in a Monte-Carlo simulation study that the use of an expected income-mean absolute deviation (E-M) model generates plans similar to those generated by an expected income-variance (E-V) model. It is assumed in both approaches that the decision maker is risk-averse, so that expected income would have to be greater for him to prefer higher variance of income. This compensation must increase at an increasing rate as variance increases.

faced by the tribal farm. Nonetheless, the procedure used is easy to apply and is preferable to ignoring risk altogether, because the decision maker is still free to choose the plan which gives no weight to the risk constraints.

Validation and Generation of Plans

For purposes of validation, a one-year version of the linear programming model was constructed first and the 1977 tribal farm operation was duplicated. Refinements were made and the model was updated to produce a plan for 1978. A series of plans were generated with varying levels of profit and risk; and the tribal chairman, after a discussion with the farm manager, selected the one he preferred. The model also was run with and without irrigated cropping activities, such as corn for grain and alfalfa, to determine the effect on profits. The cropping part of the selected 1978 plan was followed fairly closely, while the livestock part was not, which led to a lower-than-planned-for profit. The information from the plan also was used to assist the tribe in presenting an irrigation project proposal to the Economic Development Administration.

The model was then extended to five years beginning with 1979. Sensitivity analysis was conducted on certain price and yield coefficients, and a series of preliminary results were discussed with the tribal chairman, tribal planners, the tribal farm manager, extension personnel, and others. Some adjustments were made, and a series of eleven plans was generated by parameterizing the risk coefficient (λ) from 0 to .5. These plans were presented to the tribal chairman, who selected the plan containing the tradeoff between profit and risk which he preferred. The values of the dual variables (shadow prices) corresponding to the land, labor, machinery, and other constraints were examined. The plans had been bounded in the first year to fit the total amount of land which the tribal farm had under lease at that time. The shadow prices on Class 1 and Class 2 land indicated it would be profitable, other things constant, to lease additional cropland. The decision was then made by the tribal chairman to include additional land, and a new set of plans was generated. The production manager—inexperienced in growing soybeans—then expressed a preference not to plant any soybeans in the first year of the plan even though it was called for under each level of risk.[6] The tribal chairman agreed and the model was rerun with soybeans forced to zero. Crop acreages were then forced to fit the fields exactly, and the result was the 1979 tribal farm plan. In summary a number of steps were undertaken, including sensitivity analysis of price and yield coefficients, risk analysis, and examination of shadow prices, and the results were discussed with the tribal leaders before arriving at a plan suitable to the tribe.[7]

Results

The five-year plan developed for the tribe includes barley, spring wheat, soybeans, sunflowers, and alfalfa as the major dryland crops and corn for grain and alfalfa as the major irrigated crops. Total acreage in the tribal farms increases 1,000 acres to about 3,000 acres by 1983, of which 2,000 acres would be crops or improved pasture and 1,000 acres in native pasture. Each class of land has a corresponding constraint and shadow price for each year. The marginal value of an acre of Class 1 land in 1979, for example, is \$42.27. If an acre of Class 1 land were removed, ending net worth would decrease by \$42. This does not mean, however, that the tribal farm can afford to pay a lease rate of \$42 for that last acre of Class 1 land in 1979, because a dollar spent in 1979 is not worth the same as a dollar spent at the end of the planning horizon. The shadow price of an extra dollar in the first four months of 1979 is \$1.62. This represents the value of an additional dollar during that time compounded to the fifth year. Therefore, a dollar spent on land or any other resource in early 1979 has an opportunity cost of \$1.62. The amount that the tribal farm can afford to pay for that last acre of land is \$42.27 divided by \$1.62 = \$26.00. This latter figure would equal the lease rate if the renting in of land were not constrained in 1979.

[6] Risk was reduced when acreage of flax, soybeans, and corn acreage declined and when acreage of barley and sunflowers increased. A reduction of summer grazing of calves reduced risk slightly as did an increase in overwintering of calves.

[7] The close examination of shadow prices on constraints and nonselected activities was especially important. Schurle and Erven, for example, warn that near-optimal solutions can be substantially different from those on the efficiency frontier. Examination of shadow prices tells one a great deal about the profitability of near-optimal solutions at each level of risk. As an example, for the medium-risk plan, the forcing in of summer grazing of yearlings in years 1–4 or additional acres of corn for grain in years 2–4 would cause a small reduction in profit. The model also provides a range over which the shadow prices hold. It should also be noted that a model such as the one presented here, with a very large number of constraints, is less likely to have radically different plans for near-optimal solutions than a model with fewer constraints.

The major livestock activities selected are summer grazing of steer calves and finishing of yearlings in a farm feedlot over the winter. Expansion of the cow herd was not recommended. At tribal request, however, the model was forced to maintain a small cow herd. Calves from this herd will be fed over the winter (backgrounded). Fifteen buffalo were also forced into the solution at tribal request and the shadow price on this varied from $145 to $176 per head. This foregone income was discussed with the tribal chairman who then discussed it with the tribal council. They felt that the nonmonetary benefits would exceed the cost.

Because the tribe already owns a fairly complete and new complement of machinery, the model suggested very few major machinery investments. However, capital is one of the factors constraining tribal farm expansion. Short-term, intermediate-term, and long-term borrowing will be required for cattle purchases, machinery purchases, and the feedlot construction. Credit limits were binding in the second, third, and fourth years. A labor force of two people was required during the winter and three to four people during the remainder of the year.

The increase in ending net worth over the five years is projected to be $62,000. Operating capital increases from an initial $60,000 to $200,000, and the value of more durable assets declines by $78,000. There are two major reasons why investments in new assets are not made as rapidly as the existing stock depreciates. First, machinery depreciation is assumed to occur on a straight-line basis over ten years, while the service flow is assumed to remain constant for ten years and then fall to zero. Second, there is some overcapacity for certain types of machinery throughout the five-year planning period.

The alternative objective function of maximizing the present value of consumption plus ending net worth also was tested. An annual discount rate of 9% was used and the model was forced to withdraw $5,000 plus 10% of the year-end cash annually.[8] The resulting return to the tribe was $16,664 less than when ending net worth was maximized.[9] This resulted primarily from having less cash to reinvest each year. The plan contained similar activities, but they came in at different levels. Although tribal objectives over the next five years suggest maximizing ending net worth, in the longer run the alternative objective function would appear to best fit their objective of providing income to the tribe.

One can make some comparisons between the first year (1979) of the plan and what has occurred on the tribal farm. It must be recognized that any plan generated is only an initial guide and adjustments must be made to it as events occur during the course of the planning period. At planting time the planned irrigation system still was not in place and this forced some changes. One 80-acre tract was not put in the tribal farm, resulting in a total of 929 acres planted compared to 1,009 planned. There were 438 acres of corn and sunflowers compared to 484 planned; 491 acres of wheat and barley compared to 525 planned; 410 acres of hay, improved pasture and set aside harvested or used compared to 418 planned; and only 380 acres of native pasture was used compared to 674 planned. This latter difference occurred because only 165 calves were summer grazed compared to 245 planned. There were 50 cows, 42 calves for overwintering, 13 replacement heifers, 2 bulls, and 17 buffalo, all of which were close to the figures in the plan. There were only 165 head finished in the feedlot during the winter, however, compared to 316 head planned. This difference was caused primarily by the delay in building the feedlot, which will not be in place until fall of 1980. The end result was the tribal farm just broke even before subtracting depreciation on equipment.

Despite the differences noted between the suggested plan and the actual activity levels, it is clear that the linear programming model has had a major effect on the decision-making process for the tribal farm. It has provided the tribe with a set of evaluated alternatives and tribal leaders have used the model to explore the implications of their ideas. This corresponds closely with the main advantage of agricultural sector models in developing countries cited by Langham. In order to have a lasting impact on the decision-making process, however, the investigative capacity of the model must be institutionalized into tribal decision making. This raises the question of how the model will be updated.

[8] The appropriate discount rate is dependent on several factors (Norton, p. 88). A sensitivity analysis was done in which the discount rate was varied from 6% to 10%, and the resulting plans were not particularly sensitive to this parameter.

[9] It was necessary to remove the discounting of values in the new objective function before making this comparison since it was not necessary to discount in the initial objective function.

Updating the Plan

Annual updating of the model will be a key to future planning efforts. The updating process will initially involve the following steps: (*a*) The tribal staff person monitoring the farm will send a list of possible new tracts of land, an inventory of crops and livestock on hand, information on loans outstanding, and other information to the person updating the linear programming model. (*b*) Crop, livestock, and input prices will be updated and the crop and livestock budgets regenerated. (*c*) This information will then be entered into a computer program which will revise the model. (*d*) A series of computer runs will be made with the model under varying levels of risk. (*e*) Tables showing projected profit and loss, the crop and livestock plans, monthly cash requirements, labor requirements, machinery and building investments, borrowing requirements, and the effects of relieving certain constraints or forcing in nonoptimal activities will be discussed with the tribal decision makers. One of the plans will then be selected or, at the tribe's request, the model will be rerun forcing certain activities into or out of the solution.

There is a possibility that a member of the tribal planning staff could be trained to run the linear programming model. The tribe has recently hired a natural resource planner with some computer experience. The tribe could connect through a telephone hookup to computers at South Dakota State University or the University of Minnesota. A great deal of care must be exercised, however, to ascertain that tribal planning personnel with responsibility to use the model, adequately understand it. Otherwise, there is a significant danger that erroneous results could be generated without their being aware of it. In the coming year, one of the authors will do the updating.

Concluding Comments

The type of analysis conducted in the Sisseton study is an attempt to provide tribal leaders with planning tools capable of considering the interrelationships among crop and livestock alternatives over time. The LP model provides plans consistent with the major components of the tribal resource base, goals, and decision-making structure. The Sisseton-Wahpeton Sioux Tribe feels the plans generated fit their needs and have generally followed the one generated for 1979.

It is clear from the LP results that the tribal farm can contribute to the objectives of providing a small economic base and helping the tribe maintain control over its land base. However, the effects on income and employment of tribal members will be mostly indirect, because profits will not be distributed and the size of the farming operation projected over the next five years is small in relation to the size of the reservation. There will be some income and employment multiplier effects; and, if the farm is successful, the tribe undoubtedly will take pride in managing a viable economic venture. In addition, the farm may attract capital for expansion in other areas on the reservation. Tribal farming will never be a major source of employment on the reservation but may have a useful role as a part of an overall development program. The tribal farm also provides examples and can be used for training of individual Indian farmers.

An important question is whether the planning approach used here might be useful for other tribes. A brief look at certain aspects of the project provides some insights into the answer to this question.

The LP model contains a good deal of reservation-specific information which was needed to provide reliable results. This means that modifications in activities and constraints as well as coefficients would have to be made before transferring it to other situations. The basic structure, however, could be transferred to other settings without much difficulty. This type of analysis is especially useful in situations where the resource base allows a large number of production alternatives.

A number of aspects besides the analytical technique were important to any success the Sisseton project has experienced. Frequent communication with the tribe was of primary importance in all stages. Personal communication was used to transfer ideas, to obtain feedback, to develop credibility, and to provide a general understanding of what a linear programming model is and how tribal planning personnel can interact with it.

Second, the tribe was committed to the project and participated in terms of time, labor, ideas, and money. A good indication of their commitment was their attempts to solve their own agricultural problems even before they solicited outside assistance.

Third, the plan involved an adaption of the current situation rather than a drastic change in what was already being done. Plans were

also kept flexible. In 1978, for example, they were altered, first, to compensate for credit difficulties and, second, to compensate for a slowness in constructing a fence. Changes also occurred in the 1979 plan as noted above.

A fourth important aspect of the project was the strong technical support from various institutions such as South Dakota State University. Information and assistance were needed from a number of disciplines, and the tribe needed to be advised where they could obtain various types of technical assistance.

The real cost to the tribe of the planning project was about $2,500 per year for two years, which represented about 15% of the total project cost. The remainder was provided by the institutions noted earlier.[10] Part of the project cost, however, resulted from time spent evaluating the feasibility of other activities, such as a slaughterhouse, a poultry operation, and a sunflower processing plant, as well as from time spent developing an agricultural training program. The tribe will bear 100% of the cost of updating the tribal farm plan.

Another important question is, will the SWST continue to support the planning process described here and, indeed, will it continue to support the tribal farm? The farm and the planning approach have received strong support from the tribal chairman and planning director. Tribal activities often are not fully understood, however, at the grass roots level on the reservation. In addition, small groups of tribal members frequently try to work together to improve their economic positions at the expense of the rest of the tribe. Also, it is common for a new political administration on the reservation to try to replace as many of the programs begun by the previous administration as possible. To prevent this, tribal leaders have been exploring possibilities for restructuring the first level of decision making, such as incorporating the tribal farm and selecting a board of directors.

Careful planning is a necessary, but not a sufficient, condition for a financially successful tribal farm. Among the other conditions are factors influencing the implementation of the plan, such as the dedication and skill of the labor force. The farm changed managers in April 1980. The new farm manager is an Indian. Before hiring the new manager there was a great deal of discussion within the tribe about whether a tribal member could be placed in this position. The issue revolves not around just skill but around the Dakota cultural system.[11] Workers on the farm are also Indians, and the turnover has been fairly rapid. It is important for the labor situation to stabilize.

There is evidence that other tribes are watching the Sisseton planning approach to see if this is a strategy that they can pursue. It is perhaps premature to estimate the financial return to this planning effort, but the Sisseton-Wahpeton Sioux tribal leaders feel strongly that it has been worthwhile.

[10] It is interesting to note the absence of the Bureau of Indian Affairs (BIA) in this planning effort. Demallie has noted recently a growing tendency to bypass the BIA when possible and to attempt to minimize its role on the Pine Ridge Reservation. The SWST is perhaps one of the few tribes with a well-organized tribal planning staff independent from the BIA. This planning staff handles the leasing of all tribally owned land, develops housing plans, health plans, natural resource management plans, and other such matters.

[11] The manager, if he is a tribal member, has to come to grips with a cultural system that dictates that every man is completely independent and equal and that no one has the right to tell anybody what to do. In addition, the moral system of kin relationships demands that an individual share with his relatives (Demallie, p. 298). As a result, it is difficult for a tribal member as manager to direct the activities of the labor force or to say no to requests for use of farm equipment, gasoline, or other goods.

Machinery Selection Modeling: Incorporation of Weather Variability

Abdulla B. Danok, Bruce A. McCarl, and T. Kelley White

An alternative analytical approach to the important and complex machinery selection problem is proposed. A mathematical programming model is developed which embodies (*a*) the integer nature of machinery decisions, (*b*) the stochastic nature of weather, (*c*) the joint selection of machinery and crop plans, and (*d*) selection among machinery sets rather than among individual machines. Optimal machinery and crop plans are determined for selected weather probability levels. The robustness of machinery sets over a range of weather conditions is evaluated by subjecting the distributions of outcomes for alternative machinery sets to stochastic dominance criteria. Bias of good-field-day distributions is also discussed.

Key words: machinery selection, mixed integer programming, stochastic dominance.

The machinery selection decision confronting farmers is recurrent, complex, and important. Machinery by its nature begins to deteriorate or become obsolete from the moment of purchase. Thus, the established farmer must continually choose whether to keep, upgrade, or replace items of equipment. Conversely, the beginning farmer must select machinery with which to begin operations. Machinery selection is complicated by many interrelated factors which jointly determine the final impact of a particular machinery decision on farm profitability (or other goals). Among the more important factors that should be considered in the selection of machinery are (*a*) weather conditions, especially as related to the probability distribution of availability of time for fieldwork during critical seasons; (*b*) the effect of timeliness of operation on yield; (*c*) availability of labor at crucial times of the year; and (*d*) the farmer's goals and attitudes toward risk. The interaction among these factors as they influence crop planning and machinery selection imply that machinery selection and crop planning should be considered simultaneously.

Abdulla B. Danok is an assistant professor, Department of Agricultural Cooperative and Extension, Sulaimania University, Iraq; Bruce A. McCarl is an associate professor, and T. Kelley White is a professor, Department of Agricultural Economics, Purdue University.

Journal Paper No. 8037 Purdue Agricultural Experiment Station.

The authors wish to thank Rick Klemme, Craig Dobbins, Tim Baker, Gil Rodriguez, and an anonymous reviewer for helpful comments.

The importance and complexity of the machinery selection problem has resulted in numerous efforts to develop analytical models which will either yield generalizable selection guidelines or be useful directly by the farmer as a decision aid. The approaches that have been proposed are (*a*) calculator-type programs (e.g., Von Bargen and Hines), (*b*) simulations (e.g., Donaldson, Sorensen and Gilheany), and (*c*) mathematical programming approaches (e.g., Danok, McCarl, White; Kletke and Griffin). To date, many sophisticated models have been developed, but to the authors' knowledge only simple budgeting and static linear programming (LP) approaches (as discussed in Brink and McCarl) have had extensive extension application and farmer use.

The research reported in this paper is an attempt to develop an alternative analytical approach to machinery selection problems. First, a mathematical programming model is developed which embodies (*a*) the integer nature of machinery decisions, (*b*) the stochastic nature of weather, (*c*) the joint selection of machinery and crop plans, and (*d*) selection among machinery sets rather than among individual machines. Then alternative ways of employing the model to choose "good" machinery sets are explored.

A Model Based on Machinery Sets

Mixed integer programming is an appropriate modeling technique for the crop and ma-

chinery choice problem. The model developed herein is a mixed integer model (MIP). This model, however, differs in one important aspect from previous work (e.g., Danok, McCarl, White; Kletke and Griffin). Unlike earlier formulations, the machinery representation is operationalized as a choice among sets of machinery rather than individual machines. This is based upon several considerations. First, the authors feel that the essential reason simple budgeting and linear programming have been successful in extension is they impart a degree of control over the machinery selection process to the farmer. The generation of technically balanced machinery sets is done easily with MIP, yet technical balance alone is not sufficient for farmer purposes. Control is necessary to assure consistency of the selected set with an individual farmer's situation (e.g., existing equipment, institutional arrangements). The second advantage of the proposed approach is the power of MIP, which by nature evaluates multiple alternatives efficiently. Thus, consideration of multiple sets can be accomplished with MIP without a cumbersome set-by-set search using linear programming. The set concept embodies mutually exclusive machinery sets which lead to an MIP with a number of feasible integer solutions equal to the number of alternative machinery sets. This is much smaller than in other machinery MIP formulations (e.g., Danok, McCarl, White; Kletke and Griffiin).

The machinery selection model proposed is as follows:

$$\text{(1)} \quad \underset{\substack{Y_j = (0,1) \\ X_{jk} \geq 0}}{\text{maximize}} \quad \sum_j C_j Y_j + \sum_j \sum_k d_{jk} X_m$$

$$\text{(2)} \quad \sum_j e_{ij} Y_j + \sum_j \sum_k a_{ijk} X_{jk} \leq b_i \quad \text{for all } i$$

$$\text{(3)} \quad \sum_j Y_j = 1$$

$$\text{(4)} \quad M Y_j + \sum_k X_{jk} \leq 0 \quad \text{for all } j$$

$$\text{(5)} \quad \sum_j \sum_k g_{Ljk} X_{jk} \leq f_L \quad \text{for all } L$$

where c_j is the annualized cost of machine set, j, Y_j is a zero-one variable indicating whether machine set j is adopted, e_{ij} is the amount of resource i provided by machine set j, d_{jk} is the per unit return to cropping activity K using machine set j, X_{jk} is the number of units of cropping activity k employed using machine set j, a_{ijk} is the per unit usage of resource i by cropping activity X_{jk}, g_{Ljk} is the per unit usage of resource L by cropping activity X_{jk}, b_i is the farm's endowment of resource i, f_L is the farm's endowment of resource L, and M is a number larger than the number of acres which can be treated by any set times the number of operations.

The model maximizes profit, which is cropping profit less machinery cost, subject to (a) constraints on resources which link machinery and cropping activities, (b) constraints that reflect mutual exclusivity of machinery,[1] (c) constraints which link machine set purchase and use, (d) and constraints on other cropping resources.

Consideration of Uncertainty in Field Time Availability

Weather affects farm production and profitability in numerous ways, but the effect most directly associated with machinery selection is uncertainty in the time available for field work. Available field time is an important constraint in mathematical programming models of crop production and machinery selection-use. However, the means for realistically reflecting uncertain field time availability on the model constraints is not necessarily obvious. Several approaches are possible. For example, the average time available may be used for each period, or, conversely, conservative (or optimistic) estimates of field time may be generated by discounting average field time [using the essence of chance constrained programming (Charnes and Cooper)]. The most common approaches involve discounting of field time available. This often leads to selection of a larger machinery set that can perform well under poor conditions (Kletke and Griffin). In following this approach, the time specified for each period is the minimum time which would be available at a prespecified probability level, say 85% of the years.[2] The

[1] Mutual exclusivity is not absolutely necessary. In some types of applications it may be desirable to have, for example, tillage and harvesting sets.

[2] In the Purdue Model B-9 (Doster and McCarl), the seventeenth worst year out of twenty was chosen.

choice of this probability level is arbitrary. Wagner (p. 675), in discussing chance-constrained programming, states that "B_1 (the probability level) should be part of the optimization problem." Alternatives to period-by-period discounting would involve running the model repeatedly with either actual or randomly selected weather years. Such approaches would be suspect in a mathematical programming model due to the certainty assumption (i.e., the model is given perfect knowledge of time available).

This study will use the period-by-period chance-constrained approach. However, our interest is in maximum profit and in robustness of machinery to many types of weather assumptions. Formally, the model to be solved will be the same as (1)–(5) above. However, the estimates of field time available (e, b, f) will be formed so that these elements are discounted for uncertainty. Further, the probability level will be changed and the effect of different probabilities explored.

Robustness and Stochastic Dominance

Because weather is variable, farmers most likely would choose a machinery set that performs well under a wide range of weather conditions. This characteristic will be referred to as robustness herein. Machinery sets will be tested under a wide variety of time availabilities to determine their robustness. This produces a distribution of outcomes for each machine set which is appropriate for the application of stochastic dominance (Anderson, Meyer).

Stochastic dominance generally refers to a set of techniques wherein distributions are compared under the basic assumptions that any decision maker prefers more income to less (degree 1) and that, as income increases, less variability is preferred to more (degree 2). Meyer has also introduced a form of stochastic dominance in which comparisons are made utilizing limits on the Pratt risk-aversion parameter.

Stochastic dominance provides an approach to machinery selection. Given a probability distribution of machinery performance under uncertain field time, stochastic dominance analysis may be applied to choose a machine set that is robust to a wide range of field time outcomes. This is an alternative to choosing the optimal set for a specific set of field times.

Case Analysis

The above machinery selection modeling proposals are applied to a hypothetical case farm. The farm is a 600-acre cash grain farm in central Indiana. Four crops are considered: corn, soybeans, wheat, and double-crop soybeans. The farm characteristics are essentially those of Purdue's Model B (McCarl, Doster, Candler, Robbins). Danok provides details on specification.

The base analysis was carried out over fifteen machinery sets which were developed in conjunction with knowledgeable extension specialists (Parsons, Doster). These sets (see Danok for details) were used in both a mixed-integer programming model and in a linear programming model. Within both models good-field-days data for the twenty-two periods in the years 1960–77 (from the Purdue agricultural statistician as discussed in Danok) were used to calculate the right-hand side values. The periods include eleven spring periods during which plowing, planting and post-planting of corn and soybeans are done; five early summer during which post-planting for corn and soybeans, wheat harvest, and double-crop planting are done; and six fall periods in which wheat planting, fall plowing, and harvesting operations are done. The field days' right-hand side corresponds to the minimum number of good field days that would be expected with the stated level of probability. The probabilities used were .1, .15, .33, .5, .6, .67, and .9.

Mixed Integer Programming Application

An MIP based upon (1)–(5) was formulated and solved. An overall schematic of the model is presented in figure 1. The model maximizes profit subject to constraints on (a) machinery ownership—a constraint which insures that only one machinery set is chosen [equation (3) above]; (b) tractor time—constraints which link tractor time provided by the machinery sets with use by period [equation (2) above]; (c) machinery set presence—constraints which relate machinery set presence to activities which use that machine set [equation (4) above]; (d) land, a limit on land available; (e) land reconciliation, a limit which restricts land used during any time period to be less than or equal to total land available; (f) labor availability—a constraint which balances labor use with labor available from hired and

Constraint	Machinery Sets Ownership	Plowing	Discing	Crop Production	Hired Labor	Crop Marketing	Input Purchase	Income	Right-Hand Side
		Activity							
Objective function	−							+	
Machinery ownership	+								= +
Tractor time	−	+	+	+					≤ 0
Machinery sets presence	−	+	+	+					≤ 0
Land		+							≤ +
Land reconciliation		+		+					≤ +
Labor availability		+	+	+	−				≤ +
Hired labor					+				≤ +
Land preparation time:									
a. Plowing time		+							≤ +
b. Discing time			+						≤ +
Crop production time									
a. Planting time				+					≤ +
b. Harvesting time				+					≤ +
Land precedence									
a. Land ready to disc		−	+						≤ 0
b. Land ready to plant			−	+					≤ 0
Yield				−		+			≤ 0
Input purchase				+			−		≤ 0
Income				+	+	−	+	+	< 0

Figure 1. Schematic of model matrix

on-farm sources by period; (*g*) hired labor—a limit on hours of hired labor available by time period; (*h*) plowing time—a limit on hours of plowing time available by time period (assumed constant across machine sets); (*i*) discing time—a limit on hours of discing time available by time period (assumed constant across machine sets); (*j*) planting time—a limit on hours of planting time available by time period (assumed constant across machine sets); (*k*) harvesting time—a limit on hours of harvesting time available by time period (assumed constant across machinery sets); (*l*) land ready to disc—a constraint which links plowed ground supply with plowed ground use (discing) by time period; (*m*) land ready to plant—a constraint which links ground that has been plowed and disced with its use (planting) by time period; (*n*) yield—a set of rows balancing production with sale by crop; (*o*) input purchase—a set of rows balancing input use with input purchase; and (*p*) income—an income-accounting row.

The activities in this model are (*a*) machinery set ownership, activities representing the adoption of various machinery sets; (*b*) plowing, activities for plowing by crop, time period, and machine set; (*c*) discing, activities for discing by crop, time period, and machine set; (*d*) crop production, activities for planting thru harvesting by crop, planting date, harvesting date, and machine set; (*e*) hired labor, activities representing the hiring of labor by period; (*f*) crop marketing, activities representing sale of each crop; and (*g*) input purchases, activities representing purchases of each input.

Solution Method

The mixed-integer programming model is, as formulated, particularly adaptable to solution by iterative methods. Clearly, one alternative is to solve an LP for each machinery set and pick the best. However, given the formulation structure, Benders decomposition (Benders; Danok, McCarl, White; Hilger, McCarl, Uhrig) is a particularly appropriate solution method and is used to solve this model.[3]

MIP Results

The first approach to machinery selection used in this study was to solve the MIP model for optimal machinery set and crop plan under specified weather assumptions. The results of the seven runs of the model are presented in table 1. The principal results obtained are as follows:

(*a*) As long as available field time is an effective constraint, the optimal machinery set changes as the weather probability is increased (i.e., the amount of field time available is increased). At higher probability levels, other constraints become more important.

(*b*) The size (capacity in acres per unit of time) of the optimum machinery set decreases as weather probability (available field time)

[3] Although not implemented here, the mutual exclusivity of machine sets allows the problem to be reduced to a small MIP and a one machine-set LP, given the machine set chosen. Thus, a series of ordinary farm-planning models can be solved. The only difficulty arises from the need for dual variables on constraints, equation (4). However, analysis of the formulation (as in Geoffrion and Graves) allows the dual variables to be constructed analytically (see Danok for details).

Table 1. Net Farm Income, Optimal Machinery Set, Crop Acreage by Weather Probability Level for 600-Acre Farm

	Weather Probability Level						
Item	.1	.15	.33	.5	.6	.67	.9
Net farm income ($)	79,773	127,462	147,438	148,584	149,166	149,583	150,221
Selected machinery set	9	9	11	2	2	2	2
Plowed acres	387.2	600	600	600	600	600	600
Disced acres	437.5	600	600	600	600	600	600
Planted and harvested acres							
a. Corn	104.6	266.6	600	600	600	600	600
b. Soybeans	282.6	333.4	0	0	0	0	0
c. Wheat	50.3	0	0	0	0	0	0
d. Double-crop	0	0	0	0	0	0	0
Crop sales (bushel)							
a. Corn	14,721	37,927	86,162	85,953	86,207	86,358	86,694
b. Soybeans	12,500	14,865	0	0	0	0	0
c. Wheat	2,882	0	0	0	0	0	0
d. Double-crop	0	0	0	0	0	0	0

increases. The important variable determining net farm income is the amount of work that can be accomplished during critical time periods in the spring and fall. Obviously, more machine capacity and more field time during a given period are substitutes.

(*c*) Given the resource constraints used to define the typical farm employed in this study, field time and machine capacity cease to be effective constraints as weather probability increases. Thus, at a weather probability of .33, it is possible to plant all land in corn (the crop giving the highest return to land). At a probability of .5 and greater, it is possible to plant and harvest corn at the most favorable time. Thus, as available field time increases, the farm becomes specialized in corn; further, the least-cost machinery set for corn production is chosen and net farm income stabilizes.

Solution performance of the model is discussed extensively by Danok. The number of machine sets examined by a run in order to conclude optimality varied between two and nine, and exhibited an inverse correlation with the probability level used.[4]

Use of MIP to Modify Existing Machinery Set

The MIP results discussed above were derived from a specification that assumed no existing machinery set on the farm. The more normal situation is that a farmer possesses a set of machinery and wants to evaluate alternative modifications of that set. In order to demonstrate the usefulness of the MIP model in this situation, a particular machine set was assumed and alternatives generated. Shadow prices obtained from solving the crop-planning model with this existing machinery set indicated that it was characterized by (*a*) excess plowing and tractor capacity, (*b*) insufficient planter capacity, and (*c*) insufficient harvesting capacity. The MIP model was then respecified with eight integer activities—one representing the existing set and seven representing modifications including various combinations of machines that could correct one or more of the deficiencies of the existing set. Machinery acquisition activities reflected cost and performance of the existing set and the existing set with alternative modifications.

When the respecified MIP model was run, a modification of the set that included less tractor capacity and more harvesting capacity was chosen. Thus, the MIP model was shown to be an effective tool for evaluating alternative modifications of existing machinery sets as well as choosing among totally new sets.

Stochastic Dominance

The MIP results for alternative weather probability levels (table 1) would be of limited use to a farmer in making a machinery decision. Clearly, within limits, the choice of a probability level for good field days is arbitrary. The results show that when different probability levels are chosen, different "optimal" sets result. Thus, the farmer would not receive a clear indication of which set to use. Farmers, however, potentially are interested in a trade-off between robustness and expected profit. Consequently, two questions arise: (*a*) which probability level should be used (Shurley and McCarl examine this), and/or (*b*) can a machine set be chosen for which the probability level does not matter that much? Question (*b*) led to the stochastic dominance analysis.

Each of the original machine sets was imposed on the model, and it was run for nine different probability levels. Table 2 presents the results. From these results, a cumulative probability distribution of net farm income was formed for each machinery set. Stochastic dominance analysis, as discussed above, was applied to these distributions to choose dominant sets (assuming them to be unbiased as discussed below). Using the distributions, first and second degree stochastic dominance tests were applied. Table 3 displays the results.

Distributions for machinery sets 1, 2, 3, 4, 8, 9, and 11 form a group with first-degree dominance over the remaining distributions. If one is willing to make the assumption that more income is preferred to less, then these machine sets eliminate the other machine sets from consideration. From this group, distributions 1, 3, and 9 dominate the others under second-degree stochastic dominance. Under the assumptions that more is preferred to less and that the farmer is risk-averse (and, naturally, that the distributions are proper), then these distributions eliminate all other distributions. Stochastic dominance tests, as in Anderson, do not distinguish among these three machine sets.

Meyer has provided a method by which dis-

[4] Computer time and cost in an inefficient implementation (a better implementation is discussed in footnote three) varied from 1,600 seconds ($51) to 900 seconds ($26), depending upon number of Benders cuts required.

Table 2. Net Farm Income Generated by Using Different Machinery Sets on 600-Acre Farms under Different Weather Probability Levels

Machinery Set No.	Weather Probability Level								
	.1	.15	.2	.3	.33	.5	.6	.67	.9

10	60,796	109,461	133,847	140,646	141,490	143,625	144,189	144,755	145,388
11	56,158	103,997	140,587	147,069	147,438	148,430	148,702	148,861	149,487
12	77,868	127,082	128,253	140,366	140,461	140,881	140,959	141,005	141,036
13	62,401	113,317	138,277	143,999	144,069	144,442	144,713	144,872	145,499
14	49,957	88,689	132,511	146,711	146,979	147,350	147,526	147,628	148,214
15	54,111	99,361	135,781	143,572	144,416	146,551	147,215	147,681	148,314

tributions may be compared with respect to ranges of the Pratt risk-aversion coefficient. Application of this method shows that distribution 3 is preferred to distributions 1 and 9 for a Pratt risk-aversion coefficient between .000001 and .1.[5] The stochastic dominance analysis then suggests the choice of machine set 3. This leads to an interesting observation, because machine set 3 was not optimal under any of the various weather probability levels (table 1). Thus, a farmer interested in robustness may choose a machine set which is not optimal under any individual state of nature but which behaves well over a wide range of states of nature. This leads one to doubt the utility of using the MIP model with a given weather expectation as a means of choosing machinery.

Bias in Distributions

Because of the method used in constructing the MIP right-hand sides, the probability distributions used in the stochastic dominance analysis are biased. The results would be unbiased only in the case of perfect correlation

[5] The Pratt risk-aversion coefficient appears to be most likely to appear in this range based upon its theoretical properties [one divided by expected income for the utility function log of income (Lin and Chang)] and its equality to the risk-aversion parameter from an EV portfolio selection model (Lin and Chang display this relationship). Values for this parameter are given in Lin, Dean, Moore, table 2, p. 504, where the Pratt coefficient varies from 0 to .02 (neglecting subject 5), and Weins (.0085–.091).

Table 3. Stochastic Dominance Results

Distribution	Distributions This One Dominates		Distributions This One is Dominated By		Distribution Over Which There Is No Dominance
	First-Degree	Second-Degree	First-Degree	Second-Degree	
1	5,6,7,10,13	2,4,14,15			3,8,9,11,12
2	14	15		1,3,11	4,5,6,7,8,9,10,12,13
3	5,6,7,10,13	2,4,11,14,15			1,8,9,12

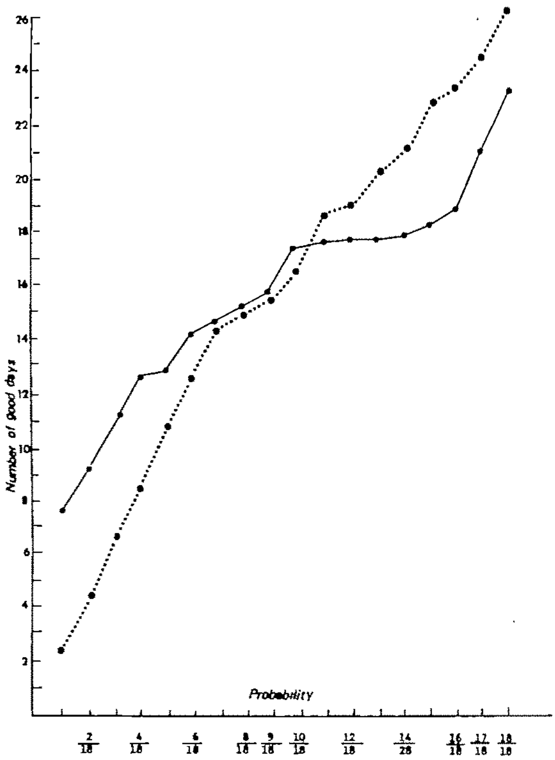
15		14	11	1,2,3,4	5,6,7,8,9,10,12,13



Key: solid line is summed four-week distribution. Dotted line is horizontal sum of four-week distribution.

Figure 2. Comparison between distribution of good days selected period by period and for group of periods

among all time periods. The nature of the bias was examined by taking the actual good field days for a four-week spring period and comparing the distribution of the time available during the period with the horizontal sum (at each probability level) of the distribution of the individual weeks. Figure 2 portrays the two distributions. Clearly, the use of period-by-period expectations biases the distribution. What is deemed to occur at low probabilities from the summed individual distributions in fact is much less likely when examining the possibilities from the four-week distribution. For example, less than seven good field days did not occur in the 1960–77 period for the individual distributions, taking the worst possible event in each period and summing yields 2.5 days. On the other hand, good-field-days distribution at the high end should, in fact, have lower probability. These results do indicate bias in the distributions. We feel, however, that first-degree stochastic dominance would yield the same results, regardless. Under this sort of bias, the second-degree criterion would be altered. The discovery of the correct probabilities for a chance-constrained probability level is virtually impossible in the context of this study. The probability depends not only upon the total number of field days across periods but also upon the number of field days within each period. The dominance criterion, however, does appear to be useful in this case (when the bias is understood) and very attractive in cases where an unbiased distribution of outcomes may be constructed (i.e., possibly through Monte-Carlo simulation, as in Edwards).

Concluding Comments

The effect of field time uncertainty on machinery selection was not surprising. First, the results presented herein reaffirm the rather obvious conclusions that pessimistic field time estimates result in the farm carrying larger machinery (as in Kletke and Griffin and undoubtedly many other places). Second, field time uncertainty tends to discourage those crops which are planted in the more uncertain periods. Third, model income rises as field time expectation becomes more optimistic. However, income increases at a decreasing rate and virtually no increase occurs for a field time expectation above the average. This would have some implications for returns to weather modification efforts.

The most fundamental question to be addressed in concluding this paper is: How should machinery selection be modeled? Four alternative approaches appear to be suggested by this and other studies. First, mixed-integer programming with individual machines (not sets) may be used. A second approach would be mixed-integer programming with sets. Third, a distribution of outcomes for alternative machinery sets can be generated and stochastic dominance (or some other risky choice criterion) applied. Fourth, simple budgeting or deterministic models can be used to examine the impact of alternatives. Clearly, combinations of the above may also be used.

Machinery selection obviously may be done for a multitude of purposes. Research objectives may emphasize the desire to know how machinery complements will change, given various changes in the farm environment. Extension objectives could focus on the desire to provide a tool for farmer use and/or education objectives in terms of problem formulation and resolutions.

Many types of research objectives would seem to be best met by either the first, second, or third methods. The mixed-integer results seem to be heavily biased by the good field days expectation level; thus, some distributional approach may be desirable. This is particularly evident when one considers that the stochastic dominance approach resulted in the choice of a machine set which which was not optimal under any probability level but did well overall.

For extension and some types of research, we feel that the machine set idea is extremely promising. The MIP model is computationally tractable (which has been an obstacle in previous studies) and with sets, can handle more of the farm level realities. Further, the burden of definition of machine-set alternatives is placed on the decision maker (as in the commonly used budgeting approaches). This, however, should not be too difficult except for the new farmer, as we feel many farmers will have an idea of what changes are potentially attractive. Shadow price information also is generated to aid in machine set definition and refinement. The farmer then controls the domain of feasible machinery. True optimality, however, may not be attained.

A tempting and seemingly attractive machinery selection strategy would be to use the MIP to select some machine sets. Information about the marginal costs of other sets could be used to choose a few other machine sets. From here some sort of distribution-generating model (probably different from the approach used in this study because of the problem of bias) could be used in conjunction with stochastic dominance to study these machine sets in detail. This probably would be an acceptable research technique but might be awkward in an extension setting.

Reforming Cameroon's Government Credit Program: Effects on Liquidity Management by Small Farm Borrowers

Francois Kamajou and C. B. Baker

Higher interest rates and credit limits as well as modified lending practices have been proposed to improve the performance of credit programs for small farmers in developing countries. Models based on Cameroon field data are used to generate results from such reform proposals. The results suggest that small farmer benefits could be increased by increasing credit limits and flexibility in the use of loan proceeds, while reducing default rates and expanding program outreach.

Key words: Cameroon, credit, development, small farmers.

Operation Ceinture Verte (Green Belt Operation) is designed to accelerate the economic development of agriculture and improve the economic welfare of small farmers in Cameroon. The project has production, marketing, educational, and credit components (Cameroon, Ministere de l'Agriculture). In this report the focus is on the credit component of that part of the project designed to modernize plantain (vegetable banana) farms around Yaounde, the capital city.

Kamajou has estimated the annual net rate of return from the credit component of the plantain project to be 56% for society as a whole and 85% for the typical participating farmer. But the responsible government unit suffers a substantial loss even under conditions of mild default rates. There is an evident need to revise the sharing of costs and benefits so as to increase the viability of the program without unduly restraining net benefits to participating farmers. It is the objective of this article to report findings from a study of alternatives to achieve this goal.

The Problem

It is contended widely that capital shortages significantly constrain the economic development of small farms in developing countries. Cameroon is no exception. The remedy perceived in Cameroon, as in most developing countries, is to provide public sector loans to enable small farmers to modernize their production. Typically, the loans are made at concessionary rates of interest and so disbursed as to limit the borrower's use of loan proceeds; e.g., loans frequently are disbursed in kind or in coupons exchangeable for designated production inputs.

Credit, defined as capacity to borrow, can be exchanged by the farmer in a loan transacted with the lender with whom the credit is defined. As an alternative to borrowing, the farmer can reserve that credit, holding the reserve as a form of liquidity. If loans in the government credit program are restricted in use, reserved government credit has little liquidity value. However, if the loans can be used for unpredicted obligations, credit reserves do have liquidity value. They lessen the farmer's need to hoard gold, jewelry, and other liquid assets and allow him to commit more cash to production. They also lessen the farmer's dependence on the moneylender.

To have liquidity value, the credit must be perceived as available on a permanent basis and in predictable quantities and terms (Baker, Baker and Bhargava). Moreover, the proceeds must be usable over the whole range of expenditures faced by the small farmer (Singh). In contrast, the government's small farmer credit program often is perceived (all

The authors wish to thank two reviewers who commented usefully on an earlier version of this article.

too accurately!) to be temporary, subject to changing rules, and restrictive in the use of the loan proceeds. Often, too, loan acquisitions are slow, costly, and bureaucratically cumbersome. A survey of participants reveals that the credit component of *Operation Ceinture Verte* shares many of these properties. Hence the credit it produces has limited liquidity value, is costly to administer, and is limited in outreach among small farmers.

Interest rates lower than lending costs restrict the outreach of the program and/or size of individual loans, drain resources from the public sector, and threaten the continuation of the credit program. It is this threat, as perceived by the borrowers, that induces a further incentive toward default. As default rates increase, they quickly become destructive to the lending program.

Viability of the lending program can be increased by raising interest rates and by lowering lending costs. The commercial loan alternative for the small farmer is the moneylender. The substantially higher rates charged by the moneylender allow a considerable rate increase available to the small farmer credit program before the borrower is diverted to the moneylender because of interest rate.

Modeling the Small Farm

To infer the on-farm effects of varying credit limits, interest rates, and other terms of loans, linear programming was used to model the small farm borrower, with data from a survey of participants in *Operation Ceinture Verte* (Kamajou). In addition to such technical data as resource endowments and production and cost coefficients, the small farm is modeled under a variety of conditions in its financial environment. Each depicts a policy position of the government credit program and responses to that position on the part of the small farmer. Data were obtained from secondary sources to supplement the survey data. The unit was modeled to be representative of small farms in the area covered by the survey (Kamajou).

Objective Function of the Model

The farmer is assumed to maximize the end-of-period net cash flow and, in some specifications, the value of cash and credit held in reserve. The end-of-period net cash flow is shown by the activity level of cash transfer to the objective function. The values of cash and credit reserves are determined by liquidity

valuation activities described later. Because the reserves do not product cash flows, their contributions to the value of the objective function must be subtracted from its total value to obtain net cash flow to the household.

Constraints of the Model

The study focuses on the financial environment of the producer with the constraints listed in table 1. Some of the family food needs are met with subsistence crops. Cash is required to buy food and pay for other living expenses, mainly schooling; clothing; health; and traditional, civil, or religious obligations. Seasonal variations (see note a, table 1) reflect differences in length of season as well as seasonal distribution of requirements.

Initial cash supplies also differ by season. A sum of 20,000 CFA francs (1 CFAF = US $0.0042), for example, is assumed available to the household on 15 March. Seasonal cash supplies are increased by sales, by interseason transfer, and by borrowing. Any cash surplus is transferred to the next season or, in the case of the last season, to the objective function. All available cash is allocated between the cash account and the cash reserve. From the cash account, cash is available for consumption, production, and debt payment. Cash in reserve is valued to reflect liquidity preferences. The percentages for reserved quantities allow for approximately nonlinear value functions (Baker and Bhargava).

Government credit also is specified by season. Government loans are disbursed for cocoa (with no interest charge) and for plantain (with a 6% interest charge) at the beginning of each planting season: March for season one and September for season two. Loan limits are set by the application rates per hectare for fertilizers, insecticides, and other inputs. The farmer is not required to borrow the total available.

Government credit is allocated between the government credit account and the government credit reserve. The government credit account is available for borrowing, which adds to the farmer's production assets or to cash, depending on the type of loan disbursement. The amount not borrowed is held in reserve. Government loans for plantain production require the producer to commit 14,000 CFAF to plantain. Therefore, the total value of the loan the farmer receives in kind is equal to his needs (as determined by the area farmed) minus 14,000 CFAF.

Lending limits (i.e., "credit") are assumed to be 25% of the borrower's net worth. The net worth itself is assumed to be approximately 50% of his gross annual money income, an estimate obtained by survey. Moneylender credit differs by season, as shown in the constraint levels in column 4 of the footnote of table 1.

Moneylender credit is allocated between moneylender credit account and moneylender credit reserve. Borrowing from the moneylender draws upon the moneylender credit account. Moneylender credit reserve constitutes a source of liquidity.

Liquidity requirements reflect needs to meet unexpected cash expenses or cash obligations despite adverse cash flows. They are functions of expected money income and are shown to vary among seasons (column 5) and to reflect the risk factors of each season (such as drought, epidemy, plant destruction by insects, prices for cash crops).

Borrowing creates debts which must be repaid or, if unpaid, carried over as liabilities. Debt balances are described in constraints differentiated by source and time of borrowing (government or moneylender), and use of loans, for government loans (plantain or cocoa).

Activities of the Model

Activities most relevant to financial aspects are listed in table 2, expressed in terms of activity units given in the last column. Some (though not all) of the activities related to production, marketing, and consumption are omitted.

Food requirements are expressed in terms of major nutrients or dietary requirements—protein, fat, iron, and vitamin A—and reflect safe levels of energy and nutrient intakes, as established by recent documents of the Food and Agricultural Organization of the United Nations (FAO). The outlays supplement food produced within the unit. Subtracting home-produced supplies from the (FAO) safe levels determines the balance to be met by purchasing. This balance is converted into actual weight of food and then stated in terms of cash requirement. The most expensive source among alternatives for each nutrient is chosen to calculate cash requirements for that nutrient cash need. Thus the model provides the

Table 2. Model Activities

Column Description	Unit
Buy protein items (by season)	kilograms
Buy fats items (by season)	kilograms
Buy iron items (by season)	milligrams
Buy vitamin A items (by season)	000 International Units

Transfer cash: between seasons and to objective function	CFAF

[a] In some specifications government loans are disbursed in kind.

household with flexibility in making up its daily diet. Other family living expenses are specified to be paid with cash.

Crop expenses also are specified to be paid with cash, except for models in which government loans are disbursed in kind. Hired labor is assumed identical to family labor in terms of quality and is paid with cash.

Borrowing activities are differentiated by source, use (in the case of government loans), and season. Government loans for plantain and for cocoa currently are disbursed in kind. Loans from the moneylender are assumed to be disbursed in cash at a 50% annual rate of interest. The moneylender is included in the model because informal lending in the rural and even in the urban milieu is an important part of the small farmer's financial environment. To qualify for a government plantain loan, the farmer must commit 14,000 CFAF in cash for every planting season. Hence, activities are specified that commit cash to plantain activities by planting season and thus to meet the qualification requirement.

Borrowing from either source reduces the level of the credit account of that particular source. Credit accounts of both government program and moneylender are reduced by one unit for each unit of borrowing. In addition, the credit programs interact. Moneylender credit is reduced by .50 CFAF when the farmer borrows one CFAF from the government. Government credit is reduced by one CFAF when the farmer borrows one CFAF from the moneylender.[1]

Finally, borrowing creates a debt. The debt repayment activities are differentiated by source of debt, use of borrowed funds (plantain and cocoa), and by season the debt is contracted. A debt is assumed contracted the first day of the borrowing season. The earliest repayment date is the first day of the following season. Repayment coefficients are calculated as one plus the interest due on one CFAF in the period of repayment.

Current policy provides for government loans to be disbursed in kind. However, in alternative models cash disbursement is substituted and input-purchasing activities specified. Comparing outcomes between models determines the effects of in-kind disbursement on the net cash flow of the small farmer, as well as on farm organization.

Cash used for cash requirements is drawn from cash accounts. Also, activities are specified that value reserved cash. The proportions of cash used and cash reserved must always add to one. The value of a CFAF of cash held in reserve is the reservation price the producer sets for cash to be committed to use, and is—at that price—what a unit of the cash reserve contributes to the objective function. The values of these cash reserves are given in footnote a, table 3. The value of a unit of cash in reserve increases as the percentage of cash held in reserve decreases. Every unit of re-

[1] These coefficients are chosen so as to reflect each lending agent's perception of ability to recover loans it disburses. The well known low repayment record of the government credit programs is reflected by a reduction of its loan as a response to the borrower's commitment to another lender. The private moneylender has enjoyed over the years a relatively high repayment record. Therefore, he reacts to the borrower's commitment to the public lender by reducing his credit availability by 50%.

served cash satisfies one unit of liquidity requirement.

Credit is an asset which the borrower allocates between a credit account and a credit reserve. The proportion allocated to credit account is used for borrowing, while the rest is kept in reserve. Credit allocation activities are specified just like the cash allocation activities. Credit allocation activities are specified for both government and moneylender credit.

Credit reserves are valued by season, by percentage of credit held in reserve, and, where relevant, by the source of credit. The procedures are the same as those for the valuation of cash reserves. The credit reservation prices differ from those of cash because of the difference between cash and credit as contributors to liquidity. (See footnote b, table 3.)

The differences in the reservation prices between government and moneylender credit reflect a judgment on the effects of restrictions on use of government loan proceeds and the perceived unreliability of government loans. Any surplus cash is transferred from the cash account of a given season to the cash account of the next. From the last season, cash is transferred to the objective function.

Results

Several models were specified, as indicated in table 3. In model 1, government loans are as-

Items	Changes				
	(%)				
Credit limits	10	20	30	40	50
Cash reserve value	−10	−20	−30	−40	−50
Credit reserve value	+10	+20	+30	+40	+50

sumed to be disbursed in kind. In contrast, moneylender credit is available for loans disbursed in cash. In model 1, the concessionary interest rates and loan disbursed in kind lead the small farmer to question the viability of the government credit program and to perceive it as valueless in terms of credit reserve. Model 1 reflects the current situation. In model 2, the government is specified to disburse its funds in cash rather than in kind, thus allowing the producer to make choices among input mixes for his production processes. Flexibility in choices, made available by cash disbursement, elicits a liquidity valuation for reserved government credit. Reduced administrative costs also improve the prospects of program viability.

Models 3 and 4 are variations on model 2. Loan proceeds are in cash for both, and credit reserves are valued for government as well as for moneylender credit. In model 3, government credit limits are varied as shown in footnote c of table 3. Note also the associated changes in reserves values. Model 4 is the same as model 2, except that interest rates on government loans are varied, as indicated in the last column of table 3.

Liquidity Management and Producer Behavior

Results from model 1 are reported in the first column of table 4. They suggest outcomes to be expected if the government loans are disbursed in kind and at high net lending costs. One reason loans are disbursed in kind is to try to assure the use of loans for "productive" purposes. Comparing results from models 1 and 2 reveals that it is optimal for the farmer to produce in either case with highly intensive technology. Yet, survey observations revealed that the typical farmer uses somewhat less intensive technology, despite disbursements in kind. In sum, the choice of technology is largely independent of type of disbursement. The farmer will find a way to respond optimally to his options, whatever the form of loan disbursement.

Model 1 holds cash 404,674 CFAF in reserve. The size of the reserve depends on the cash reservation prices in relation to rates earned from cash committed to production. The value of the objective function, as generated by the model, includes the value of the liquid reserves (cash and moneylender credit). The value reported in table 4 (679,352 CFAF) reflects a reduction for the value of reserves. If the cash held in reserve is added to the net cash flow, the total comes to 1,084,026 CFAF.

In model 2, reserved government credit is valued at reservation prices shown in footnote b of table 3. The prices are used to value government credit reserve in the objective function, just as cash reservation prices were used to value cash in reserve. Model 2 lessens borrowing from both government and moneylender, increasing cash committed to production and leaving the production organization unchanged from model 1.

Model 2 generates the same optimal production activities as model 1. Government borrowing is reduced to 169,418 CFAF (122,531 from a plantain loan and 46,787 from a cocoa loan) and borrowing from the moneylender to 15,000 CFAF. Cash held in reserve is reduced to 301,019 CFAF.

Committing more cash and near-cash assets to production is an important social, as well as private, contribution and reduces the burden on the government in its attempts to generate more funds for loans. Note that in model 2 the net cash flow increases to 756,753 CFAF. Added to cash in reserve, the total comes to 1,057,771 CFAF, nearly the same as produced by model 1. In model 2, the farmer is more secure than in model 1, owing to a considerably greater reserve in credit.

Effects of Credit Limit (Model 3)

The theory of liquidity management suggests an inverse relationship between the reservation prices of cash and the amount of cash committed to productive use. When credit limits are increased, the value of cash in reserve is decreased. The change in cash reservation price schedule, associated with the increased credit limits, is shown in footnote c, table 3. The associated increase in the credit reservation prices also are shown.

The results are summarized in table 4. The increase in government credit limits does not affect the production organization found optimal under specifications of model 2. However, after a 30% increase in the loan limits, the producer ceases to borrow from the moneylender. The increase in government credit limits considerably reduces the amount of cash held in reserve, releasing it for production activities. Credit limits and the allowable use of loan proceeds are important factors in reducing the small farmer's reliance upon the mon-

Table 4. Optimal Activity Levels for Models 1–3

Activity	Model 1	Model 2	Model 3: Increments to Government Credit Limit of Model 2 (%)					Unit
			10	20	30	40	50	
Produce plantain	1.00	1.00	1.00	1.00	1.00	1.00	1.00	hectare

[a] Disbursed in kind in model 1.

eylender and in freeing some of the cash "trapped" for liquidity needs for use in production activities. Both results are vitally important for all government credit programs for small farmers.

It is of interest to note the increased net cash flow as the government loan limit is increased. On the other hand, the amount of cash reserved diminishes. The net cash flow and cash reserved are summed in the last row of table 4. The sum is shown to diminish slightly as the government loan limit increases. The behavior of this sum is influenced by reservation prices assumed for cash and for credit. Little empirical evidence is available on reservation prices. Logic strongly supports the assumptions made on reservation prices in response to reserved levels of either cash or credit. The assumptions made on reservation prices of cash in relation to credit are perhaps less certain.

Effects of Higher Interest Rates for Government Loans (Model 4)

Model 4 is the same as model 2, except the government interest rate is permitted to vary from the current 6% (as in model 2) to 36%, by five equal increments of 6%. Results are reported in table 5. Until the interest rate reaches 24%, few changes occur in the optimal solution. Land use, intensity of input use, and borrowing activities remain unchanged. There is a slight reduction in labor hired.

At interest rates above 24%, changes occur in crop mix and technology. At 30%, the producer reduces cocoa production and fertilizer intensity in plantain production: 0.87 hectares of plantain are produced with high fertilizer use and 0.13 with medium fertilizer use. Increasing the cost of borrowing shifts the production mix from the capital intensive technology, but the total area in plantain is unchanged. At 36%, the shift of plantain toward lower technology continues. So does the reduction in cocoa production. However, there is a 12% increase in land used for plantain. Hired labor increases as interest rates increase beyond 24%. The shift in technology, however, occurs only after the interest rate is raised above 24%.

Changes also occur in financial organization. While the size of cocoa loan remains unchanged (as does the amount borrowed from the moneylender), the size of plantain loan diminishes as the interest rate is increased beyond 12%.

Cash reserves diminish for the increment, 6% to 12%, and again for the increment, 24% to 30%. In contrast, reservations of moneylender credit increase for the increment, 6% to 12%, and diminish for the increment, 30% to 36%. The diminution in net flow is surprisingly slight over the range of increase in interest rates, and the size of cash reserve varies little. Hence the total of net cash flow plus cash reserve is little affected by the wide range of interest rates.

Summary and Conclusions

Relaxing restrictions on the use of government loan proceeds is beneficial in terms of output and income. Liquidity needs force the farmer to reserve large amounts of cash and credit for adverse contingencies. A reliable source of credit, with flexibility in use of loan proceeds, allows him to increase his production commitment of cash and its equivalents otherwise reserved to respond to risk.

Disbursements in cash also reduce administrative costs in lending, adding to perceived viability of the government lending agency. Comparing the results of models 2 and 4 reveals that credit limits are far more important in improving the farmer's income than is the rate of interest he pays. A 400% increase in the rate of interest (from 6% to 30%) reduces the farmer's income by about 2%, while a 50% increase in the loan limits increases his income by about 20%. Higher interest rates would provide the lending agency with resources that could be used to strengthen its performance.

While not demonstrated in the programming results, there are persuasive reasons to suppose that incentives to default also would be lessened. The larger and more certain credit supply, along with increased flexibility in use of loan proceeds, would add to the value of government credit, making it more worthwhile to the farmer to protect it.

These findings were confirmed largely by results of the field survey. Asked about interest rate, size of loans, flexibility in use of loan proceeds, and the length of time for loan disbursement, 37% of the farmers interviewed ranked the flexible use of loan funds as most important, 31% chose the rapid disbursement of funds, 27% chose the size of loan, and only 5% chose the level of interest rate as a major factor in their borrowing decision.

[a] High intensity fertilizer use.
[b] Moderate intensity fertilizer use.

In Cameroon, as in many other developing countries, formal financing of small farmers is mainly from the public sector. Many current government agricultural credit programs for small farmers are performing poorly. Criteria for success or for evaluating credit policies are several and diverse: (*a*) lending costs (including default costs), (*b*) the number of farmers served (the outreach of the program); (*c*) the degree to which the farmer's financial needs are met, including risk bearing and the average size of loans made available; (*d*) increase in farmer's output, income, or welfare; and (*e*) impact on income distribution between various farm groups.

High administrative costs and low repayment records together with low interest rates produce prohibitively high net costs. In spite of attempts to justify the low rates of interest, it remains that they contribute to a misallocation of resources, the weakening and the distortion of capital markets, reduced incentives to save, and costly, nonproductive forms of liquidity management (Gonzales-Vega, Donald, Osuntogun). Moreover, the high net costs severely restrict the outreach of the programs.

In terms of criteria (*c*) and (*d*), results from this research suggest that performance could be improved by offsetting increases in interest rates with higher loan limits, and by reducing costs associated with restricting uses allowed for loan proceeds. An interest rate of 18%–24% has been suggested by various sources (e.g., Donald). This range in essence was confirmed by the results of this study. The higher interest rate would increase the feasibility of a savings program. Mobilizing rural savings would broaden the institutional resource base. The research did not address criterion (*e*) directly. However, by increasing program outreach, the suggested reforms would lessen the inequities now current because of the restricted scope of the program.

The project, *Operation Ceinture Verte*, has increased the participating farmer's output and income substantially. In terms of the other criteria, the results are less satisfactory. The

program exhibits excessive and perhaps prohibitive costs. Two major reasons account for these excessive costs: (*a*) the program does not charge its customers for the full cost of services rendered; (*b*) the administration of such small credit schemes requires a large amount of supervision. Lending in kind complicates the problem still further. The high default rate seems likely to be due in part to the low value the borrower ascribes to the loan program's credit. Finally, only a small proportion of small farmers are reached by this program, owing largely to its high net costs.

Notes

Fungibility and the Design and Evaluation of Agricultural Credit Projects

J. D. Von Pischke and Dale W Adams

Agricultural credit is an important element in development efforts in most low income countries. Some countries such as India, Brazil, and Thailand assign credit a leading role in rural development. The World Bank, the Inter-American Development Bank, and the Agency for International Development have aggressively promoted agricultural credit, committing in excess of $5 billion through hundreds of projects. The popularity of credit is due in part to the notions that loans are necessary to accelerate technological change in farming and that formal credit is required to release peasants from dependence on moneylenders. In certain situations the relative ease with which credit projects can be initiated adds to their appeal.

Most credit projects are aimed at stimulating the production of commodities such as rice or dairy products, augmenting the use of an input like fertilizer or improved breeding stock, encouraging investment in machinery and irrigation, or providing more financial services to target groups such as the rural poor, cooperative members, or corn producers. Agricultural banks, cooperative banks, credit unions, and supervised credit agencies have been created under some of these projects. Other projects have augmented loanable funds flowing through existing parts of rural financial markets (RFMs).

A number of these projects have been evaluated formally.[1] Major measures of performance emphasized by donor agencies are disbursement of project funds and recovery rates on loans to farmers. Most evaluations also attempt to measure the impact of loans on farm activities. Impact is usually expressed in terms of increases in crop area or yields financed by the project and by the quantity of animals, fertilizer, or tractors bought with loans. Numbers, amounts, and kinds of loans made, and farm income and net worth are also used as performance measures. These evaluations typically include little analysis in depth of the credit institutions handling project funds.

While project evaluations may show slow loan disbursement or loan repayment problems, they often indicate that production, input use, investment, and target group participation goals were generally met, and that projects achieve many of their objectives. Despite this, a number of observers are increasingly concerned about the quality and quantity of services provided in low income countries by rural credit institutions and by the RFMs of which they are a part. Critics charge that although donor funding for agricultural credit has increased substantially, the real value of total agricultural loans has decreased in many countries, that concessionary loans often end up in the hands of the well-to-do, that loans for agricultural purposes are diverted to nonagricultural uses, that policies in many RFMs encourage consumption and discourage savings, that the term structure of agricultural loans often contracts or fails to expand, and that RFMs are adopting few cost-decreasing technologies in the provision of financial services. It is disconcerting that rural financial markets could perform poorly while projects within these markets are judged to be doing well. An attempt is made in the following discussion to resolve this paradox by showing how design and evaluation procedures which ignore fungibility lead to faulty conclusions about agricultural credit project results.[2]

Fungibility, Additionality, Substitution, and Diversion

Fungibility is a prime characteristic of modern currency. Standardization, or interchangeability, enables money to serve as a *numéraire* and medium of exchange, and makes monetized transactions more efficient than barter. Fungibility underlies the role of money in efficient resource allocation in classical economic models and in increasing monopoly ac-

J. D. Von Pischke is a financial analyst with the World Bank, and Dale W Adams is professor of agricultural economics at Ohio State University.

The views in this paper are those of the authors and should not be attributed to the World Bank, its affiliated organizations, or to any individual acting in their behalf, or to the Agency for International Development, which has funded rural finance research at Ohio State.

The authors would like to thank V. V. Bhatt, Cristina David, Jack Kordik, Millard Long, U Tun Wai, Robert Vogel, and two anonymous reviewers for their comments on earlier versions of this paper.

[1] Only a few of these evaluations are available in published form (e.g., Adams, Giles, Pena; Daines). Some overview publications, however, do give a flavor of project results (Agency for International Development, Donald, Food and Agriculture Organization, Kratoska, Reserve Bank of India, Shaw, World Bank, 1975, 1975–79).

[2] Fungible: "of such a kind or nature that one specimen or part may be used in place of another specimen or equal part. . . . ; interchangeable." (*Webster's New Collegiate Dictionary*. Springfield, Mass., 1973.)

cumulation in Marxist models. This important quality of finance may cause difficulties when it is not understood, when efforts are made to limit exchange by the imposition of controls, and when channels through which funds are directed prove too small to accommodate the desired flow. Agricultural credit project design and evaluation often encounter these problems.

Fungibility makes credit activities hard to evaluate. Its effects appear at the national level, the credit agency level, and the farm level. Reasons given to justify a loan at any of these levels may or may not be related to the activities stimulated at the margin by the additional liquidity a loan provides. At the farm level, for example, many credit projects treat loans as if they were production inputs, ignoring the fact that a unit of borrowed money is identical to other units of money held by the borrower. Even if a loan is given in kind, such as bags of fertilizer, the goods provided can often be sold and converted into cash if the borrower desires (Scobie and Franklin). For all practical purposes, loans in cash or kind can be used to buy any good or service available to the borrower in the market.

Additionality, substitution, and diversion are terms that clarify the problems fungibility poses for credit projects. Additionality is jargon for the changes created by a project: it is the difference between the with and without project situations. It is generally assumed, for example, that a donor-funded credit project should induce the borrowing country to increase loans to farmers by an amount at least equal to the donor's loan. At the RFM level, credit for target purposes should expand by an amount at least equal to the project funds provided. Likewise, it is expected that farmers will increase their input purchases and investments by amounts comparable to the loans they receive and augment production of goods promoted by the project.

Measuring additionality is difficult because it is impossible to know exactly what governments, lenders, and farmer borrowers would have done in the absence of a credit project. To what extent would the government have allocated more funds to agricultural credit without project assistance? Would credit institutions have channelled funds away from other activities to serve project objectives in the absence of a project? Would borrowers have used cash from their own reserves or informal credit sources, or reduced their consumption, to fund an activity without a project? In other words, to what degree do project funds simply substitute for other resources which would have been used, in any event, for project purposes?

Diversion is a more extreme form of substitution. Diversion occurs, for example, when a farmer obtains a cattle loan but does not buy any cattle and uses the funds for a purpose not authorized by the loan contract. It is usually difficult for lenders, governments, and project personnel to divert credit project funds unless donors are lax in supervising projects, or unless the administration and accounting systems used by project agencies are faulty. Close supervision of thousands of rural borrowers, however, can be a costly task, and diversion occurs even in well-administered programs.

Changes in the purchasing power of money further complicate analysis of additionality. While nominal amounts of loans and farmer expenditures may expand in the desired direction, the real value of loans may remain constant or decline as inflation erodes the purchasing power of financial instruments.

The three synthetic case studies that follow illustrate the difficulties of measuring the impact of credit projects. The case studies illustrate analytical problems arising at the three different levels from fungibility, additionality, substitution, and diversion. Following the case studies, some suggestions are presented for improving the design and evaluation of credit projects.

A Farm Household in Africa

Mrs. Kariuki is an African farmer who recently received a loan for the purchase of three milk cows and other materials needed to establish a dairy operation. The amount of the loan was $1,200, divided as follows on the loan contract: three milk cows, $800; fencing, $200; a water tank, $100; and a milking shed, $100.[3] She went into debt because of the easy terms offered (80% financing, five years to repay, 10% interest) and the range of attractive investment opportunities available in her locality. Many of her neighbors are expanding their dairy and tea enterprises, and several have entered the transport business. Land prices are increasing, and many families are improving their homes.

Mrs. Kariuki is an attractive credit risk because her family's farm is productive and well-maintained. In addition to the 10-acre farm owned by her husband, she owns an urban lot which she used as loan collateral. She has $600 in her Post Office savings account, which, in conformity with local traditions, was not disclosed on her loan application.

Mrs. Kariuki used the funds borrowed to obtain the goods specified in her loan agreement. Her loan was disbursed by the lender, out of funds supplied by a donor agency, against invoices submitted directly by the suppliers from whom Mrs. Kariuki obtained the improved dairy cows and materials. But, the $100 worth of iron sheets and lumber for the milking shed were not used to build a shed, which in the local community would be considered ostentatious. Rather, they were used to extend and reroof the familiy's house. In addition to the loan proceeds, Mrs. Kariuki invested $300 of her funds

[3] For consistency, all values in the three cases are expressed in a common currency.

n the dairy project to help purchase the cattle and ›ther investment goods, to pay for labor to install he fencing and water tank, and to transport loan-inanced items to the farm.

Mrs. Kariuki's first investment priority was to :stablish a dairy enterprise because of its expected ›rofitability and steady labor demands and the famiy's preference for fresh milk. Just before the loan vas approved, she sold her entire herd of five in'erior dairy animals for $800 in cash. She obtained :redit for the purchase of new stock and materials :ven though she could have financed most of the ›roject out of the sale of the five cows and the $600 n her savings account.

Her other priorities include planting more tea, which requires hired labor; acquisition of more and; and joining her husband and some friends in purchasing a taxi so that their community would be inked more dependably with a market town 12 niles away. Reflecting these priorities, Mrs. Kariuki spent $250 for tea planting and $300 to purchase a half acre from an elderly neighbor after receiving the dairy loan. In addition, Mrs. Kariuki's family decided to increase consumption expenditures by $100. Part of this went to buy a new coat for her husband and two new school uniforms for her children, while the remainder financed a visit to relatives. Of her $1,400 in cash and in the post office savings bank, $450 remained after these expenditures. Since she wanted to keep $200 on hand for a rainy day, this left $250 for investment in a share of a taxi.

The conventional project interpretation assumes that Mrs. Kariuki's loan financed a dairy enterprise establishment. Therefore, the impact of the loan is assumed equal to changes in Mrs. Kariuki's dairy enterprise. This approach ignores changes in consumption and adjustments in all other uses and sources of household liquidity associated with the loan. It overlooks the fact that Mrs. Kariuki substituted fungible loan funds for a part of the investment in dairying, which she would have undertaken in any event because dairying was her highest priority. It also fails to take into account that Mrs. Kariuki diverted iron sheets and timber to house improvement rather than using these materials for a milking shed.

In contrast to the conventional project evaluation approach, a financial view of Mrs. Kariuki's activities would take a broader perspective that the loan gave her liquidity—an increase in her general command over resources. Because of fungibility, a financial view does not attempt to relate the loan to just one use of liquidity. The impact of the loan can be found only in the marginal changes in all sources and uses of household funds which resulted from the additional liquidity provided by the loan. Obviously, the type of information needed to document these liquidity flows for a representative sample of farm households is very time-consuming and costly to collect.

A Credit Agency in Asia

The effects of fungibility also are found at the level of agencies lending to farmers. The institutions involved in the following hypothetical example from an Asian country are a diversified local lender called the Farmers Small Enterprise Bank (FSEB), a central rediscounting agency (CRA) which uses donor and government funds to make loans to lenders like FSEB, and a donor agency which helped design the project. The main objective of the project is to increase the volume of loans to small farmers.

The mechanics of the credit project are as follows: the target group consists of farmers with less than two hectares of land. CRA advances $0.80 for every $1.00 lenders extend to the target group. The interest rate on CRA loans to lenders is 4%, while the lenders charge farmer borrowers 10% per annum. CRA, in turn, claims from the donor agency 75% of its advances under the project, and obtains the other 25% from the national treasury. The project supports an important national credit priority, which is also reflected in Central Bank regulations, favoring agriculture. One of these is that at least 20% of the outstanding loans of each bank must consist of agricultural loans, while banks like FSEB which are located in farming communities must devote 40% of their loan portfolios to agricultural activities.

The effect of the project on lender behavior is illustrated by FSEB's plans and actions before and after the project. Before the project in 1978, FSEB directors developed a sources-and-uses-of-funds budget for 1979. As shown in table 1, the major source in the original 1979 budget was loan repayments received from borrowers. The allocation of new loans was budgeted to ensure compliance with the requirement that 40% of total loan balances on the books are farm loans, and FSEB directors expected that new loans of $750,000 to these borrowers would meet this target. The directors also expected an increase in deposits at their bank because of a recent increase in interest rates paid on savings from 5% to 6% per annum. The directors allocated a portion of the expected deposit increase to non-interest-bearing reserves held with the Central Bank, and to liquidity reserves in the form of government bonds and cash required to support the expanded level of deposits.

Shortly after FSEB directors approved the 1979 budget, the general manager was visited by representatives of the donor agency and CRA, who informed him that the FSEB could participate in the small farmer credit project. The general manager later presented to his board a revised budget assuming FSEB participation in the project (table 1). In presenting the revised budget, the manager noted that about $300,000 of the $750,000 in loans to farmers in the original budget met the credit project's lending criteria. FSEB could discount with

Table 1. Projected Sources and Uses of Funds by the Farmers Small Enterprise Bank (FSEB) in 1979

Sources of Funds		Uses of Funds	
Original budget	($ thousand)		($ thousand)
Loan repayment from borrowers	1,500	Increase in statutory reserves (25% of increase in deposits)	75
Increase in deposit liabilities	300	Increase in cash and government securities held	25
Net profit	50	New loans made:	
		Farmers	750
		Others	1,000
Total	1,850	Total	1,850
Revised budget			
Loan repayment from borrowers	1,500	Increase in statutory reserves (25% of increase in deposits)	50
CRA rediscount of project loans	240	Increase in cash and government securities held	40
Increase in deposit liabilities	200	New loans made:	
Net profit	55	Farmers	755
		Others	1,150
Total	1,995	Total	1,995

CRA 80% of the $300,000 and gain $240,000 in loanable funds. The manager proposed to his board that $15,000 of these additional funds be used to buy more high-yielding government securities (9% per annum), and that $150,000 be used in loans to landlords and businessmen in the area who could offer substantial collateral. He recommended that FSEB roll back its interest rates paid on savings from 6% to 5%, in order to reduce projected increases in deposit liabilities from $300,000 to $200,000 in 1979. The addition of project resources to the previous deposit target would cause FSEB to fall below the minimum capital-to-assets ratio required by the Central Bank. Because the revised budget would increase FSEB net profits by 10%, it was approved by the board. Late in 1979 the manager reported to the board that budget targets were substantially achieved.

The net result of FSEB participation in the new loan program was a decrease in local deposit mobilization, lower rates of return to all depositors, an increase in government securities held by the bank, and an increase in the amount of money loaned to borrowers other than the project's target group. The project resulted in only a small amount of additional lending to the target group. Substitution washed out almost all of the intended effects of the project in this particular lender's activities.

A Latin American Country

From 1960 to 1978, a Latin American country received $80 million in ten loans or grants from donor agencies for agricultural credit projects. These credit projects had four objectives. First, four projects established institutions to serve rural areas: a supervised credit program, an agricultural cooperative bank, rediscount facilities for agricultural loans at the Central Bank, and private finance agencies to provide risk capital for agricultural enterprises. Second, all ten projects provided funds to expand agricultural credit supply. Third, seven of the projects aimed at expanding the amount and number of loans to the rural poor. Fourth, three projects sought to provide more medium- and long-term loans to farmers.

All ten projects have been evaluated. Several had loan recovery problems which undermined at least one of the new institutions. Analysis of loan applications and interviews with loan officers and borrowers indicate that objectives regarding type of borrower, enterprise, inputs, and loan term structure were largely met. Overall, these evaluations suggest the projects did a surprisingly good job of achieving their goals. One donor was sufficiently satisfied with its projects to give the country an additional loan of $15 million to expand medium- and long-term lending to small farmers. During 1979, the loan was disbursed for the purposes intended. An evaluation gave a glowing report of the results.

Despite these projects, farmers, and especially small farmers, continued to complain about the shortage of loans. As a result, one of the donors engaged consultants to prepare another sizable agricultural credit loan proposal. A financial analyst on the consulting team was asked to assess the performance of the country's financial markets. He did not take a conventional project focus in his analysis, but examined imports, the government budget, and overall RFM performance. He rea-

soned that changes in activities associated with the most recent loan would be the best indicator of what might be expected from the next loan.

The analyst collected information on imports, as presented in table 2. Agricultural investment goods imported increased by $15 million in 1979. Because of inflation in world prices, however, the real value of these imports in 1978 prices declined from $200 million in 1978 to $195 million in 1979. At the same time the real value of imports of nonagricultural investment goods and government and defense goods increased. Military hardware and supplies to furnish new tourist hotels accounted for most of the real increases in imports. From these figures the analyst concluded that the 1979 agricultural loan relaxed the country's foreign exchange constraint and that arms for the military and bathtubs and toilets for new hotels were the main result.

The analyst then reviewed the 1979 government budget. What he found is also shown in table 2. The government increased the nominal amount allocated for agricultural programs from $250 million in 1978 to $265 million in 1979. The government met the conditions of the agricultural loan agreement by adding to the Agricultural Bank's loan portfolio the $15 million generated by sales of goods imported under the loan. But because of domestic inflation the real amount in 1978 prices allocated to agriculture decreased from $250 million in 1978 to $241 million in 1979, despite the donor's loan. Real increases in the 1979 budget for defense, nonagricultural development, and general expenses reflected government priorities. From these data the analyst concluded that the government budget was not influenced in the desired direction by the agricultural credit project.

The analyst next looked at activities in formal rural financial markets in the country, and collected the data presented in table 3. The nominal amount of new agricultural loans made each year increased from $50 to $144 million between 1960 and 1980. In real terms, however, the amount of purchasing power represented by the formal agricultural loan portfolio peaked in 1975 and declined by about 5% through 1980. The $94 million increase in the nominal amount of new agricultural loans made annually from 1960 to 1980 can be explained largely by the $95 million in foreign grants and loans for agricultural credit, given the average term structure of approximately one year. The analyst concluded that foreign funds substituted for at least some local funds which would have been allocated to agricultural credit in the absence of external assistance.

The analyst was disappointed to see that ratios of agricultural credit to total credit and agricultural credit to GNP from agriculture declined after 1970. In spite of heavy emphasis by donors on expanding agricultural credit during the 1970s in the country, it appears they were unable to effect structural changes in credit allocation in favor of agriculture. Furthermore, the decline in the deposit to loan ratio after 1970 shows that some portions of RFMs were becoming more, rather than less, dependent on outside resources.

Table 3 shows no increase after 1970 in the proportion of farmers who received credit: over the twenty-year period, levels of access were not significantly altered. Most of the increase in agricultural credit apparently went into large loans for experienced borrowers. Because agricultural lenders' records did not include details on borrowers' economic characteristics, the analyst could not

[a] Excludes commercial banks

document loan allocation by economic class: small loans do not necessarily go to low income borrowers, and a wealthy borrower may have multiple loans. He did find, however, that those agencies serving mainly the rural poor had modest real increases in their loan portfolios from 1970 to 1980, while agencies lending mainly to high income borrowers expanded substantially.

Finally, the analyst concluded that the credit projects of the 1970s were associated with a trend towards shorter average agricultural loan term structures. While in 1970 the average loan matured in fifteen months, in 1980 the corresponding term was only eleven months. Between 1978 and 1980, this average dropped from thirteen to eleven months, despite the two- to five-year loans under the $15 million 1979 project. Funds from medium- and long-term loans which matured outside that project were reloaned at shorter maturities.

In his report the financial analyst argued that fungibility and substitution had substantially diluted the intended impact of the eleven credit projects, especially the 1979 project. While the 1979 loan did relax the foreign exchange constraint, it was associated with additional imports of military and tourist hotel hardware. It was not accompanied by a net increase in real imports of agricultural investment goods, and it did not reverse the trend towards shorter average term structures of formal agricultural loans. Because of inflation and concessionary interest rates to farmers, the flow of external resources for agricultural credit failed to maintain, let alone increase, the purchasing power of the formal agricultural portfolio. There is little evidence that the rural poor received much additional funding, despite the emphasis in various credit projects on expanding financial services for this target group. It also appeared that donor funds accounted for virtually the entire nominal increase in agricultural credit.

Recommendations

At the farm level it is very costly, if not impossible, to determine the impact of credit. At the national and lender levels, many countries provide an ideal environment for substitution and diversion to flourish. This environment is created by distorted exchange rates, balance of payments problems, rigid interest rate policies, and substantial inflation coupled with negative real rates of interest. Because of these facts, we feel that it is necessary to alter the traditional design of credit projects and also to modify substantially the way they are evaluated. Several different approaches, used singly or in combination at the project, sector, and national levels, might be taken to diminish the extent to which RFM performance varies from project objectives.

Three points must be recognized in order to understand the approaches and to effect the changes we propose. The first is that loans provide additional liquidity, which tends to flow toward the most attractive use available from the perspective of the loan recipient. The second is that credit project impact, elusive at the farm level, should be viewed in the context of RFM performance. The third is that the major determinants of the financial situations at the farm and RFM level which credit projects seek to ameliorate are not necessarily most effectively tackled on a project basis alone, but rather reflect policies which repress RFM development.

At the project level it is vital to view loans as additional liquidity rather than as farm inputs. This would force project designers to be more sensitive to the alternatives available to those with access to additional liquidity. For example, if a credit project were designed to stimulate cotton production in Northern Colombia, designers ought to be aware of the returns available in the area to production of

marijuana. Likewise, credit for "productive" purposes will be used for consumption if family members are hungry or lack profitable investment alternatives. Only after it can be shown that target activities are among the more profitable or satisfying uses of additional liquidity can it be concluded that a major part of the liquidity provided by the loan will be used as projected.

Farm activities receive primary emphasis in the traditional credit project. The strategy we propose would be centered on the performance of institutions responsible for project implementation, based on the assumption that target groups are most effectively benefitted when institutions serving them are efficient, strong, and independent. This perspective is perhaps more consistent with concerns for local participation and control than the traditional project approach, since implementing agencies have to relate to local circumstances in order to be successful. The traditional format finds justification in tons of grain or increases in farm incomes without necessarily having to come to grips with the vitality of RFM intermediaries. Projects which undermine the vitality and financial integrity of a credit agency should not be termed successes.

In addition, specific additionality requirements stated in real terms might be written into a project. Any such targets should apply to the entire RFM. For example, if a project objective is to lend to 5,000 new small borrowers through a supervised credit program, the 4,000 borrowers transferred to the supervised credit agency from the agricultural bank should not count toward this requirement. Progress toward additionality targets can be measured at the national and credit agency levels, although such requirements could raise problems of data reliability and create incentives for evasion if not carefully designed.

Because of fungibility, project design and evaluation should consider rural financial market performance in general. For example, if an agricultural credit project is aimed at supplying more medium- and long-term credit, project design should include an assessment of why the RFM is not adequately providing this type of financial service. Once this deficiency is explained, the designers of the project should show how the project will induce the RFM to offer a service which it is presently unable or unwilling to provide.

At the national level, credit projects usually result in more direct government participation in RFMs. Various rationing schemes are typically part of this involvement. Because of fungibility, finance is difficult to control. Direct attempts to gain control are usually costly, often fail to achieve stated objectives, and generally result in secondary effects that are unexpected—the worst possible development for planners (Kane, McKinnon, Schatz, Shaw). We feel that the best intervention is often indirect. Attempting to tackle problems in RFMs at the project level or through individual institutions may be less fruitful than use of the price system to encourage priority activities and to discourage less useful ones. Experiences from the application of this strategy suggest that many of the problems associated with RFMs respond favorably to flexible interest rate policies supported by other measures designed to increase competition in finance. This approach accommodates fungibility and encourages resource reallocation by enabling financial markets to function more efficiently.

In sum, we feel that because of fungibility the focus of project design and evaluation should shift away from the traditional emphasis accorded the demand side of farm credit. A better perspective on farm credit would incorporate attention to important variables on the supply side which are reflected in the performance of lenders in RFMs. Less emphasis should be given to evaluating the impact of credit use at the farm level, and more emphasis placed on how intervention in RFMs affects lender behavior, lender vitality, and the overall operation of RFMs. Less time should be spent measuring what is virtually impossible to measure. More attention should be accorded those things which can be documented.

A Simulation Study of Maximum Feasible Farm Debt Burdens by Farm Type

Gregory D. Hanson and Jerry L. Thompson

Financial leverage, which magnifies the effect of farm income instability upon "bottom line" profitability, becomes less feasible as income fluctuation increases. The combination of wide fluctuations in income coupled with heavy debt-servicing commitments can render the farm insolvent, imperiling continued survival. Determining how much debt a given farm can service is therefore a matter of considerable importance.

Studies that have explored the effects of income variability upon debt usage have for the most part focused upon one or limited farm types. Few have attempted to identify maximum feasible debt burdens consistent with continued survival of the firm. In an analysis of Ohio dairy farms, Falls found that changes in interest rates had only slight effect upon maximum feasible debt levels and also that large dairy farms could sustain greater debt-to-asset (D/A) ratios than small farms. Wehrly and Atkinson estimated that dairy-hog farms could service debt loads ranging from 46% to 60% of assets, depending upon farm size and ability of the farm family to "live frugally." Patrick and Eisgruber found that managerial ability and long-term loan limits were the most important factors influencing farm growth; while Boehlje and White determined that maximization of net worth requires heavy debt loads. Finally, Baker has proposed to index land payments to farm prices and yields in a model including amortization insurance and a mandatory debt reserve.

Research Objectives

This paper probes the question of how much debt could have been maintained successfully by farm types in southern Minnesota 1966–75. Because it is the low return years that pose the real threat to debt-servicing ability, a financial leverage strategy that attempts to maintain the maximum amount of debt (as a percentage of assets) that can be safely carried in low return years will present no debt payment difficulties in high return years.

With this perspective in mind, the approach was to (*a*) obtain yearly estimates of enterprise cash flow rates of return;[1] (*b*) to estimate annual cash income for representative farms of specified asset size and enterprise types, and relate this to consumption, taxes, and debt service demands on cash income; (*c*) to identify the maximim feasible debt ratio (MFDR, i.e., maximum "safe" total debt divided by total assets) for farm types under strict and more lenient loan-servicing conditions; (*d*) to explore the sensitivity of MFDRs to changes in rates of return earned on assets, enterprise diversification, and farm size.

For the third item, two levels of satisfactory debt service were defined: (*a*) all principal and interest payments made strictly as scheduled, (*b*) a two-year deferment on non-real estate loan principal payments. The latter comparatively lenient and perhaps more realistic condition permits deferral of non-real estate loan principal payments in a year of low income, provided that at the end of the following two years, additional interest and principal payments are made so that all originally scheduled loan servicing is once again on a current basis.

Under this flexible condition, a bad year followed by two strong years will support more debt by "averaging" returns across three years. Usually the farmer tends to work more closely with the short-term lender and it may prove to be less difficult for the farmer to defer short-term than mortgage debt. In view of this, two-year deferral of non-real estate debt was chosen as a conservative yet flexible form of finance assistance.

The Data

Farm records for 1966–75 were examined. The records are for members of the allied farm management associations in southern Minnesota. Association members are generally full-time farmers. While these farmers may be somewhat above average in managerial ability, their farms are of average size (459 acres in 1975) for the region. Approximately

The authors are indebted to Thomas Browning, agricultural economist, USDA/ESCS for his important contributions in the formative stages of this project, including the estimation of the family consumption function utilized in the simulation model (the usual disclaimer applies). The authors also gratefully acknowledge the initial programming assistance of Henry Hwang.

[1] The cash flow *ROR* is not strictly "cash flow," because it includes adjustments for crop and livestock inventory changes. It is actually net working capital generated by the farm operation.

250 individual farm records were analyzed per year. Less than 4% of the completed association records were excluded from the data base due to either lack of sufficient detail or farm record error. Farmland was priced at estimated current county-wide average values (based upon annual surveys). Finally, earnings and expenses on a total farm basis with no division between operator and landlord shares were used.

The Model

In this study, a multiple linear regression was used to estimate rates of return by farm enterprise. In the regression model, the sum of the weighted enterprise returns is equated with the total farm cash flow rate of return (*ROR*). The model is

$$(1) \qquad ROR_{jt} = \sum_{i=1}^{I} r_{it}\, w_{ijt} + \epsilon_{it},$$

for enterprises, $i = 1, 2 \ldots I$; farms, $j = 1, 2 \ldots J$; and years, $t = 1, 2 \ldots T$. (ROR_{jt}) is farm cash income in year t divided by total farm assets; cash income equals the sum of enterprise values added plus miscellaneous income less operating expenses; (r_{it}) is the average rate of return on enterprise i in year t; (w_{ijt}) is value added for enterprise i in year t divided by the farm's total value added in year t. Value added consists of cash sales less purchases plus adjustments for inventory change and transfers between enterprises. Operating expense includes purchases of nonbreeding livestock, feed, crop expense, livestock expense, real estate tax, and hired labor. Miscellaneous income consists of work for other farmers, patronage refunds, and other such items.

Equation (1) was estimated for both cash flow and accrual income rates of return for each of the ten years. It represents an attempt to "decompose" the observed whole farm rate of return into a linear sum of enterprise rates of return. By relating the farm *ROR* to the observable value-added-by-enterprise variables, regression coefficients can be interpreted as enterprise rates of return if the fraction of a farm's total resources invested in an enterprise is proportional to the fraction of total farm value added that originates in the respective enterprise. This is a strong assumption that may warrant empirical verification. In the present framework, value-added weights serve as instrumental variables for the unobserved fractions of total farm assets invested in each enterprise. (Alternatively, this approach can be viewed as a means to control for variations in enterprise composition of mixed enterprise farms.)

With this assumption, the farm is treated as a "portfolio" of hog, dairy, beef-feeding, and cash crop enterprises. By using the estimated enterprise weights, we can control large variations in the relative importance of, for example, beef-feeding versus hog-finishing activities that likely characterize the farm records.[2]

Finally, and somewhat more complex, specifications of equation (1) were tested for the existence of size and enterprise interaction effects on cash flow *ROR*s. However, no consistent, significant size and/or interaction effects existed in the sample (Hanson and Thompson).

Debt Structure

Because farm debt was not broken down into current, intermediate term, and real estate categories in the records; debt composition by maturity type (with the exception of seasonal debt) was posited to be proportional to asset composition by length of asset life. That is, the proportion of farm type k's total debt in the form of mortgages in year t is equal to the ratio of real estate to total assets for farm type k in year t, etc. Decomposition of farm assets into current, noncurrent chattel, and real estate assets, by enterprise, also was carried out with regressions analogous to equation (1).

Because the farm records also did not provide sufficient detail for seasonal expenses, seasonal debt by farm type was estimated from the Census of Agriculture (Allen, p. 9, and U.S. Department of Commerce).

Determining Maximum Feasible Debt Ratios

To avoid financial distress, annual cash inflows must meet or exceed consumption expenses, taxes, debt service obligations, and cash operating expenses. That is (see Hanson and Thompson),

$$(2) \quad \begin{array}{c}\textit{Gross}\\ \textit{Cash Flow}\end{array} \geq \begin{array}{c}\textit{Minimal}\\ \textit{Household}\\ \textit{Expenditures}\end{array} + \begin{array}{c}\textit{Marginal}\\ \textit{Consumption}\end{array}$$
$$+ \begin{array}{c}\textit{Nonfinanced}\\ \textit{Operating}\\ \textit{Expense}\end{array} + \begin{array}{c}\textit{Interest}\\ \textit{Expense}\end{array} + \begin{array}{c}\textit{Debt}\\ \textit{Principal}\\ \textit{Expense}\end{array}$$
$$+ \begin{array}{c}\textit{Income}\\ \textit{Social Security}\\ \textit{Taxes}\end{array} + \begin{array}{c}\textit{Seasonal}\\ \textit{Debt}\\ \textit{Repayment}\end{array}$$

Seasonal debt repayment is a programming device to enforce short-term borrowing to be less than or equal to operating expenses. Consumption consists of a large minimum family living allowance and a linear marginal propensity to consume of .097 (estimated farm records). Effective (semilog) tax rate functions were estimated from aggregate tax data for married persons filing jointly. The effective tax rate (estimate) was then appled to accrual income after interest payments to compute total

[2] One beef feeding-complete program hogs farm type has been defined where each enterprise provides at least 20% of sales and both enterprises account for more than 80% of all sales. In this scheme, either enterprise may substantially dominate total sales.

taxes. The current interest rate is an annual average of southern Minnesota Production Credit Association interest rates; the intermediate term rate is a five-year average of PCA loan rates. The real estate mortgage is assumed to be in the third year of a twenty-year term; five-year average St. Paul Federal Land Bank interest rates were used (all rates adjusted for stock purchase requirements).

Thus, estimated gross cash inflows must equal or exceed estimated gross cash outflows. It was assumed that excess cash generated in high return years was used to expand assets and that no cash reserve or loan prepayment reserve existed. Also, off-farm income was not available for the full-time operators analyzed in this study.[3] While the absolute level of debt typically will expand in the years immediately following a deferral of principal payments (in proportion to the increases in reported assets), it was assumed that such increases in the absolute amount of the farm unit's debt was used entirely to finance acquisition of new assets and not to repay the deferral. That is, absolute debt may increase in response to increases in assets, but the amount of debt relative to assets remains constant at the MFDR level determined for the low income year.

Once repayment assumption, deferral status, enterprise types, and enterprise weights have been initially set, MFDRs are discovered through an iteration technique that solves equation (2) as an equality. This is done by increasing or decreasing the debt ratio (D/A) until cash available for debt service is exhausted. The process is applied for each farm type for each of the ten years in the sample period; however, only the maximum debt ratios in the low return or "critical" year are reported.

As indicated above, size and variability of enterprise rates of return, covariation of enterprise rates of return (as reflected in the whole farm *ROR* for two-enterprise farm types) and enterprise weights (the elements of portfolio risk) are processed to generate MFDRs. The reader may note that risk is evaluated implicitly by looking at debt-servicing ability in low income years. Downside variability (from trend) is of crucial concern in this analysis; and the MFDR approach effectively distinguishes upside from downside income variability. An example of this in the present study will be complete program hog earnings, which, although highly variable, support high debt burdens because of the upside nature of their income variability.

[3] Farmers, in the aggregate, do hold financial assets that could serve as a cash reserve (Penson). We believe it is realistic to assume no such holdings exist for farm operations pressing the limits of their debt carrying capability. (This viewpoint is supported by the experiences of extension fieldmen for the farm management associations.) The absence of a cash reserve in the model is consistent with recognition that infrequent use of the Federal Land Banks' cash-reserve option results from borrowers obtaining higher returns by investing excess funds in the farm operation (Baker, p. 2).

The Results

The employment of historical production returns data in a simulation approach facilitates examination of a rich variety of questions while subscribing to a reality that does not abstract from changing weather conditions, deviations from optima, or other such factors.

Cash Income Variability by Farm Type

Cash income from dairy operations exhibited the least annual variability while obtaining the median income ($34,340) among the nine farm types of table 1. Beef-feeding and cash grain enterprises were each characterized by both large income variability and low average incomes. However, in combination, these two enterprises accomplished much of what is intended by an ideal diversification scheme. The relatively high cash grain and beef-feeding coefficients of variation, .478 and .475, re-

Table 1. Cash Income Variability and Rate of Return (*ROR*) by Farm Type 1966–75

Farm Type[a]	Coefficient of Variability[b]	Mean Cash Income *ROR*	High Annual Cash Income *ROR*	Low Annual Cash Income *ROR*	Mean Cash Income ($)
Dairy	.181	.15	.19	.09	34,340
Cash grain-beef feeding	.259	.11	.18	.08	26,965
Dairy-complete program hogs	.325	.16	.29	.13	39,918
Beef feeding-complete program hogs	.391	.15	.25	.11	35,677
Cash grain-complete program hogs	.430	.15	.30	.09	36,784
Complete program hogs	.463	.18	.38	.11	45,497
Beef feeding	.475	.11	.16	.01	25,858
Cash grain	.478	.11	.22	.07	28,071
Hog finishing	.956	.11	.25	−.02	24,763

[a] Two enterprise farms are comprised of equal value-added shares per enterprise.
[b] Coefficient of variability = standard error around the linear trend divided by the mean.

spectively, are almost halved to .259 in the combination of cash grain-beef-feeding operation; while average cash income stays essentially the same $26,965 (as against $28,071 and $25,858 for cash grain and beef feeding, respectively). Because hog finishing had a much greater income variability than cash grain-beef feeding, the latter farm type could successfully service a much higher level of debt (even though both farm types experienced the same average rate of return of all).

Effects of Farm Size and Debt Repayment Flexibility on Debt Capacity

The ability to defer debt principal payments affected debt capacity more than increases in farm size (this is partly due to the fact that we found no significant large-scale cash flow rate-of-return effects in the sample). To analyze size effects on debt, alternative size farm units were developed from the record data. Small, medium, and large farms are defined, respectively, as farms with assets equal to 25th, 50th, and 75th percentile of sample assets. Two enterprise farms derive 50% of total value added from each enterprise. Estimated asset size of small farms ranged from $109,000 in 1966 to $325,000 in 1975; similarly, from $148,000 to $478,000 for medium-size farms, and from $206,000 to $681,000 for large-size farms.

When debt service obligations are required to be fulfilled as scheduled (table 2A), among the small farm types only dairy-complete program hogs could sustain an MFDR greater than 40%. Among large-size farms, only complete program hogs and dairy-complete program hogs sustained more debt than equity. While the annual flow of income from complete program hogs was much less stable than that of dairy (table 1), the lowest returns year for dairy (1975) provided less debt capacity than the poorest returns year for farrow-to-finish hogs (1967).

Comparison of MFDRs with the more flexible and realistic two-year debt deferral condition (table 2B) versus the no-deferral condition (table 2A) reveals dramatic increases in debt capacity for all farm types except those with a cash grain or dairy enterprise. (Because 1976–77 farm record data were not available for this study, the flexible credit debt ratios for 1974 and 1975 are based upon estimated cash flow for the years 1976–77, projected from growth trends in the data.) Comparison by farm size under the flexible default condition (table 2B) reveals that medium-size operations supported MFDRs substantially higher than small-size operations (by about 10%). However, the increase in maximum debt ratios accompanying an increase in farm size from medium to large was less, about 7%. Finally, observe that a small farm with two-year permissible debt deferral typically could sustain proportionally as much debt as a large farm with no debt deferral permitted (table 2B, column 1 versus table 2A, column 3). Only MFDRs under the two-year deferral repayment condition are presented in following sections.

Effect of Enterprise Diversification on Debt Capacity

The importance of enterprise selection to maximum debt levels is illustrated in table 3. The left-hand percentage in each column heading of table 3 indicates the enterprise share of the first farm enterprise listed in the far left, "farm type," column. For example, a farm type that obtains 75% of its value added from cash grain production and 25% from dairy production has an MFDR of .376 (column 2).

Perhaps the most interesting trend in the MFDRs is that, while the largest debt ratios in each farm-type row tend to occur in the one-enterprise columns (columns 1, 5), in seven of the nine farm types the maximum debt ratios for evenly diver-

[b] Limitation on current debt in effect.

sified farm types are in the upper half of the row range. For example, for the evenly diversified beef feeding-complete program hogs, the MFDR of .665 is markedly closer to the row's highest debt ratio of .77 than to the lowest of .362 (column 3 versus columns 5, 1). Thus, it can be argued that if diversification is undertaken to increase the feasibility of debt leverage and there is a large degree of uncertainty as to which of the selected enterprises may be most profitable, it may best be accomplished by dividing resources equally among enterprises.

Effect of Management Ability on Debt Capacity

Improvement in managerial ability (demonstrated by a 2%–4% increase in rate of return to assets) increased debt capacity significantly. To explore the influence of management ability on debt capacity, cash flow rates of return estimated from sample records were varied upward and downward from the yearly average. Resultant MFDRs are presented in table 4, where a 1% increase above the average cash income return to assets usually permitted an increase in maximum debt ratios of 5% to 7% (column 4 versus 3). This increase is about equal to that associated with increasing farm size from medium to large (table 2B, columns 3 versus 2). The 4% rate-of-return increase (table 4, column 5 versus 1) enables cash grain, beef feeding, hog finishing, and cash grain-beef feeding to double or triple debt loads. Finally, observe that medium-size farms with a 2% superior earnings (table 4, column 5) have markedly higher MFDRs than large farms with average earnings (table 2B, column 3). This demonstrates the importance of farm management skills to successful debt leverage.

Validation

With the exception of hog-finishing operations, the standard errors of the enterprise rate-of-return coefficients (table 1) are generally quite low. The

Cash grain-complete program hogs	1967	.406	.474	.542	.609	.676
Dairy-complete program hogs	1967	.547	.603	.652	.712	.766

[a] Two-enterprise farms derive 50% of total value added from each enterprise.
[b] Limitation on current debt in effect.
[c] Critical year, 1974.

average and largest standard errors (in parentheses) for each enterprise during the ten-year study are cash grain .007 (.009), dairy .007 (.010), complete program hogs .010 (.015), beef feeding .013 (.021), hog finishing .035 (.053).

Except for the regression relationship, the model employed primarily accounting identities. A limited number of farm management specialists and agricultural lenders were asked to evaluate this study's rate of return and MFDR estimates against their own experiences. They found the results "reasonable." For example, three of four loan officers interviewed ranked farm types by lender preference. A rank correlation test found their ranking positively correlated with this study's at a significance level less than .02.

Conclusion

Within the framework of this study, a flexible repayment agreement was found to be generally essential for heavy reliance upon debt financing. With a flexible repayment agreement and with land valued at current prices, substantial debt use was feasible for many farm types in the years 1966–75. Management ability appeared to have a greater influence upon debt capacity than farm size. Debt-servicing ability was improved more by becoming a good manager than simply by becoming a large operator.

Farms with a labor-intensive livestock component sustained the highest maximum debt ratios (generally by wide margins). If past trends continue, this indicates that a beginning farmer may have great difficulty financing a cash grain operation, while a labor-intensive dairy-complete program hog operation may prove to be an especially attractive entry-level farm type. Study findings lead us to stress the role of farm type as possibly the most basic variable in the successful use of farm credit when limited equity financing is available. That is, MFDRs differed substantially by farm type. It has been our impression, however, that some farm lenders (while agreeing that debt usage differences by farm type exist) have been reluctant to quantify or clearly differentiate maximum "safe" debt usage on the basis of the enterprise mix. While the actual values of MFDRs estimated may not be of particular interest to analysts outside the agricultural region examined, the relative financial strength of the farm types analyzed (or ranking) may be of interest, especially as related to changes in such key economic variables as equity funds available, farm size, the power of flexible credit arrangements, management improvement, and others.

Choosing Optimum Application Rates in Developing Countries

Philippe Savoie and Michel Kabay

The introduction of new varieties or of new cultivation techniques should be preceded by thorough agronomic research and economic analysis. This preparation is particularly necessary in developing countries, where peasants are rightfully conservative. Because they often barely manage with the food they produce, they are little inclined to take risks. They may try new varieties or techniques if they do not involve much capital outlay, but they will quickly abandon the innovations if they appear no better than the older techniques or varieties.

A rational approach to agricultural intensification in developing countries should start with precise characterization of plant performance not only in experimental plots but also in the peasants' fields. Once enough experimental data become available, these should be translated into continuous response functions, which are more convenient for analysis (Heady and Dillon).

These production functions help establish optimum levels of application rates for various such inputs as seed density, manure fertilizer, and pesticide rates. Because of the variability of plant response, these optima should be defined with confidence limits, to permit evaluation of risks to the farmers. Ideally, these levels can be estimated for individual farmers according to their personal preferences and attitudes toward risk (Dillon; Anderson, Dillon, Hardaker). Dillon and Scandizzo have shown how risk aversion or preference can be gauged in a peasant economy. In practice, however, we usually are faced with time and money constraints that prevent us from measuring preferences and estimating optimum production levels on an individual basis (Moscardi and de Janvry). The degree of unreliability inherent in such efforts may also deter such tedious work. Anderson, Dillon, and Hardaker point out that in many cases preferences are unknown and it may be more useful to establish a set of alternatives.

Using agronomic data, simple statistics, and elementary economic theory, this paper presents a method for optimizing application rates and for estimating the probability of success (or failure) in implementing new techniques in a peasant economy. An example using the seed density of Saxa dwarf beans in Rwanda (Camerman) is presented; the same method could be applied to other crops and treatments such as fertilizers and pesticides.

Philippe Savoie is a professor of agricultural engineering, National University of Rwanda; Michel Kabay is a professor of biology and biometry, University of Moncton, New Brunswick, Canada.

Agronomic Model

Assuming a quadratic production function and a single variable input, we may define the yield increase per unit treatment as follows:

$$(1) \qquad Y = \frac{Y_T - c}{X} = a + bX,$$

where Y is yield increase per unit of X, usually in kilograms per kilogram (kg./kg.); Y_T is total yield (kg./ha.); c is the control yield (kg./ha.), when $X = 0$; X is the amount of treatment (kg./ha.); and a and b are, respectively, the Y intercept and the regression coefficient, estimated for the specific crop and the specific treatment. The variable Y varies linearly with treatment. The slope (b) is negative for most agronomic treatments, because yield increases are greatest at low application rates and decline in relative terms with increased application. Given sufficiently detailed agronomic information, it may be possible to apply linear regression analysis to compute confidence limits for predicted specific yields at various treatment levels.

Economic Analysis

We now consider profit as the value of total yield minus the cost of the treatment. From this statement and equation (1), maximum profit is seen to occur at

$$(2) \qquad X_{opt} = \frac{(V_t/V_y) - a}{2b},$$

where X_{opt} is the optimal level of X for maximum profit; V_t is the cost of the treatment in francs per kilogram (FR./kg); V_y is the cash value of the crop (FR./kg.). This optimum would be correct if the coefficients of the regression equation could be established without error. The intrinsic variability of biological materials requires statistical analysis to give confidence limits for X_{opt}. The width of the confidence interval will depend on the validity of the linear model and on the intrinsic variability of the plants.

Statistical Methods

A preliminary analysis of linear regressions of yield per unit seed of Saxa dwarf beans (kilograms of harvest/kilogram of seed) on seed density (kg./ha.) in four growing seasons showed significant differences among the equations fitted to the seasons ($F = 21582$, with three and sixteen degrees of freedom). (See Sokal and Rohlf, p. 450.) Considering the seasonal fluctuations as part of the fundamental variability of the system, we computed the analysis of variance with regression and found the highly significant regression equation

$$\hat{Y} = 33.9962 - 0.1830\,X, \tag{3}$$

where $\hat{Y}$ is the predicted yield per unit seed (kg./kg.) and X is the seed density (kg./ha.).

Table 1 shows the 95% confidence limits for predicted future yields, which were estimated using standard methods. The standard error of prediction was calculated in our example for individual farmers, not for farmers as a group, thus widening somewhat the confidence limits.

Using costs of twenty-five francs per kilogram for seed and fifteen for yield, we calculated the profit for each level of seed density and the lower and upper bounds and expected yields as

$$P = 15YX - 25X, \tag{4}$$

where P is profit in francs per hectare (FR./ha.).

Figure 1 shows these values plotted against seed density. Several strategies can be adopted, depending on which curve is used for decision. For example, if it is desired to maximize the minimum likely yield, a seed density of about 40 kg./ha. should be chosen. If a density of 90 kg./ha. is used, expected profit is maximized, but the probability of loss would be increased.

Table 1. Ninety-five Percent Confidence Limits for Predicted Yields for One Field in a New Season

	Yield per Unit of Seed (kg./kg.)		
Density	Lower Bound	Expected	Upper Bound
10	11.458	32.166	52.874
20	9.948	30.336	50.724
30	8.399	28.506	48.613
40	6.808	26.676	46.544
50	5.173	24.846	44.518
60	3.495	23.016	42.537
70	1.771	21.185	40.600
80	0.000	19.355	38.710
90		17.525	36.867
100		15.695	35.070
110		13.865	33.319
120		12.035	31.615
130		10.205	29.955
140		8.375	28.399
150		6.545	26.766
160		4.715	25.233

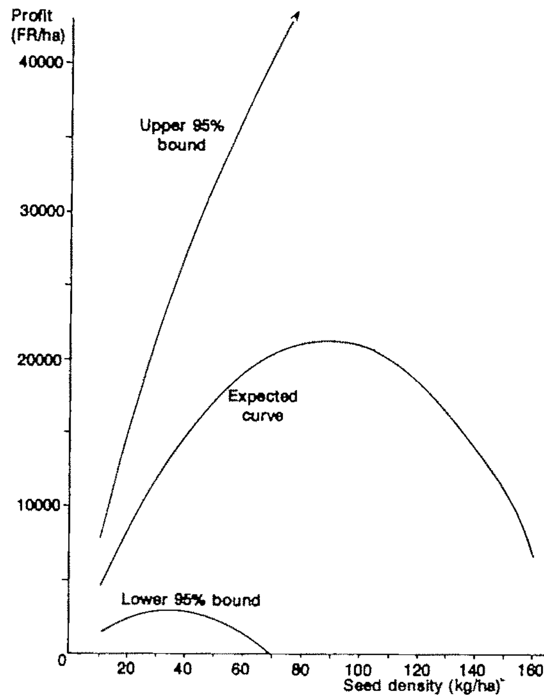

Figure 1. Profit versus seed density

What would the probability be of various profits at 90 kg./ha.? Applying the confidence interval formula to equation (4), we have

$$P_c = 15(\hat{Y} + t_{\alpha\beta}\, s_{\hat{Y}})X - 25X, \tag{5}$$

where P_c is the critical profit (FR./ha.), $t_{\alpha/2}$ is the one-tail t critical value with ν degrees of freedom, and $s_{\hat{Y}}$ is the standard error of prediction in a new test situation. For a given value of t, we have the cumulative probability of observing a profit greater than P_c. Figure 2 shows cumulative probability curves for seed densities equal to 40, 90, and 140 kg./ha.

Consider the curve for a seed density of 90 kg./ha. from figure 2. The probability of a net loss is about 5% (compared to less than 1% when density

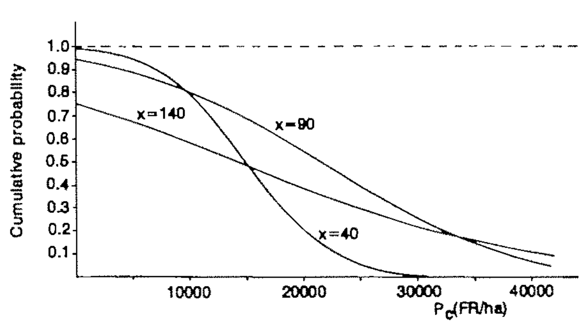

Figure 2. Probability of observing a profit greater than critical profit P_c

is 40 kg./ha. and about 25% when density is 140 kg./ha.). The probability of getting a greater profit than the maximum lower 95% confidence bound at 40 kg./ha. (where maximum profit was about 3,100 FR./ha.) is 92%. The probability of exceeding the expected profit at 40 kg./ha. of 15,005 FR./ha. using 90 kg./ha. is 69%. Also, the probability is about 71% that profit at 90 kg./ha. will be greater than the expected profit at 140 kg./ha., which is 14,087 FR./ha.

Other curves could be drawn for various levels of seed density. Based on the expected profit of a seed density of 60 kg./ha., a seed density of 90 kg./ha. is seen to yield a better profit, with a 56% probability. Compared against 80 kg./ha., a seed density of 90 kg./ha. would yield a better profit, with a 52% probability. As the distance between the optimum level and the actual practice decreases, improvements due to implementation of the optimum become less apparent.

Conclusions

We have applied elementary statistical and economic methods to optimize seed density of Saxa dwarf beans in Rwanda, using available agronomic data. If actual seeding practice is 40 kg./ha., an extension program recommending that farmers increase their seed density to 90 kg./ha. would have a good chance of succeeding: the likelihood of exceeding the expected worst profit at the lower density of 40 kg./ha. is 92% and the likelihood of doing better than a farmer using 40 kg./ha. is 69%. These confidence bounds, being calculated for individual farmers and not for the mean profit of groups of farmers, are conservative; the average profit will have tighter confidence bounds. Barring extraordinarily bad climatic conditions, the peasants would quickly be convinced of the value of the proposed seed density.

Ex Ante Appraisal of New Technology: Sorghum in Northeast Brazil

Joseph B. Goodwin, John H. Sanders, and Antonio Dias de Hollanda

With the renewal of interest in agriculture in developing countries during the sixties, there has been much concern with the policy instruments to stimulate output without penalizing the urban consumer. Many countries have utilized the rationing of subsidized inputs such as credit for this purpose. In the seventies, international donors—such as the World Bank and USAID—began pressing developing countries to aim more of their agricultural development programs at small farmers. One response has been to extend the use of a major instrument variable, credit policy, to small farmers. However, small farmers often use very few cash inputs; hence, the effectiveness of this instrument may be low unless combined with others.

A second instrument to increase small farmer incomes is the development of new agricultural technology. Besides the developmental costs of the new technology, recent literature has implied that risk aversion may impede its adoption (Benito, Brink and McCarl, Sanders and Hollanda, Schulter and Mount, Wiens, Wolgin). Econometric analysis of this risk-aversion characteristic has not yet clearly indicated instrument variables to reduce it (Dillon and Scandizzo; Binswanger; Moscardi and de Janvry).

Farmers also will have difficulty subjectively estimating the distribution of returns from new alternatives. The desired information would be this distribution over all possible states of nature, which is unlikely to be available to the farmer presented with an adoption choice. Policies to improve risk perception, such as farm level experiments of new technology, are another type of instrument variable to influence adoption.

Three categories of instrument variables are considered in this paper: a traditional instrument, credit policy; policies to affect risk through reduction in the income variance; and, finally, increased information to improve perception of the distribution of returns from new technology. Modeling is utilized to analyze the relative importance of these instruments on the decisions of small farmers in the northeast of Brazil.

The Region: Semiarid Northeast of Brazil

A principal production system of semiarid northeastern Brazil includes tree cotton, corn, cowpeas, and cattle (Sanders and Hollanda). The small farmer is more crop oriented whereas the large landowner is primarily concerned with livestock production. Other minor crops include sweet potatoes and rice, which are produced on areas with a more dependable supply of water. The above systems utilize a minimum of purchased inputs with seeds and insecticides for cotton as the major expenditure. Long rotation periods are substituted for fertilization. A major feature of this agricultural system is the large yield variance due to the low level and variability of rainfall.

An anomaly of the present cropping system is the production of corn as the principal cereal. In other areas of the world with a similar climate, the major cereal is millet or sorghum rather than corn (Johnson). These crops have two advantages over corn. First, most varieties have shorter maturity periods, typically 70 to 100 days, while corn requires 120 to 150 days. Hence, sorghum and millet generally require a shorter rainy season to achieve a reasonable yield. The second advantage is that sorghum and millet are better able to withstand moisture stress than corn, due to the deeper and more diffuse rooting systems and better stomata control over evapotranspiration (Stewart et al.).

Recognizing this superior production potential in regions with inadequate and irregular rainfall, the Brazilian government, with help from the Ford Foundation, began a research program in 1972 to study the suitability of sorghum varieties. The varieties studied gave substantially higher yields than corn in adverse rainfall years and also have slightly outyielded corn in normal and good rainfall years (Sanders, Johnson). Thus, the sorghum varieties selected demonstrated yield potential equal or

The authors would also like to express their appreciation to SUDENE and the World Bank for providing data from their 1973 farm survey.

superior to the existing corn varieties of the region with less yield variability. Besides experiment station and regional variety trials, the research program included farm trials.

The Model

Because sorghum has consistently outyielded corn under experimental conditions and budgeting analysis indicated its profitability in farm trials (Barbosa et al.), *ex ante* analysis of its inclusion as a production alternative taking into account risk aversion and risk perception was a next logical step. The farm-level linear programming model used was a variation of Hazell's MOTAD model. The basic model here includes minimum consumption requirements for corn and cowpeas and is represented by

$$(1)\quad \text{maximize } \mathbf{C}'\mathbf{X} + \Omega\, \mathbf{E}'\mathbf{Y} - \phi K\mathbf{L}\mathbf{d} - (\phi\psi)K\mathbf{R}\delta,$$
$$\text{subject to } A\mathbf{X} + S\mathbf{Y} \leq \mathbf{B}$$
$$D\mathbf{X} + I\mathbf{d} \geq \mathbf{0}$$
$$Z\mathbf{Y} + I\delta \geq \mathbf{0}, \text{ and}$$
$$\mathbf{X}, \mathbf{Y}, \mathbf{d} \text{ and } \delta \geq \mathbf{0},$$

where **B** represents resource availabilities to the farmer and **X**, A, and **C** represent activity levels, resource uses, and expected gross incomes for the nonsorghum activities. **Y**, S, and **E** represent the activity levels, resource use, and expected gross incomes for the sorghum activity. The elements in the deviation matrix D represent the difference between observed and expected gross income for the nonsorghum activities for the years covered in the analysis, while the elements in the deviation matrix Z are the differences in observed and expected gross incomes for the sorghum activities for the years included in the model. The vectors **d** and δ represent the yearly total negative deviation summed over the nonsorghum and sorghum activities, respectively, while **L** and **R** are vectors of ones which sum the elements of **d** and δ over the k years in the model. They provide the estimates of the summed negative deviation, which are transformed, respectively, into estimates of the standard deviation of income for the nonsorghum and sorghum activities by multiplication by the constant K, converting the total negative deviation to an estimate of the standard deviation (Brink and McCarl, Simmons and Pomareda).

In the above model formulation, risk affects the farmer's decision to adopt new technology in two ways: risk aversion and risk perception. The risk-aversion coefficient, ϕ, is the standard utility function weighting of income and a proxy for income variance. The farmer's perception of new technology from limited observations is an innovation in this model. The behavioral assumption about perception is that a farmer will observe a new technology in the same or similar agro-climatic conditions. Then he will discount the yield data according to his knowledge of the probabilities for the states of nature observed and fill in the missing observations with his subjective expectations about prices and yields. As the farmer's utility function trade-off between income and variance has proven to be useful in explaining present cropping patterns, the farmer's subjective estimate of the potential returns to a new technology is expected to be an important factor in the adoption decision. The coefficients, Ω and ψ, adjust for the farmer's perception of expected returns and the proxy for income variance of the new technology activities.

The Data

The above model was developed for a representative small farm of the Brazilian semiarid Northeast, based upon the 1973 SUDENE/World Bank farm level survey and subsequent field interviewing in the Serido of Rio Grande do Norte. Activities in the linear programming model consists of both pure stand and intercropped combinations. New sorghum activities also were introduced into the intercropped system, with sorghum substituting for the corn or the corn and cowpeas. Price of sorghum was set equal to 90% of corn, the relative price at the time. For those years in which farm level data for sorghum were lacking, the same perceptual relationship between sorghum and corn yields, as observed in experiment station trials, was utilized to synthesize the farm yields. For further description of the region and activity choices, see Sanders and Hollanda.

Model Validation and New Technology

In simulating the choice of cropping activities, there have been two predominant methods for estimating the risk-aversion coefficient: direct elicitation, as used by Dillon and Scandizzo and Binswanger; observed factor demand and output supply behavior as in Moscardi and de Janvry and in Brink and McCarl. In the latter, indirect method utilized here, the risk-aversion coefficient is selected, which minimizes the difference between predicted and actual plans. This may overestimate risk aversion by attributing the entire difference between risk neutral and actual output levels to risk aversion. Other explanations, such as differences in resource availability, imperfect information on future prices, and differences in subjective probability assessments, could explain the differences between actual and simulated cropping plans. Even if overestimated, the risk-aversion measure is still useful to evaluate the total impact of uncertainty about various parameters and aversion to risk upon farm plans and income levels.

The model estimated a high risk-aversion level of 3.28 for the small farmers utilizing the present crop mix. In other runs not reported, cropping decisions

were insensitive to changes in credit conditions and to the availability of more land at these high risk-aversion levels. An extensive land use is encouraged by the livestock operation and the substitution of long rotation periods for fertilization. As shifts occur to more intensive land use, the livestock operation must become intensive or decrease.

At the present level of risk aversion, the gains from new technology are small, as indicated by the distance AC in figure 1—which also shows that the income gains from reducing risk aversion are substantial for either present or new technology. Reducing the income variance of new technologies through yield insurance or price supports would have the same effect as reducing the risk-aversion coefficient. With the correct perception of the returns to the new sorghum activities, a sorghum association enters at even the highest level of risk aversion. At lower levels of risk aversion, a more intensive sorghum technology with fertilization was introduced further augmenting the income level (table 1).

For simplification, the perception of the income variance of the new technology activities was assumed exaggerated. That is, farmers were assumed to overestimate the downside risk and the extension agent to overstate the potential profitability ($\Omega = 1$ and $\psi = 1.5$). Even with the variance of income from sorghum overestimated and at the highest risk-aversion level, a sorghum activity still came into the solution. Input use and area in sorghum were less than with the "correct" perception of income variance. Nevertheless, the new technology was still introduced on a small area.

At present levels of risk aversion, demonstration plots of the new technology at the farm level to improve the perception of the distribution of returns would be expected to be effective in hastening farmer awareness of the advantages of sorghum, thus speeding the adoption process; whereas credit policy of variation in the interest rates had no effect. At lower risk-aversion rates, the adoption of new sorghum technology with fertilization was hastened with subsidized credit (compare cases 2 and 3 of table 1).[1]

The largest income gains would come from a policy mix that would reduce both risk aversion and risk misperception associated with the new technology. With risk misperception, the reduction of risk aversion from 3.28 to 2 results in a 43% in-

[1] For informal credit, a 40% interest rate was considered to be a conservative estimate based upon unpublished data from farm surveys in Canindé, Ceará, 1973–75, Department of Agricultural Economics, Federal University of Ceará, Fortaleza, Brazil. There exists a government credit program in which farmers are eligible to receive loans at 8% up to a ceiling of fifteen minimum salaries.

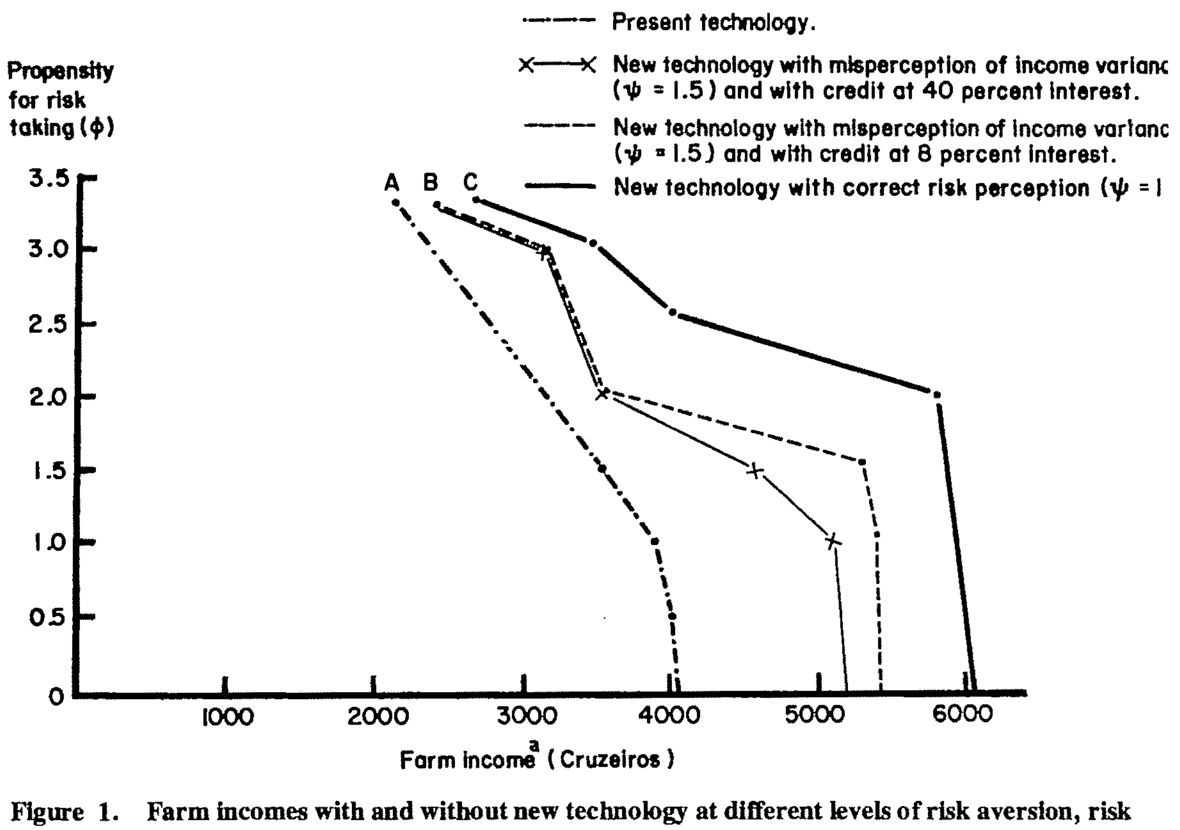

Figure 1. Farm incomes with and without new technology at different levels of risk aversion, risk perception, and varying credit conditions

[a] This is a standard gross margin of programming analysis.

Table 1. New Technology and Income at Different Risk Aversion, Risk Perception, and Credit Conditions

Case 1. New Technology with Risk Correctly Perceived (ψ = 1 and credit at 40%)

Case 3. With Risk Misperception and Subsidized Credit (ψ = 1.5 and credit at 8%)						
Risk aversion	$\phi = 0$		$\phi = 1.5$	$\phi = 2.0$	$\phi = 3.0$	$\phi = 3.28$
Income[a]	$\pi = 5{,}405$		$\pi = 5{,}323$	$\pi = 3{,}551$	$\pi = 3{,}250$	$\pi = 2{,}476$
	Cotton-Sorghum Fertilized 5.6 ha.		Cotton-Sorghum Fertilized 5.6 ha.	No sorghum activity	Cotton-Sorghum-Cowpeas Unfertilized 0.7 ha.	Cotton-Sorghum-Cowpeas Unfertilized 0.8 ha.

Note: Nonsorghum activities were not included in the table.
[a] Gross margin in cruzeiros; ψ is perception of the variance of income from sorghum; Ω = 1, or there is correct perception of the expected returns from sorghum.

crease in mean income (Case 2 in table 1). However, an equivalent reduction in risk aversion accompanied by the elimination of risk misperception would give a 133% income increase. Similarly, income gains from elimination of risk misperception of only 9% and 63% at risk-aversion levels of 3.28 and 2 are obtained.

Conclusions

High levels of risk aversion have led many to be pessimistic about the potential for raising the income of small farmers with new agricultural technology, especially in resource poor regions such as the Brazilian Northeast. In developing countries, research and extension efforts generally have concentrated on the agricultural regions with the best resources and often the largest farmers. Outmigration to urban areas or decentralization of industrialization have been recommended to raise the income of small farmers in these poorer agricultural resource areas. However, income increases are possible in agriculture with new technology and associated policy measures. The model indicates that new technology, appropriate for the farmers and the region, should be adopted by farmers highly averse to risk even with an overestimation of the variance of the returns. For nonadopters, improved estimates of the distribution of returns will occur over time as their neighbors adopt and they obtain more information on the new technology.[2] Crop research programs may need to consider several alternative technologies, as the model results for the sorghum technology adopted were highly influenced by the farmer's risk-aversion coefficient.

Ex ante technology evaluation by simulating farm conditions appears to be useful for ascertaining the feasibility of new technology and the farm level constraints to its introduction. A series of complementary policy measures to the introduction of the new technology were identified; however, these are still model results and clearly depend upon verification of both the synthesized data for sorghum and the assumptions about farmers' perceptions of the returns to the sorghum activities (Ω and ψ).

[2] The adoption process is analyzed for an individual farm and does not consider the market effect of expanded production.

An Evaluation of Goal Hierarchies for Small Farm Operators

Wilmer M. Harper and Clyde Eastman

Considerable attention recently has been focused on the small farm sector in the United States. Regional small farm conferences were sponsored by the U.S. Department of Agriculture (USDA) during 1978 (USDA 1978b); the ESCS held a Small-Farm Workshop (USDA 1978c); and the National Small Farms Conference was sponsored by the National Rural Center (Madden and Tischbein) in February 1979. If agricultural policy is to facilitate the accomplishment of small farmers' objectives, then a central issue must be the determination of small-farm operators' goals and objectives. If these differ substantially from those of large farm units, one policy position hardly could be consistent with meeting the needs of both groups.

Although economic theory of the firm typically assumes the maximization or minimization of a single goal or objective, a body of knowledge concerning the behavioral framework within which the firm functions has been queried and delineated. Simon developed the conceptualization of rational behavior that is compatible with the access to information and computational capacities as a replacement for the global rationality of economic man. With respect to the family-managed farm, Heady further emphasized the fact that the farm is a complete economic unit in which the interdependence between income and consumption casts doubt upon the assumption of profit as the ultimate quantity which the farm family attempts to maximize. Although multiple goals and lexicographic ordering are recognized (Ferguson), analysis tends to focus upon an identifiable, operable goal, such as profit maximization. Research has defined and quantified the hierarchy of goals, attitudes, and decision-making criteria for production units that may be classified as commercial and/or large-scale producers (Harman et al.; Bostwick, Esmay, Rodewald), but attention has not been directed toward the small farm unit.

Low or negative returns to equity and high opportunity costs for both human and equity capital are frequently cited as reasons why farm operators, particularly small farm operators, should, if judged within the criteria of a rational profit maximizer, be expected to cease agricultural production and reallocate their resources. Development of goal hierarchies for the operators of small farm enterprises will serve as a departure point for the evaluation of the position that small farm operators exhibit incongruent economic behavior.

Typical of the general analytic approach taken by most agricultural economists toward small farm organization and operation is that chosen by Metzger and Flanders. On the basis of a linear programming model, they develop strategies for maximizing income within a set of resource constraints. Complementary to this procedure is the position that increasing the managerial skills and capabilities of limited resource farmers is an effective means of integrating them into the process of economic development (McKenzie). Even when directed toward behavioral parameters of small farm operation, studies have focused more on behavior than determinants of behavior. In their study of limited resource farmers, Blackburn, Brinkman, and Driver indicate that one of their objectives was to determine the social, economic, and humanistic expectations of the farmers who plan to stay in agriculture; however, the study addressed behavioral characteristics such as amount of fertilizer used rather than goals and objectives for the family or farm. Behavioral characteristics are important in the evaluation of goal achievement, but they do not constitute goals and objectives. It is conceivable that behavior may preclude the accomplishment of a given goal or objective, particularly if the goal is taken to be profit maximization. For example, a family that indicates that income or profit is the major goal may engage in a traditional production activity even though an alternate activity would yield higher profits.

The analysis reported herein develops a goal hierarchy for a randomly selected sample of small farm operators in New Mexico and is part of a larger study for the determination and analysis of the socioeconomic characteristics of New Mexico's small farm and small ranch operators. Two sets of goals are evaluated: goals for the family unit and goals for the agricultural enterprise. Given that many operators of small farms and ranches in New Mexico or their spouses have off-farm employment, these two goal sets allow an evaluation of the poten-

tial conflict between family unit goals and agricultural enterprise goals.

Analytic Framework

The method of paired comparisons (Edwards, Bradley) was used to develop the ranking of a goal hierarchy for the small farm units. The assumptions of the paired comparisons model used by this analysis are those of the model formulated by Mosteller (1951a). The model allows the determination of a rank ordering of the goals, and with the selection of one goal as *numeraire*, scale values may be developed for each goal, which places the goals on a relative continuum.

The most probable violations of the model and, therefore, potential criticisms are a contingent lack of normality in the sample and failure of the population to have equal standard deviations. Mosteller indicates, however, that normality is not essential for the application of the method of paired comparisons, being more in the nature of a computational device (1951b).

Goal Selection

The method of paired comparisons requires that the respondent be presented with a list of all possible pairs of goals within the given set and that the respondent select the preferred goal in each pair. The number of pairs for a given set is equal to n ($n - 1$)/2, where n is the number of items in the set.

The sets of goals were required to meet two criteria: that they allow a comparison of the family goals with goals for the agricultural enterprise and that goals for the agricultural enterprise approximate items used in a prior study of goal hierarchies for agricultural enterprise operators (Harman et al.). Some questions from this earlier study of goal hierarchies were modified to facilitate their interpretation by the respondents and their applicability to the area, but comparability with the prior study was retained.

Based upon pretest results, the analysis utilized the following sets of goals:[1]

	Goal Identification Code
Family Goals	
To maximize social status/prestige	G1
To maximize income	G2
To maximize material accumulations (net worth)	G3
To maximize quality of life	G4
To maximize consumption	G5
Agricultural Goals	
To control more acreage (to increase the size of your operation by leasing, renting, or buying more land)	AG1
To have newer and larger equipment and buildings	AG2
To make more profit each year (net above farm costs)	AG3
To avoid being forced out of agriculture	AG4
To avoid years of low profits or high losses	AG5
To increase your net worth as derived from your agricultural operation	AG6
To maintain or improve the family's quality of life that results from its involvement in agriculture	AG7

[1] The goals were designed to measure preferences toward certain socioeconomic goals or concepts: Quality of life—G4, AG7, and AG4; preference for income—G2, AG3, and AG5; preference for net worth—G3 and AG6; preference for consumption—G5 and AG1; and preference for more social status or prestige—G1 and AG2.

Respondents were presented with each pair of goals and asked, for example, "Would you prefer to maximize social status and prestige or to maximize income?" If the respondent indicated an uncertainty concerning the meaning of a given goal or concept, the interviewer offered one example for clarification. Although this may have resulted in some bias in these responses, all interviews were conducted by one individual so that there was consistency in the interpretations given to respondents.

Family goals were stated in terms of "maximizing" rather than "satisficing," to minimize the subjectiveness of the standard against which the respondents would evaluate each pair of goals.

Data

The state was divided into nine regions, classified as homogenous by type of agricultural activity, and a county was then drawn at random from each region. From lists of agricultural producers maintained by each county extension office, a set of farm operators who met the criterion of less than $40,000 gross agricultural sales for the accounting period 1977 were selected at random. These lists contain the names of individuals who have contacted the extension office for information or services or who have participated in extension-sponsored activities of any type. Although not all-inclusive, these lists represented the best available defined frame from which to draw a sample. A screening question eliminated those with gross agricultural sales exceeding $40,000.

Analysis

Significance of goal rankings was determined at the 0.05 significance level by the method reported in

Urquhart and Eastman. The test statistic for the chosen significance level was

$$LSD = 1.96\,[B(t)(t+1)/6]^{1/2},$$

where LSD is the least significance difference between the number of responses, B is the number of respondents, t is the number of items to be ranked, and the hypotheses evaluated were

$$H_0\colon R_i = R_{i+1}$$

$$H_1\colon R_i \neq R_{i+1},$$

where R_i is the rank of the ith item in the set of goals. The null hypothesis is rejected if $(T_i - T_{i+1}) < LSD$, where T_i is the total number of times that a given goal is preferred over any other goal (see tables 1 and 2).

Rank Order of Goals

The results of the survey of operator goals are presented in tables 1 and 2. The numbers in each column indicate the frequency with which a goal was preferred to each other goal, represented by the respective rows. Reading across the tables, the numbers in a given column of that row indicate the frequency with which the goal represented by that row was not preferred to the goal represented by the given column.

The columns in each table have been arranged so that the goals appear in ascending order. T_i for any goal is the sum of the representative column. LSD for tables 1 and 2 are 46.76 and 34.23, respectively. Given the test criteria and LSD statistics, the analysis fails to reject the null hypothesis only in the case of AG1. This results in the following hierarchies of goals:

	Goal Identification Code
Family Goals	
To maximize quality of life	G4
To maximize income	G2
To maximize material accumulations (net worth)	G3
To maximize consumption	G5
To maximize social status/prestige	G1
Agricultural Goals	
To maintain or improve the family's quality of life that results from its involvement in agriculture	AG7
To avoid being forced out of agriculture	AG4
To avoid years of low profits or high losses	AG5
To make more profit each year (net above farm costs)	AG3
To increase your net worth as derived from your agricultural operation	AG6
To control more acreage (to increase the size of your operation by leasing, renting, or buying more land)	AG1
To have newer and larger equipment and buildings	AG2

Within each hierarchy, each goal is significantly more important than the succeeding goal with the exception of AG6. In this case the total times that AG6 was preferred to AG1 was not sufficient to differentiate statistically between AG6 and AG1.

Table 1. Frequency Matrix and Rank of Agricultural Goals for Sixty-One Small Farm Families in New Mexico, 1977

Goal	AG2	AG1	AG6	AG3	AG5	AG4	AG7	Total
AG2	—	42 (68.85)[a]	52 (85.25)	60 (98.36)	60.5[b] (99.18)	59 (96.72)	61 (100.00)	334.5
AG1	19 (31.15)	—	28 (45.90)	58 (95.08)	60 (98.36)	60 (98.36)	60 (98.36)	285
AG6	9 (14.75)	33 (54.10)	—	48 (78.67)	55 (90.16)	57 (93.44)	58 (95.08)	260
AG3	1 (1.64)	3 (4.92)	13 (21.31)	—	50 (81.97)	58 (95.08)	58 (95.08)	183
AG5	0.5[b] (0.82)	1 (1.64)	6 (9.84)	11 (18.03)	—	54 (88.53)	58 (95.08)	130.5
AG4	2 (3.28)	1 (1.64)	4 (6.56)	3 (4.92)	7 (11.48)	—	53 (86.88)	70
AG7	0 (0.00)	1 (1.64)	3 (4.92)	3 (4.92)	3 (4.92)	8 (13.12)	—	18
Total	31.5	81	106	183	235.5	296	348	1,281
Rank	7	6[c]	5	4	3	2	1	n.a.

[a] Numbers in parentheses indicate the percentage of the total respondents represented by the frequency.
[b] If the respondent could not choose between the two goals, the response was divided equally between the two goals.
[c] Ranking not significant at the 0.05 level.

Table 2. Frequency Matrix and Rank Ordering of Family Goals for Sixty-One Small Farm Families in New Mexico, 1977

Goal	G1	G5	G3	G2	G4	Total
G1	—	57 (93.44)[a]	61 (100.00)	61 (100.00)	60 (98.36)	239
G5	4 (6.56)	—	48.5[b] (79.51)	54 (88.52)	60 (98.36)	166.5
G3	0 (0.00)	12.5[b] (20.49)	—	53 (86.88)	59 (96.72)	124.5
G2	0 (0.00)	7 (11.48)	8 (13.12)	—	48 (78.69)	63
G4	1 (1.64)	1 (1.64)	2 (3.28)	13 (21.31)	—	17
Total	5	77.5	119.5	181	227	610
Rank	5	4	3	2	1	n.a.

[a] Numbers in parentheses indicate the percentage of the total respondents represented by the frequency.
[b] If respondent could not choose between the two goals, the response was divided equally between the two goals.

These two goals would, therefore, be considered of equal significance in the hierarchy.

Family versus Agricultural Goals

Family goals in this study focus upon the respondents' appraisal of goals which are homocentric to the family unit. The generalized goals utilized in the survey were intended to define the socioeconomic orientation of the family unit rather than to focus upon specific activities.

Agricultural goals focus upon specific objectives for the agricultural activities of the family unit. These allow identification of the socioeconomic goals for the family's present and continued involvement in agriculture.

An evaluation of the consistency between goals for the family unit and goals for the agricultural enterprise is relevant to a consideration of small farm operator goals for three reasons: the large amount of nonfarm income earned by these family units, the opportunity cost of farm labor, and the returns to equity. Only 4.9% of the small farm units surveyed relied totally upon the income generated by their farm operation and more than 50% of the units had more nonfarm than farm income. Opportunity cost of farm labor enters any comprehensive consideration of farm policy (Tweeten). In 1976, the U.S. farm population received 59% of its personal income from nonfarm sources (USDA 1978a, p. 464), and the off-farm income for farm families with gross agricultural sales of $39,999 or less ranged from $5,762 to $15,630 (USDA 1977, p. 94). The percentage of returns to equity for the classes of farms considered in this study range from −6.5 to 4.4 for the United States and from −3.9 to 4.2 for the Mountain States (Hottel and Reinsel, pp. 25, 60). The magnitude of nonfarm income to farm income and the negative or low returns to farm equity suggest the possiblity that agricultural goals may be in conflict with family goals.

To evaluate consistency between the ranking of the two sets of goals and, therefore, any conflict between family and agricultural goals, the analysis considered the two sets in terms of their socioeconomic content. To accomplish this comparison, agricultural goals were compared with family goals to see if goals with similar socioeconomic content had a similar relative rank within their respective hierarchy. Because there are more goals in the set of agricultural goals, relative rank becomes the relevant judgmental criterion for consistency. When the two hierarchies are grouped such that the socioeconomic content corresponds across groups (see fn. 1), the following grouping results where the numbers in parentheses are the respective ranks (see tables 1 and 2) of the goals within the given hierarchy:

Family Goals	Agricultural Goals
G4(1)—quality of life	AG7(1)—quality of life AG4(2)—remain in agriculture
G2(2)—income	AG5(3)—avoid low profit/high loss AG3(4)—profit
G3(3)—net worth	AG6(5)—net worth
G5(4)—consumption	AG2(7)—new/larger equipment
G1(5)—social status	AG1(6)—more acreage

Quality of life ranks highest in both sets of goals. AG7 deals directly with quality of life, and, if one considers quality of life derived from agricultural activities to be important, then AG4 must also contribute to agriculturally derived quality of life. AG5 and AG3 are both directly related to the income to be derived from agricultural activities. In the grouping shown above, AG7 and AG4, and AG5 and AG3 were grouped together so that relative rank of the socioeconomic content within the hierarchies may be compared more easily. After quality of life, income and net worth rank, respectively, are highest in both hierarchies. The relative ranking of goal

content across the hierarchies fails to correspond at the lower end of the two sets.

Although the symmetry of the socioeconomic content of the goals in the two sets is not complete, it is sufficient to support the tentative conclusion that for this set of small farm operators, family and agricultural goals are compatible and appear to be nearly congruent.

Agricultural Goals

Having established a correspondence between the family goals and the agricultural goals for the small farm unit in New Mexico, the analysis evaluated the symmetry between the hierarchy of agricultural goals established by this analysis and the hierarchy of goals for a set of farm operators in a study conducted in Oklahoma and Texas (Harman et al.). The study does not assume that the NM and OK/TX samples are drawn from populations that are similar in all respects and are, therefore, subsets of the same population. It assumes only that with respect to income they come from the same subset of the U.S. farm population. The OK/TX study considered a much wider range of income than is included in the NM sample, but it determined goal hierarchies for various subsets of the total study population. The OK/TX goal hierarchy used for comparison in this study for the income range which, when converted to 1977 dollars, corresponds to the income range of the NM sample.

The rankings for each goal as established by the New Mexico study (NM) and the Oklahoma-Texas (OK/TX) study, respectively, are

	AG7	AG4	AG5	AG3	AG6	AG1	AG2
NM:	1	2	3	4	5	6	7
OK/TX:	5	6	2	1	3	7	n/a

The OK/TX study did not include a goal similar to AG2 of the NM study, and since New Mexico small farm operators traditionally prefer not to borrow capital, a "reduce borrowing needs" question of the OK/TX study was not included in the NM survey.

Although the goals presented to each study group were not precisely the same, the similarity is sufficient for some tentative generalizations. First and most obvious is the lack of correspondence between the rankings of the two groups. Second and equally important is the reversal of emphasis in the rankings with respect to profit and quality of life. This reversal may be due to a regional/cultural difference or to a general change since 1972 in the socioeconomic environment of the country, but as a source of variation, either of these has significant implications.

Conclusions

The results of this analysis demonstrate the feasibility of developing a statistically significant hierarchy of goals for small-farm production units, and the hierarchies developed allow some tentative conclusions to be drawn about the decision-making criteria of the small farm unit. The attitude toward profit maximization from agricultural activities suggests that they may, in part, view involvement in agriculture as a consumption good. The emphasis upon family quality of life derived from agricultural activity, above profits, indicates that the family is the relevant unit of analysis rather than the farm enterprise. This socioeconomic orientation suggests that operators of production units similar to those in the data set of this analysis may view their agricultural activities as meeting a personal, nonmonetary need first and an income need second. Although the sample used in this analysis is not large enough to extrapolate to all small farm units, the results suggest the existence of a large group of farm operators who may be hypothesized to be less responsive to the standard commodity-oriented agricultural policy. It would appear, therefore, that a household production function approach (Becker, Gronau) or an allocation of time and goods among activities approach (Pollack and Wachter) would yield more insight into the economic activity of the small farm unit than would a profit maximization approach.

Finally, the lack of correspondence between the hierarchy rankings of the New Mexico and the Oklahoma/Texas groups demonstrates the need for additional study. Any policy determination must have at its center an expectation of the behavior which the affected individual or group of individuals will exhibit.

The Effect of Mining on Agricultural Hired Labor in the Northern Great Plains

Richard M. Adams and Dale J. Menkhaus

The supply and demand of labor to agriculture is a topic which has generated little research interest in recent years. Since the comprehensive work by Schuh and associates on the structure of national and regional agricultural labor markets, there have been few studies directly related to such concerns. Recent events suggest that the agricultural labor market may again be a relevant research issue.

On a regional level, the Northern Great Plains (Montana, North Dakota, and Wyoming for the purpose of this study) are experiencing a rapid and unprecedented increase in energy exploration and extraction. While coal production leads the growth of this sector, petroleum, natural gas, and uranium also are being affected by national and international adjustments in the energy market. Physical and economic aspects of energy resources and potential development patterns within the region are well documented (Tyner, Kalter, Wold; Dalsted and Leistritz; LeBlanc, Dalter, Boisvert; Libbin and Boehlje).

The effects of rapid economic development within a predominantly rural setting, such as the Northern Great Plains, involve adjustments within the agricultural labor market. Similar adjustments in the structure of rural labor markets also may be occurring in other regions. For example, the decentralization of manufacturing in the South and the general rural "turnaround" observed by Beale for the nation as a whole indicate potential structural changes within the market for agricultural hired labor.

The purpose of this paper is to investigate the nature of the market for hired agricultural labor in the Northern Great Plains, with particular reference to adjustments attendant to energy development. Specific objectives include: (*a*) specification of a regional labor market model defining the supply and demand for hired agricultural labor; (*b*) assessment of the importance of wages in agriculture and mining in explaining the supply of labor to agriculture, with emphasis on the plausibility of mining growth as an incentive for the transfer of labor out of agriculture; and (*c*) comparison of these results with earlier supply and demand studies for agricultural labor.

Richard M. Adams and Dale J. Menkhaus are associate professors of agricultural economics, University of Wyoming.

This is Wyoming Agricultural Experiment Station Journal Article No. 1064.

The authors gratefully acknowledge the helpful comments of two anonymous reviewers.

The Problem Setting

Estimates of labor supply elasticities generally are dated, with few available at the regional level. Existing studies thus would not necessarily reflect the current structure of the labor market for the Northern Great Plains. The rural nature of the area, when coupled with the imposition of the growth of mining, adds support to such research, particularly in light of the concerns of agricultural producers for present and future supplies of agricultural labor.

An examination of agricultural and mining employment within the three-state region indicates dramatic changes in employment patterns. For example, between 1970 and 1978 mining employment increased from 20,000 workers to over 42,000, or 110% (U.S. Department of Labor 1979). During this same period, agricultural employment decreased from 26,000 to approximately 23,000 hired workers (USDA *Agricultural Statistics*). Wage rates in each industry increased (in nominal terms), but the absolute difference in wage rates between industries grew substantially, from \$2.40 per hour in 1971 to \$6.19 per hour in 1978. Such a growing differential could constitute a transfer incentive between the two sectors in a regional economy. Further, the rapid growth of mining and other energy subsectors, with high multiplier effects, is creating employment and income growth in the service sectors.

This descriptive evidence lends plausibility to the assertion that the mining industry is accelerating the transfer of labor from agriculture. The Powder River Basin of Wyoming, the principal coal production area in the Northern Great Plains, is typical of the economic base in many of the rural areas experiencing energy expansion, i.e., livestock oriented with no industrial base other than mining. This simple economic structure and the isolation of energy extraction sites from more populous areas of the region suggest that mining employment (and rising wages) may indeed represent an opportunity cost of agricultural employment.

The Model

A simultaneous equation model of the regional demand and supply of hired farm labor was specified to determine the impact of growth in the mining sector on the agricultural hired labor market. The

model follows that developed by Schuh; Tyrchniewicz and Schuh; and Hammonds, Yadav, and Vathama, with minor deviations for the mining sector. The growth of the mining sector is assumed to generate substantial economic activity within the region. The resultant economic growth, particularly as manifested in rising wages, may affect the agricultural labor market, even in the absence of direct substitution between mining and agricultural employment. Specifically, the quantity of hired labor demanded is assumed to be a function of the real agricultural hired labor wage, index of prices received by farmers deflated by the index of prices paid by farmers, and an index of productivity (technology). The quantity of hired labor available (supplied) to agriculture is hypothesized to be a function of the real agricultural hired labor wage, the regional civilian labor force, the real mining wage, and a trend variable.[1] Consistent with the Schuh formulation, each equation is specified in the Nerlove framework to facilitate estimation of both long-run and short-run elasticities.

The Statistical Model

The statistical model is as follows:

$$(1)\quad Y_{1t} = \beta_0 + \beta_1 Y_{2t} + \beta_2 X_{1t} + \beta_3 X_{2t} + \beta_4 Y_{1t-1} + \mu_{1t}$$

$$(2)\quad Y_{1t} = \alpha_0 + \alpha_1 Y_{2t} + \alpha_2 X_{3t} + \alpha_3 X_{4t} + \alpha_4 X_{5t} + \alpha_5 Y_{1t-1} + \mu_{2t},$$

where Y_{1t} (endogenous) is agricultural hired labor for Montana, North Dakota, and Wyoming in year t in thousands (USDA *Agricultural Statistics*); Y_{2t} (endogenous) is the average of Montana, North Dakota, and Wyoming hourly agricultural wage in year t deflated by the Consumer Price Index (USDA *Agricultural Statistics*); X_{1t} is the ratio of the index of prices received over the index of prices paid by U.S. farmers in year t (USDA *Agricultural Statistics*); X_{2t} is the farm productivity index of output per unit of input for the Northern Great Plains in year t (USDA 1977); X_{3t} is the average of Montana, North Dakota, and Wyoming hourly mining wage in year t deflated by the Consumer Price Index (U.S. Department of Labor 1977); X_{4t} is the first difference of the civilian labor force in Montana, North Dakota, and Wyoming in ten thousands in year t (U.S. Department of Commerce 1979); X_{5t} is a time trend variable; and μ_{1t} and μ_{2t} are random disturbances. The α's and β's are structural parameters; β_4 is $1 - \gamma_1$, where γ_1 is the coefficient of adjustment for demand and α_4 is $1 - \gamma_2$, where γ_2 is the coefficient of adjustment for supply.

[1] This variable represents a deviation from the model developed by Schuh (1962, 1966). Schuh used "corrected" nonfarm income to represent alternative employment opportunities. Since the main emphasis of this study is on the impacts of the mining sector on agricultural hired labor, alternative income opportunities are represented by the mining wage.

Data

Several assumptions pertaining to the data require discussion before evaluating the results. First, the selection of the study region is motivated by the significant position of this region in national coal production. The Fort Union Coal Formation, located primarily in Montana, North Dakota, and Wyoming, is experiencing rapid exploitation.

The data for agriculture and mining wages are represented by those observed in the above states. Consistent with the Schuh, and Hammonds, Yadav, and Vathama formulations, wage data are deflated. Agricultural employment represents the hired farm labor force in Montana, North Dakota, and Wyoming. The civilian labor force includes nonagricultural employees in the three-state region. Finally, national data for prices received and paid by farmers are used to represent the income to farming and ranching in the region. All data are for the period 1964–78.

Statistical Considerations

There are problems associated with the application of the above model, especially with time-series data. The issue of serial correlation and the test for its presence are well-documented (Griliches 1961, 1967; Durbin). One means of dealing with serial correlation is to assume its existence and adjust for its presence using appropriate estimation procedures, such as the Cochrane-Orcutt iterative technique. The Cochrane-Orcutt technique, incorporating suggestions by Fair concerning the formation of instrumental variables, was employed to estimate the economic model.

Another common problem in Nerlovian-type models is the tendency of the lagged dependent variable to pick up the effect of omitted variables, leading to potential specification bias. This problem may be treated in part by inclusion of a trend variable (Schuh, p. 313; Hammonds, Yadav, Vathama, p. 245). Including trend, however, aggravates the already severe collinearity problems associated with models of this type. In the present study, high intercorrelation (.98) exists between the trend variable and the real agricultural wage, which appears in both the supply and demand equations. As a result of this high interdependence and supported by results of previous studies (Schuh and Leeds; Hammonds, Yadav, Vathama), the trend variable was not included in the demand equation. Thus, caution should be exercised in interpreting the direct price elasticities obtained from the estimated demand relationship due to possible specification bias.

From an economic standpoint, the omission of the trend variable from the demand equation may not be particularly serious, because the production index variable included in the demand equation should be measuring the influence of technology.

However, in the supply equation the inclusion of a trend variable is deemed important in terms of explaining the secular movement in the flow of labor out of agriculture due to changes in tastes for employment in specific industries, aspects of industrialization, and the level of education (Tyrchniewicz and Schuh, pp. 542, 551). Even though collinearity exists between trend and the real agricultural wage, there appears to be theoretical justification to retain the trend variable in the supply equation.

High collinearity also exists between the civilian labor force and real agricultural and mining wage, .97 and .95, respectively. Following Kmenta (p. 390), the civilian labor force data were transformed to first differences to reduce the collinearity.

Results and Implications

A priori expectations concerning the signs of the variables included in the above model are suggested by theory. Within the demand structure (derived), one may hypothesize that the quantity demanded is inversely related to the price (wage) of labor and the productivity index and directly related to the price indices ratio and the lagged value of the dependent variable. On the supply side, quantity supplied is expected to be directly related to the agricultural wage and the civilian labor force and inversely related to the mining wage and trend. The simultaneously estimated regression coefficients for the above economic model are presented in table 1. The results appear to be generally consistent with theoretical expectations.

As is evident from table 1, the statistical results for the demand equation are more robust than for the supply relationship. Specifically, the agricultural wage, the price indices ratio, and the lagged dependent variable are significant at the 5% level and display signs consistent with expectations. Also, the R^2 associated with the demand equation is greater than that observed for the supply relationship.[2] Only the productivity index displays an inconsistent sign. On the supply side, the results are less robust but do display general consistency of signs. Only the change in the civilian labor force, which is insignificant at the 10% level, displays an incorrect sign. Both the agricultural and the mining wage are significant at the 10% level, with the time trend being significant at the 5% level. The F-statistic in both equations is significant at the 5% level.

For economic implications, the significance of several variables bears closer examination. Within the demand equation, the lagged dependent variable (and resultant coefficient of adjustment) is significant, which indicates that substantial adjustments are occurring within the labor market, and

[2] The R^2 in both equations may be artificially inflated due to the presence of the lagged dependent variable.

Table 1. Simultaneous Equation Regression Coefficients for the Northern Great Plains, 1964–78

Equation	Constant	Agricultural Wage	Prices Received ÷ Prices Paid	Productivity Index	Y_{1t-1}	Mining Wage	Change in Civilian Labor Force	Time Trend	Summary Statistics[a] R^2	F	Rho
Demand	8.52 (1.01)	−13.84**[b] (−4.73)	0.25** (4.65)	.08 (1.69)	0.26** (2.73)	—	—	—	0.89	18.05**	−0.49
Supply	66.21 (1.35)	56.04* (1.64)	—	—	0.05 (0.28)	−3.26* (−1.43)	−1.32 (−0.45)	−1.58** (−2.32)	0.72	4.24**	0.19

[a] The t, R^2 and F values are not strictly valid for the second stage of TSLS, since they are based on estimates instead of actual values of endogenous variables. In addition, the t-statistics are biased upward because of the use of the Cochrane-Orcutt iterative technique (Cooper). Since the Cochrane- Orcutt procedure was used to adjust for assumed serial correlation, the value of the Rho is reported rather than the Durbin-Watson statistic.

[b] Single asterisk indicates significantly different from zero at the 10% level; double asterisk indicates significantly different from zero at the 5% level; figures in parentheses are t-values.

conforms to the distributed lag hypothesis. However, the lagged dependent variable in the supply equation, while having the correct sign, is not significant, an observation consistent with Hammonds, Yadav, and Vathama. Also, the significance of the mining wage within the supply equation provides some support to the hypothesized importance of this variable in the agricultural labor market. The implication of this relationship is that continued change in the mining wage does appear to have an effect on the supply of labor to agriculture in this region. The significance of the trend variable lends support to Tyrchniewicz and Schuh's assertion that this variable may be an important shifter of the supply of labor to agriculture.[3]

Based upon the estimated structural relationships presented in table 1, short- and long-run supply and demand elasticities were calculated (table 2). Specifically, demand elasticities were calculated with respect to the agricultural hired labor wage at mean levels and for 1978 to investigate any shifts in the underlying relationship. For the supply equation, elasticities with respect to agricultural wage as well as the mining wage were derived.

The demand elasticity for 1978 was approximately 30% greater than that calculated at the mean level (−0.76 as compared to −1.06). The long-run elasticities increased over short-run values within periods as well as between mean and 1978 levels; i.e., the long-run elasticities are approximately 40% greater in 1978 than for the mean. The absolute levels observed for these elasticities fall within the range observed in earlier studies. The lower elasticities, as compared with those estimated for Oregon, may be attributed to the livestock orientation of the agricultural sector in the Northern Great Plains, which limits the range of substitution possibilities on the input side. The higher values observed in this study, when compared to those estimated by Schuh and Leeds for the Mountain States, may be attributable to a difference in time periods and the larger regional definition in the Schuh study.

Given the emphasis of this study, the supply elasticities are perhaps of greater empirical importance. The values presented in table 2 for the agricultural wage are elastic both at the mean values and for 1978. Such an increase over time is consistent with both Schuh's and Hammond's observations. (Note that the long-run supply elasticity is calculated from an insignificant coefficient of adjustment.) The elasticity with respect to mining wage, which is inelastic, displays the greatest increase over the time period for any of the elasticities calculated, increasing by more than 50% between mean values and 1978. This increase in the response of supply of agricultural labor to changes in the mining wage adds support to the effect of this variable on the

[3] The trend variable may also be capturing the effects of consistent measurement error in some of the variables (Tyrchniewicz and Schuh, p. 551).

adjustment process with respect to equilibrium levels of agricultural supply and demand. It should be noted that the elasticity of labor supply with respect to mining wages is perhaps a gross effect, given the high multiplier effect of such a basic industry. Further, the elasticity need not and probably does not imply direct substitution. However, the conclusion that agricultural labor is affected by mining does appear plausible in view of the results of this analysis.

Formula Pricing in Five Commodity Marketing Systems

Marvin L. Hayenga and Lee F. Schrader

Formula pricing has been a subject of concern in the food industry for twenty years, and perhaps longer (NCFM Report, p. 98). Formula pricing contracts involve prices on individual shipments or transactions which are tied directly, by formula, to a specific market price quotation. After buyers and sellers agree on the formula, subsequent transactions are routine and low in cost.

Formula pricing is a delegation of price discovery to those who negotiate prices. Consequently, the market mechanism and the price reporting services which generate the prices used in formula-priced contracts have an increasingly important and potentially more difficult burden placed upon them. Formula-pricing arrangements reduce the fraction of total supply entering into market price determination, and the resulting, more thinly traded markets may be more sensitive to erratic or manipulative influences on market prices or market price reports.[1] More recent concerns in the beef subsector are evidenced by several court cases, hearings before a House Small Business subcommittee, a special USDA Meat Pricing Task Force, and congressional bills focusing on meat industry pricing and price reporting systems (e.g., H.R. 91, 1979).

This study focuses on formula pricing in five commodity marketing systems where formula pricing was known or expected to be heavily used. We analyze the extent of formula pricing use in those markets, the incentives for or benefits of formula pricing, and the disadvantages and problems associated with formula pricing. Through a comparative analysis of formula pricing in the beef, pork, cheese, turkey, and egg markets, we offer some insights into the similarities and differences found in these markets and the sources of the controversy surrounding formula pricing systems. A few policy alternatives are then briefly considered.

The Extent of Formula Pricing

To determine the extent of formula pricing in these five marketing systems in 1978, we surveyed via personal or telephone interviews a high proportion of the largest firms involved in the markets where formula pricing was prevalent. In beef and pork, the large slaughter-processing firms surveyed accounted for 40% and 60% of the total market volume, respectively (Hayenga 1978, 1979b); the major cheese-marketing firms surveyed accounted for 85%–90% of the cheese consumed in the United States (Hayenga, NC-117 Work. Pap. No. 38); the firms surveyed in the turkey subsector accounted for about 66% of the industry's volume (Schrader and Lang). In addition, supplemental surveys of a smaller number of buyers and suppliers provided confirming evidence of the extent of formula-pricing use and supplemental views of the perceived advantages and problems. The egg market analysis draws upon a recently completed comprehensive study of coordination systems in the egg subsector (Schrader et al.) and Schrader's experience from years of work with the egg subsector. While the firms interviewed were not a random sample of the relevant populations, they accounted for a sufficiently large proportion of the relevant market volume that the survey results should provide a reasonable approximation of the extent to which various pricing systems are used in these markets.

Our studies revealed important differences in the use of formula pricing. These differences were not only between commodities, but at different levels of the marketing system and between closely related products at the same level of the commodity marketing system (see table 1).

Beef

The primary use of formula pricing in the beef subsector occurs in the beef carcass and wholesale cut markets. In a typical formula price contract, the quantity is established one to five days (sometimes longer) before shipment; the infrequently negotiated premium or discount is applied to the carcass price reported in the *National Provisioner* (the "Yellow Sheet") on the day prior to shipment.

Formula pricing is used in approximately 70% of the beef carcass sales which comprise 50%–60% of the output of beef slaughter-processing firms. In contrast, only 10%–20% of boxed beef primal and subprimal (including ground beef) sales are formula priced. Most boxed beef formula sales involve processed carcass units (with the price related to the Yellow Sheet carcass price), or ground beef (with the price based on the lean trim quotations). Be-

Marvin L. Hayenga is an associate professor, Iowa State University. Schrader is a professor, Department of Agricultural Economics, Purdue University.

The authors acknowledge helpful comments from many, including two anonymous *Journal* reviewers.

[1] These issues are discussed in more detail in several places in the literature, including the National Commission on Food Marketing Summary Report and Technical Studies No. 1 and 2; Forker; Williams; Rogers and Voss.

Table 1. Pricing Systems in Five Commodity Subsectors, 1978

Product Submarket or Market Level	Beef: Beef Carcass	Beef: Boxed Beef	Pork: Fresh	Pork: Processed	Cheese: First Handler Transactions	Cheese: Packaged and Processed	Turkeys: Live	Turkeys: Processed	Eggs: Nest Run	Eggs: Graded and Packed
Sub-market share (%)	50+	40+	60	40	100	100	100	100	100	100
	(%)									
Intrafirm transfer[a]					20		65		35	≤5
Formula priced	70	10–20	40	5+	65–70	25–35	29	16	60	90
Negotiated prices	30	80–90	50	1–4	10–15	1–2	6	29	10[b]	5
Price list			10	90+		60–70		55		

[a] Involves vertically integrated cheese-production facilities, and a combination of vertically integrated production, producer-owned cooperatives, and cost-plus or service contracts in the turkey and egg subsectors.
[b] Includes direct sales of eggs to breakers, and resales among egg handlers; thus, there is some double counting in the nest run egg estimates.

cause boxed beef is the most rapidly growing segment of the beef market, it seems very likely that the negotiated portion of beef transactions could increase. However, the increasing boxed beef market share has been removing volume from the carcass beef market rapidly.

Pork

There has been a gradual shift toward more processing of pork by slaughter firms, with a corresponding shift in the mix of pricing systems employed. Slaughter-processors sell approximately 60% of their pork as fresh pork cuts (loins, Boston butts, fresh hams, bellies). Slightly less than 40% of slaughter-processor pork sales are processed pork (smoked or canned hams and picnics, bacon, lunch meats, frankfurters, sausage).

Formula-pricing arrangements are used in approximately 40% of fresh pork transactions, negotiated or offer-acceptance pricing systems in 50% of the transactions, and a daily price list is the primary pricing vehicle for the remaining 10% of fresh pork sales. The extent of formula pricing in fresh pork is approximately the same as that reported by the National Commission on Food Marketing in 1965.

In contrast, more than 90% of the processed pork sales are based upon a weekly price list for packer-branded products. Less than 10% of processed pork sales were "private label." More than half of the private label transactions are on a formula-pricing basis, and the remainder are priced using the branded price list minus advertising costs, or are individually negotiated transactions.

Overall, approximately 25% of all slaughter-processor pork sales are formula-priced, 35% of the prices are established at the time of the transaction through negotiation or offer-acceptance, and 40% of sales are priced via a daily or weekly packed price list.

Cheese

Formula pricing in the cheese industry is found in cheese purchases by large marketing firms (like Kraft and Borden) from many cheese manufacturing plants, and in sales arrangements between these large cheese-marketing firms and their retail, food service, and industrial customers. At each level, the standard formula-pricing arrangement utilizes the prevailing price at the National Cheese Exchange on the date of manufacture as the pricing base. While the National Cheese Exchange volume is less than 1% of the nation's cheese, it plays a major role in pricing 90% or more of the cheese sold by U.S. cheese-manufacturing plants to the large cheese-processing and marketing firms. These marketing firms also manufacture about 20% of their requirements, and import the remainder (6%–7% of sales) at negotiated prices. Thus, 85%–90% of cheese purchases by the large marketing firms are priced by formulas which may remain unchanged for three to twelve months.

Formula pricing plays a less important role in marketing firm sales to retail, food service, and industrial customers. Of the 50%–55% of cheese going through retail channels, approximately 60% is sold under a manufacturer brand, with a weekly manufacturer's price list as the standard pricing mechanism. On the 40% private label sales to retailers, some marketing firms use a price list that is essentially the branded price list less advertising and promotion costs; others use formula-priced selling arrangements.

The food service industry is the most rapidly

growing market for cheese, with 30%–40% of the cheese volume. A weekly or monthly price list is used for most sales through specialized food service distributors. Approximately 20%–30% of food service sales are directly negotiated, long-term, formula price arrangements with large-volume fast food chains which have special product specifications. Some formulas use the average Exchange price in the preceding months as the base price, so menu margins are based on known costs.

Industrial cheese sales, representing 10% of sales by cheese marketing firms, typically are specially formulated ingredients for frozen pizzas, frozen entrees, cheese-flavored products, and others. A high proportion of these sales are formula-priced arrangements with large industrial customers.

Thus, 25%–35% of the marketing firms' sales are formula-priced, based directly on the National Cheese Exchange prices. Another 5%–10% of sales are based on a price list so closely tied to the National Cheese Exchange prices that they implicitly are formula priced sales. Approximately 65%–70% of sales are based on a price list which is loosely related to the National Cheese Exchange (the raw material cost is an important influence in the pricing decision). Only 1%–2% of the sales of the marketing firms are spot sales on a negotiated basis; these often are sales of surplus inventories to another marketing firm through the National Cheese Exchange.

Turkeys

Approximately 65% of the live turkeys produced in the United States are produced and slaughtered by the producing firm, slaughtered by cooperatives, or produced under contracts (e.g., cost-plus or service fee contracts), where the ultimate producer payment is not directly tied to the spot market price. Nearly 30% of live turkeys are transferred from the grower to the processor under contract terms that relate the transaction price directly to the Urner-Barry or U.S. Department of Agriculture (USDA) market price quotation for frozen, ready-to-cook turkeys (though some contracts may have price floors, ceilings, or "sharing" formulas).

Turkey products include whole frozen turkey, turkey parts, and further processed products. Whole birds may be sold as plain Grade A (commodity) turkey or in self-basting, or otherwise differentiated form. Packer-branded whole birds and further processed products are most often price listed. Prices for sales of parts and fresh turkeys often are negotiated. Formula pricing is used mostly in the trading of private label or commodity turkey sales.

The market share of plain whole frozen turkey has declined to about 15%, and 20%–30% of that volume is formula-priced. Thus, the volume of negotiated trading in the product used as the base for pricing formulas at both the live and processed turkey levels may represent as little as 10% of turkey product sales.

Eggs

Eggs are formula-priced at two levels in the marketing system—the producer-first handler market for nest-run eggs, where the first handlers typically assemble, grade, and pack eggs (though some trading among the first handlers does occur), and the next market level where graded eggs are sold to the retail and food service sectors. In the nest-run or first handler market, 35% of the eggs are produced by vertically integrated firms. Sixty percent of the nest-run eggs are transferred to first handlers under long-term arrangements. Most contracts do not have a clear cut base price or premium established, just the handler's commitment to use his "best efforts" to achieve a "competitive" price for the producer. Yet, most handlers determine their payment by establishing a fairly stable discount from the pricing formula which they, in turn, have established with their primary customers. Thus, while the formula is not explicit in many cases, it is used implicitly in a large proportion of these transactions.

Very few nest-run egg sales involve negotiated prices. However, negotiated sales of nest-run eggs to egg breakers or among assemblers and first handlers are one point in the egg-marketing system where spot market price negotiations can be observed. These negotiated transactions (which include 1/2% of the nest-run egg volume, traded through the Egg Clearinghouse, Inc., an electronic exchange for nest-run eggs) involve approximately 10% of the nest-run egg volume.

Approximately 90% of graded eggs purchased by retailers and food service firms are acquired under long-term formula-pricing arrangements. In most cases, graded eggs that do not satisfy other customers' requirements are sold to egg breakers, also on a formula price basis. Approximately 5% of graded egg purchases are negotiated price transactions, primarily when suppliers build inventories in excess of their contract commitments, or retailers require extra volume for sales promotions. Thus, negotiated sales of graded eggs are sporadic and small in volume.

The egg price quotations typically used in formula-pricing arrangements in the eastern two-thirds of the United States at both the nest-run and graded-egg market levels are the New York graded-egg price quotations by the Urner-Barry *Producers' Price Current*. The USDA price quotation is used on the West Coast. Yet, the Urner-Barry reports do not represent any specific graded-egg market transactions; rather, the Urner-Barry report reflects changes in egg prices at other levels of the marketing system, changes in inventory levels, and other factors. The USDA price quotation does reflect prices for graded eggs paid by retailers.

Benefits and Problems of Formula Pricing

Respondents in the four marketing systems surveyed were asked to list the major advantages and disadvantages or problems associated with formula-pricing arrangements. The primary benefits or advantages which emerged from those interviews can be summarized as (*a*) assured market outlets or supply sources, especially when unique product formulations or perishable products are involved; (*b*) the greater quality assurance associated with continuing buyer-seller relationships; (*c*) the reduced risk of prices on forward sales or purchase arrangements looking bad relative to current market prices or competitors' prices at the time of delivery; and (*d*) improved physical marketing and transaction efficiency.

The relative importance of the benefits cited varied greatly in the markets studied. Firms dealing with highly perishable, standardized commodities (e.g., Choice, yield grade 3 beef carcasses, live turkeys, cheese) were quite concerned with assured market outlets or suppliers, as were firms requiring unique product specifications (e.g., unusual cheese or hamburger patty formulations or private label turkeys). Quality assurance was particularly important to firms with strong brand franchises, or to retail chain buyers of private label products. Retail chain buyers were particularly interested in forward purchases to assure the quantity required for features, with the assurance that the price would be established later at levels near competitors' prices, to avoid a significant competitive disadvantage. The low transaction cost and improved coordination of a continuing buyer-seller relationship which seldom requires extensive market information and negotiation skills was a frequently acknowledged benefit, especially to buyers and sellers who were not among the largest or smallest firms in the market, though that was seldom the primary reason given for starting the use of formula pricing.

Formula pricing lowers internal transaction costs and frees people from the task of negotiating prices. It facilitates close coordination of physical transfer of perishable commodities. Often, risks are shifted in a way that is desirable for both parties involved in a transaction. When desired quality and quantity can be assured satisfactorily only through long-term sales/purchase arrangements, formula pricing is an attractive pricing system. Both buyer and seller are assured a price in line with competitors' prices at the time of delivery. Firms using formula pricing for both raw material purchasing and product sales find that system useful in managing their margins. Many small firms feel that formula pricing reduces bargaining disparities between themselves and their larger, better informed suppliers or customers, enhancing their long-term viability. Formula pricing may be an alternative to a higher degree of vertical integration in some subsectors.

In some commodity-marketing systems, shifting to alternative pricing methods would be traumatic, with a high initial cost and perhaps higher cost per unit in the long run. For example, in the beef and pork markets, packers and retailers were asked to estimate the change in their transaction costs if they could not use formula pricing. Ten firms provided estimates which indicate that a ban on formula pricing would increase transactions cost in pork by as much as $5 million, and perhaps as much as $15 million annually for beef in the United States.

Formula pricing of cheese sold by cheese-manufacturing plants has been the standard way of doing business for so many years that most cheese plant managers could not conceive of any other way of pricing cheese. In the cheese market, long-term formula price contracts were sometimes used by marketing firms to develop new supplier capacity, yet not subject themselves to the risks associated with a pre-established price level. And some respondents felt that the alternative to formula pricing in that highly concentrated market would be the (undesirable) development of explicit price leadership by the leading firm(s). In general, there was a high level of satisfaction with the performance of the formula-pricing system and the thinly traded National Cheese Exchange in Green Bay, Wisconsin, that serves as the focal point in the price determination process at all levels of the cheese-marketing system in the United States.

A primary benefit of turkey formula pricing lies in the better coordination of production and processing. In many instances, neither the producer nor the processor desires to accept the risk of a price fixed at the time of production planning. The formula-priced contract allows for supply and market outlet assurance with price open.

Formula pricing of turkey products was least used by the largest and smallest processing firms. The largest firms felt that their own perspective on the appropriate market price was equal or superior to the market price quotations, and some felt that their product was sufficiently differentiated to be unique. The smallest also produced a differentiated product with loyal local consumers, so a price list was used instead of a price formula.

Formula pricing of eggs is seldom questioned by participants in the egg subsector. A National Egg Pricing System Study Committee (an industry group) in 1971 listed as one of their recommendations, "establishment of a national base price quotation system" (Rogers and Voss, p. 254). Most industry members do not wish to abandon formula pricing, but they do desire a better system of arriving at a base quote.

The basic benefit of formula pricing in the egg subsector is improved physical marketing efficiency, achieved through better coordination of producer-handler egg movement, and a stable routing system which is essential for efficient store-door delivery.

Survey respondents were asked their views on the disadvantages or problems associated with formula pricing. The primary problems which emergd

from these interviews can be summarized as (*a*) formula pricing's reduction of the firm's potential influence on its market price; (*b*) the absence in some markets of a well-accepted, sufficiently accurate or precise market price report to serve as a base for formula prices; (*c*) inability to capture fully, in a formula price arrangement, potential benefits from superior market information, forecasting, or negotiating skills; and (*d*) significant reduction of the potential number of customers or suppliers when some buyers or suppliers refuse to use formula price arrangements.

Few survey respondents mentioned, or perhaps were cognizant of, some additional implications of formula pricing. While there were occasional complaints in some markets about unreliable or inaccurate price reports (especially beef and eggs), most respondents did not relate those complaints to the reduced volume of negotiated trading which is a result of increased formula trading. In conjunction with increased processing and product differentiation (e.g., in beef, pork, and turkeys) that removes product volume from the "basic commodity" classification, the result is a more thinly traded market which serves as the source of the base price report for pricing formulas.

Large firms with a large number of formula-priced transactions may have a greater incentive and a greater potential of manipulating the market price or report through changes in their behavior. For example, some cheese market participants expressed concern about potential manipulation of the Cheese Exchange price by four or five Exchange members who trade a high proportion of the very small Exchange volume. However, upon closer examination, significant artificial price enhancement by any one firm acting alone for more than a very short period of time seems impractical because of the instantaneous communication of prices and the potential for countervailing reactions to price distortions by Exchange participants handling 85%–90% of the cheese in the country.

The ultimate problem of formula pricing is the potential for destruction of the negotiated market which provides the base price. Haverkamp (Hayenga 1979c, p. 103) has suggested that the use of formula pricing would level off as firms limit its use in response to a thinning negotiated market. Williams (Hayenga 1979c, pp. 88, 103) argues that formula pricing is likely to increase toward an equilibrium at which private reporting remains despite the lack of an adequate number of reportable trades in the negotiated market. The markets which we studied do not provide a clear basis for choice among those alternative hypotheses. However, a small number of the firms surveyed in the beef and pork markets indicated they were attempting to limit or reduce their use of formula pricing, though no clear trend emerged. In the cheese and egg markets where formula pricing is dominant, there is no indication that any significant reduction in formula pricing is occurring or contemplated. The situation in eggs is consistent with the Williams hypothesis; that is, the market is quoted at a level where almost no trades are negotiated unless special feature sales or excess inventories require unusual negotiated transactions to supplant the non-negotiated coordination mechanisms. The egg industry did recognize that a new mechanism was required to provide a better market price quotation and organized the Egg Clearinghouse, Inc., an electronic exchange, which brought some of the previously private trading into this public market arena. However, there has been no appreciable change in the amount of formula pricing in the egg market.

Summary and Conclusions

The extent of formula pricing in the five industries studied varied significantly, ranging from 90% or more of the cheese sold by cheese-manufacturing plants to large cheese-processing and marketing firms, to less than 10% for processed pork products.

Why is the incidence of formula pricing so different in these markets? While the answer is not entirely clear, we speculate that there are several contributing causes. The least amount of formula pricing is found in the packaged and processed cheese and processed pork markets where processor brand franchises are well established and administered price lists are feasible and preferred by the seller (and perhaps by the buyer, too). Only a small amount of boxed beef is formula-priced, partly because buyers dislike the price risk associated with wide ranges on boxed-beef price reports (which may be due to poor product standardization or imperfect market arbitrage on boxed beef cuts). But, the longer shelf life of boxed beef products (compared to beef carcasses) also may reduce meat packers' incentive to insure continuing buyer-seller relationships through formula-priced arrangements on boxed beef relative to beef carcasses. More fresh pork may be formula-priced than the comparable beef primal cuts because of pork's greater perishability, the greater perceived risk of using boxed beef pricing quotations, and the relatively recent entry of many boxed beef processors, which may have prevented the development of long-term relationships. Where close coordination of perishable products is required, as in eggs and turkeys, or price risk must be avoided by one party to the transaction (e.g., a small cheese plant), formula pricing or vertical integration is prevalent.

In our judgment, the degree of dissatisfaction expressed about market-pricing systems ranged from very little in the cheese industry to substantial in the carcass beef and egg markets, with more moderate levels of concern in the pork and turkey markets. Why would there be such a difference in the apparent level of satisfaction with the pricing systems used in these markets? The egg and cheese markets appear to have similar institutional characteristics, with thinly traded negotiated markets and

an extremely high incidence of formula pricing. We would conjecture that there may be several contributing factors. While the National Cheese Exchange trades less than 1% of the total cheese produced in the United States, nearly all major market participants are present, distortions are instantly communicated, and countering reactions are quick. Further, cheese production is concentrated in one region of the United States. Contrast this with the egg market, where production is widely dispersed throughout the country and where regions that are nearly self-sufficient sometimes shift temporarily from surplus to deficit regions. Thus, a price report at one location cannot reflect accurately the changing regional price patterns in the egg market, and stable formulas based upon the New York price report will get out of alignment with opportunity costs. Thus, we hypothesize that the occasional discrepancies between the reported market price and actual market prices in some regions may be the primary cause of the greater level of dissatisfaction with pricing formulas and reports in the egg market.

In contrast, the carcass beef market still has a high volume (though declining) of negotiated trades, so the dissatisfaction noted in that market probably cannot be attributed to a thinly traded market. Rather, the dissatisfaction seems to be related to the accuracy of the reported prices and suspicion regarding potential manipulation of reported prices via various methods. This might be related to the failure of many buyers and sellers to report fully and accurately their prices to the price reporting services and to the failure of price-reporting services to increase their reported product classes to include some high volume product streams that differ slightly in trim or grade from the current report categories. At the same time, there may be imperfect regional arbitrage in the carcass and boxed beef markets due to inadequate communication of market prices that are out of line, causing occasional regional price discrepancies relative to reported prices and prompting dissatisfaction among market participants. Further, the entire pricing process and the price reporting process is clearly more difficult for the outside observer to scrutinize and understand than the "open to the public" National Cheese Exchange where fears of the unknown might be better allayed.

Policy Implications

Our study of these markets has not revealed a need for major legislative remedy at this time. The benefits of formula pricing accruing to the firms using that pricing system generally seem to outweigh the perceived problems to those firms and to society. Perhaps the major concerns related to the use of formula prices are the suspicions regarding manipulated prices or unrepresentative price reports that are used in formula price arrangements. To date, convincing evidence supporting these suspicions has not been produced in the meat industry (USDA 1979, p. 25) or in the other markets we studied.[2] Elimination of formula pricing would lead to increased transactional cost and, probably, risk. Further, the resulting changes in competitive balance and structure in the markets we have studied may not be desirable.

Marketing Alternatives and Resource Allocation: Case Studies of Collective Bargaining

Mahlon G. Lang

Agricultural economists are concerned with vertical coordination in commodity subsectors. This term was popularized by the work of Mighell and Jones, whose definition of vertical coordination is most commonly cited. "It includes all the ways of harmonizing the successive vertical steps, or stages, of production and marketing. Vertical coordination may be accomplished through the marketing price system, vertical integration, contracting, cooperation, or any other means, separately or in combination. There is always some kind of vertical coordination if any production takes place" (p. 4).

Mighell and Jones suggest that some mechanisms may bring about "better" coordination than others. In *Marketing Alternatives for Agriculture: Is There A Better Way?* several coordination mechanisms are described and discussed in terms of their possible consequences. The work edited by Marion is concerned with the definition of vertical coordination and describes coordination practices in various commodity subsectors.

Definitional and descriptive work is essential to informed public choice regarding the selection of coordination alternatives. But a need remains to develop and apply theory to the comparison of alternative coordination mechanisms.

General economists have made contributions which would aid such comparisons. In his seminal article, "The Nature of the Firm," Coase explained that the existence of the firm was predicated on economies of internal contracting as opposed to external, market transactions. Succeeding theoretical work focused on inter- and intrafirm coordination comparisons (Williamson) and on intrafirm coordination itself (Cyert and March). But the concept of market coordination has been treated as datum (Lowe), largely ignoring variations in the institutional setting of the market. Exceptions are seen in the literature of imperfect competition and industrial organization. These focus largely on market structure (narrowly defined) and its effects on allocative efficiency.

But Williamson's recent analysis of interfirm and intrafirm coordination offers a means of comparing resource allocation in different institutional settings. Williamson identifies conditions under which markets lead to greater allocative efficiency than do intrafirm decisions and vice versa. His work is drawn upon to interpret empirical observations reported in this article.

This analysis is born of concern that research on market coordination alternatives has neither drawn on this literature nor taken its own steps to develop a theory of vertical coordination. Inductive research (descriptive and definitional), while essential, has yet to produce general results which facilitate comparisons of coordination alternatives.

This article does not purport to construct a theory of vertical coordination. Rather, it is intended to provide a "building block," many of which are needed to construct such a theory.

The analysis has three specific objectives. The first is to demonstrate qualitative differences in the resource allocation consequences of independent contracting and collective bargaining in vegetable product markets. The second is to demonstrate that at least one dimension of the vertical coordination problem (minimization of joint costs of risk) can be addressed in the context of neoclassical theory. The third is to demonstrate that existing theory can be used to explain these qualitative differences.

The approach has four steps. The first is to present a hypothesis regarding risk allocation and joint cost minimization between collective bargaining associations and food processors. The second is to relate research findings and case studies of contract revisions induced by collective bargaining, each of which supports the hypothesis. Step three is to analyze the resource allocation consequences of the contract revisions. The final step is to interpret these consequences in terms of existing theory.

A Hypothesis

It is popular to assume that collective bargaining is a zero-sum game. A necessary condition for such an assumption is profit-maximizing behavior by the firms involved.

The assumption of profit maximization has been challenged by Cyert and March, whose observation of "organizational slack" in concentrated industries led them to argue that such firms may forego

Mahlon George Lang is an assistant professor of agricultural economics at Purdue University.

Journal Paper No. 7949 of the Purdue University Agricultural Experiment Station. The research upon which this article is based was supported by the Farmer Cooperative Service USDA and the Michigan Agricultural Experiment Station.

The author gratefully acknowledges departmental reviews by Emerson Babb, Jon Brandt, and Lee Schrader. The contributions of two anonymous reviewers also are appreciated.

pecuniary efficiencies to maintain good relations among managers, with employees, and among functional divisions of the firm such as procurement, production, sales, and others (pp. 36–38). Liebenstein explains the consequences of such behavior in his classic article on "*X*-efficiency." Where there exists organizational slack, firms need not "operate on an outer-bound production possibility surface consistent with their resources. Rather they work on a production surface that is well within their outer bound. This means that for a variety of reasons people and organizations normally work neither as hard nor as effectively as they could. In situations where competitive pressure is light, many people will trade the disutility of greater effort, of search, and the control of other peoples' activity for the utility of feeling less pressure and better interpersonal relations" (p. 413).

While organizational slack and *X*-inefficiency may characterize firms in concentrated industries, various pressures may discipline the firm to reduce its costs by "taking up slack." Such pressure may appear in the form of changing management, increasing costs, falling demand, and other factors. It may also appear in the exercise of countervailing power through collective bargaining. *X*-inefficiency may appear in the form of misallocated marketing functions between vertical stages in a marketing channel.

Even in relatively competitive markets such misallocation is present. Baldwin and Hill, for example, concluded that farmers had overinvested in grain-drying capacity. Country elevators, they concluded, could perform the function at a lower unit cost than could farmers. The effect was to prevent the farmers and elevator operators from minimizing joint costs. If such phenomena occur in relatively competitive grain markets, similar occurrences in concentrated markets would be unsurprising and consistent with organizational slack and *X*-inefficiency.

Vegetable product markets are spatially oligopsonistic (Lang). Further, the most common coordination mechanisms are individual contracting and collective contract bargaining. The one-time contract offer by a vegetable processor can be viewed as a compact message. Conversely, collective bargaining while time consuming and complex, involves more discussion of nonprice contract terms. (In an analysis too extensive for discussion here, Hurwicz compares the resource allocation properties of a price mechanism—analogous to one-time contract offers—and a "greed process"—analogous to collective contract bargaining.) Iterative bids, offers, and counter-offers focus more attention on each dimension of a transaction than that expected under individual contracting.

Collective bargaining is expected to bring more information to bear on the contracting process and to bring pressure to bear on organizational slack. If so, the process may lead to the reallocation of marketing functions between growers and processors such that incentives to minimize joint costs are greater than they are under independent contracting.

These observations led the author to test the hypothesis that collective bargaining, as opposed to independent contracting, can and does increase incentives or opportunities to minimize joint costs of vegetable producers and processors. The following empirical observations support this hypothesis.

Contract Revisions and Collective Bargaining: Case Studies

A nation-wide mail survey of all fruit and vegetable bargaining associations was conducted. One aim of the survey was to identify terms of trade incorporated in contracts as a result of collective action. The survey received responses from thirty-three of thirty-six associations known to be bargaining for vegetable crops. Among terms added to contracts (and the number of associations adding such terms) were those relating to quality measurement procedures (13), delivery schedules (11), raw product handling procedures (10), by-passed acreage (22), and rights and responsibilities during production (18). A total of twenty types of terms were added as a result of collective action. An implicit aim of changing terms of trade is the Pareto-better goal of reducing joint costs. Otherwise, there would be no point in making such changes. Bargaining would be a zero-sum game. Any change in nonprice terms of trade would be reflected in the price of the commodity over which negotiations take place. Given parity of bargaining power, a cost would simply shift from one party to the other and there would be a corresponding change in exchange price.

To clarify the nature of contract revisions, their effects on incentives for participants, and their effects on resource allocation, personal interviews were conducted with managers initially surveyed by mail. The interviews provided many illustrations of terms collectively negotiated to shift the incidence of costs. Five such cases are outlined below. Each illustrates a shift in responsibility from grower to handler when the handler appears to be in the best position to minimize the relevant joint cost.

Case I

When delivered from grower to plant, sugar beets sometimes remain in receiving yards until shrinkage reduces their value in use. At one time, all shrinkage was charged to growers even though it took place after delivery. Processors, who controlled the beets after delivery, had no immediate incentive to prevent or reduce shrinkage. A grower association negotiated a maximum dockage for shrinkage. Any shrinkage of more than 5% resulted in a net loss to the processing firm. The firm's reaction was to adopt an improved storage technology for the beets. The use of canopies on piles of beets and the

use of vents in the same piles reduced shrinkage and maintained desired temperatures.

Case II

In the past, pea growers were docked for split or damaged peas in their crop. Splits and other forms of damage are caused by rapid combine harvesting. Combines are owned by processors and operated by their employees.

The Western Washington Farm Crops Association negotiated the elimination of dockage for split peas. The incentive to control defects was placed on the processor who could control the damage rate. Processors now have an immediate incentive to see that combines are operated at speeds which equate marginal benefit of rapid harvesting with the marginal cost of damage to peas. They bore no immediate incentive to do so prior to the contract revision.

Case III

Contracts between processors and growers of peas, sweet corn, lima beans, and other crops frequently include a clause which provides the contracting firm an option not to harvest a field if it is too dry or otherwise unsuitable for harvest. A serious charge in connection with this practice is that processors contract acreage in excess of anticipated needs, thereby reducing the risk of short supplies. Some growers allege that if, at harvest, the processor discovers that he has overcontracted, he becomes arbitrary in deciding how much acreage is suitable for harvest and chooses to bypass acreage suitable for harvest.

Whether the clause actually is used in this way is not at issue. At issue is the fact that decision control with respect to bypassed acreage is held by the processor while the consequences of his decision inflict financial loss on the grower.

Growers were understandably unhappy with this practice. Through collective bargaining, they have shifted all or part of the risk back to processors. In one case, growers and processors contribute to a pool used to compensate growers whose crops are bypassed. In others, processors are required to cover production costs incurred by growers.

These changes do not eliminate the practice of passing acreage. They do provide the handler with a direct incentive to equate the marginal benefits and costs of overcontracting and bypassing acreage.

Case IV

The Potato Growers of Idaho negotiated to refine the quality incentive provisions of contracts with potato processors. Contracts signed by growers with some processors have long included a "bruise free" provision. But growers charged that many of the potato bruises for which they were discounted resulted from rough handling at the plant. To avoid discounts for recent bruises, growers negotiated a "recent bruise" provision. This required the adaptation of existing technology to distinguish old bruises from new bruises. This made processors accountable for new bruises and led to specific changes in handling practices at the plant. The distance potatoes drop when unloaded from trucks has been significantly reduced. As a result, the number of recent bruises attributable to handling has also been reduced.

Case V

Ohio tomato growers waited in long lines to deliver their product to processors. Because growers bore the cost of a "floating inventory," processors had no incentive to increase receiving facilities or extend hours. They benefited from a steady flow of growers anxious to deliver their crops and return to the field. The Ohio Agricultural Marketing Association negotiated demurrage charges for growers who were delayed, thereby shifting responsibility for reducing delivery time. This created an incentive for handlers to reduce waiting time for growers. Delivery coordination was improved.

Another change in coordination of the quantity and timing of tomato deliveries merits note. Growers and handlers negotiated a rate of delivery per acre per day. This reduced the probability of excessive deliveries for existing facilities. Previously, when excesses were delivered, the grower wasted time and absorbed product loss. In the absence of a specified daily quantity for all growers, individual growers had no guarantee that their tomatoes would be accepted on any given day. Tomatoes are now shipped with confidence that they will be more readily received.

A minimum quantity to be purchased by the processors also was negotiated in Ohio. Tomato contracts specify a date before which the processor will not close down. Given this guide, the grower can better plan both planting and harvest.

In each case the incidence of a joint cost was shifted from grower to processor. Examples could be cited where the cost was shifted from processsor to grower. If either party could manage the specific cost equally well, it would make no difference from a resource allocation or economic welfare point of view who were to do so. The case studies would offer no evidence of qualitative differences in the resource allocation consequences of collective bargaining and individual contracting.

In fact, each case demonstrates a change in incentives which, theory suggests, would lead to an allocation of resources different from that expected under independent contracting. The use of canopies for sugar beets and different receiving procedures for potatoes and tomatoes resulted directly from incentives created by the revision of contracts.

In each case, a risk situation leads to added costs of production and/or marketing. Imperfect knowledge regarding the rate and level of processing re-

sults in potential shrinkage in sugar beets, damage to peas in harvesting, passed acreage, potatoes bruised in handling, and demurrage in the delivery of tomatoes. In every case, growers were penalized for the effects of this risk. But in every case, the processor knows better than growers what processing rates will be. Therefore, the processor is in a position to control the risk situation and to equate the marginal benefits and costs of holding beets, damaging peas, passing acreage, bruising potatoes, and delaying deliveries of tomatoes. The grower has no such control and has less knowledge of the risk situation than the processor. The minimization of joint costs is therefore more likely when the processor directly bears such costs.

Resource Allocation Consequences

The fundamental argument is that contract revisions induced by collective bargaining lead to a different allocation of resources than did the prior contracts. This section analyzes those consequences.

Conceptually, the same contract revision is involved in each case. In general terms, the cost of risk is shifted from the grower to the processor, who can better manage it. Thus, analysis of a specific case can be readily applied to the other cases.

Prior to the contract revision discussed in Case II, processors discounted growers for peas damaged during harvest. Growers bore the cost of damage to peas even though processors were more aware of the relative importance and benefits of rapid harvesting.

The effect of the contract revision is reflected in figure 1.[1]

In figure 1, S_1 is the supply curve when growers are discounted for peas damaged by rapid harvesting; S_2 is the supply curve when those growers are not charged for such damage. Growers will contract a given number of acres at a lower nominal price per ton when not discounted for damage. Demand, D_1, is the marginal value product (MVP) per acre of peas under the original contract. Equilibrium price and quantity are P_1 and Q_1; D_2 is the demand curve (MVP) for pea acreage if processors absorb the cost of damage to peas and if the cost of pea damage is the same when borne by processors as when borne by growers. In that case, equilibrium quantity (Q_1) is unchanged as is the net contract price (although the nominal contract price drops from P_1 to P_2).

But the processor knows more about the expected speed of harvesting than does the grower.

[1] The reader who expects a quantitative measure of the consequences of these changes will be disappointed. The goal of this article is only to show the direction of the resulting change in resource allocation and the creation of an incentive to change. Measurement of those changes would involve a massive control problem with no guarantee of adding useful information to the analysis.

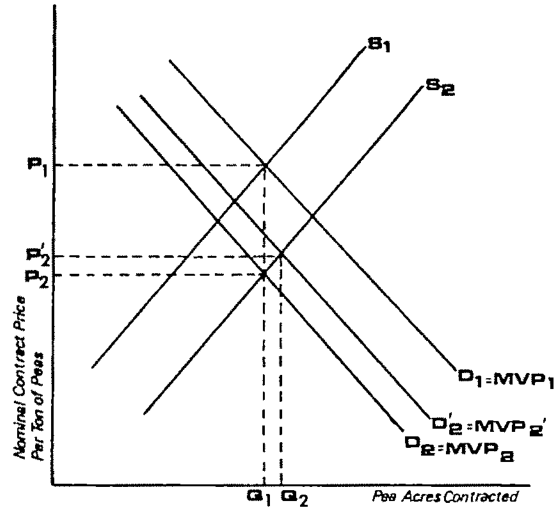

Figure 1. The effect of contract revisions to reallocate risk

Therefore, his cost of risk in managing the damage is lower than is the cost of risk faced by the grower. This is because the grower must estimate the level of damage, and therefore total discounts, on the basis of past experience. Thus, for a given level of output, $S_1 - S_2$, the amount the grower discounts a contract for expected damage, is greater than $D_1 - D_2$, the amount by which the processor discounts a contract for the expected cost of damage.

Thus, the actual demand curve (D'_2) would lie below D_1 but above D_2. Assuming that negotiators secure compensation for a higher MVP per contracted acre, equilibrium quantity will rise from Q_1 to Q_2. Because this is a partial equilibrium analysis, the effect of an increase in total supply on the level of retail price and its negative effect on MVP are not known.

Interpretation

The existence of information asymmetries in markets for processing vegetables suggests that certain joint costs will be minimized when borne by the party possessing the most information. In some cases these asymmetries are maintained because of information impactedness.

According to Williamson, "(Information impactedness) . . . exists in circumstances in which one of the parties to an exchange is much better informed than is the other regarding underlying conditions germane to the trade, and the second party cannot achieve information parity except at great cost—because he cannot rely on the first party to disclose the information in a fully candid manner" (p. 14).

This concept applies in Cases II and III. Processors, because they have greater access to demand information than growers, are in a better position to foresee the need for rapid harvesting (Case

II) than are growers, who can only estimate crop damage and the resulting discounts on the basis of past experience. For the same reason, processors can better foresee the likelihood of passing acreage (Case III) than can the growers, who would therefore discount more for the risk with respect to passed acreage.

In both cases the processor has an incentive to withhold information affecting likely harvesting procedures in order to maintain flexibility (Case III) or to avoid pressuring employees (Case II) during a hectic period. Such an intraseason incentive may lead processors to absorb higher pecuniary costs on an interseasonal basis.

But it is not clear in Cases I, IV, and V that processors could benefit by withholding information on the demand for sugar beets, potatoes, and tomatoes. In those cases, it is simply costly for growers to achieve information parity with processors. It is more difficult for producers than for processors to use information on expected processing rates to minimize joint costs.

Indeed, Phillips and his colleagues have argued, in the case of processing-potato markets (pp. 16–20), that it is impossible for growers to achieve information parity with processors. Phillips concludes that growers have no access, for example, to information on processing costs, marketing costs, or selected components of carryover and processed stock movement (p. 17). Further, neither the inventory position of individual firms nor their packing intentions are accessible to growers.

The processor's knowledge of the demand situation suggests that he is in a better position to manage the cost of demand-related risk than are growers. Growers must discount their expected returns because of this risk and do so on the basis of sketchy and sometimes inaccessible demand information.

One effect of collective bargaining in agricultural product markets has been to create incentives to minimize joint costs where information asymmetries exist. But the above is a partial equilibrium analysis. While it concludes that the revised contracts are preferable to the others in terms of economic performance, it does not address the comparative costs of coordination mechanisms. It ignores the possibility that collective bargaining involves higher transactions costs and greater buyer or seller alienation than does individual contracting. At the same time, there is no reason to believe that such costs are any lower for individual contracting.

In short, the analysis does not compare the two coordination mechanisms in terms of all dimensions of market performance. Its goal is, rather, to document fundamental differences in the resource allocation consequences of market alternatives. To this end, the following discussion explains why processors may fail to write least-cost contracts and, therefore, why collective bargaining or other forces would have been required to secure the contract revisions.

The neoclassical, profit-maximizing firm would minimize joint costs of food production and processing. Even in imperfect markets, as in vegetable product markets, the local monopsonist would increase his profits by writing voluntarily the contracts negotiated by growers. By rewriting contracts, the monopsonist could have contracted greater tonnage at the same price per acre.

In spite of this opportunity, the firms in the cases studied did not make these changes without the pressure of collective bargaining. The most appealing explanation begins with the claim of "organizational slack" suggested by Cyert and March. Managers may fail to pressure workers in receiving yards when they know they could receive tomatoes faster or handle potatoes more carefully. They may not discourage procurement personnel from overcontracting pea acreage nor caution machinery operators against harvesting too rapidly.

Thus, the original contracts may be least-cost from the point of view of the processing firm's manager. In the absence of pressure to do so, the manager may choose to avoid the frustration and friction required to reduce pecuniary costs of product handling and processing.

The consequences of such behavior are described by Liebenstein as "X-inefficiency." Processors may sacrifice greater long-term productive efficiency for the flexibility they are afforded on an intraseasonal basis. As argued in the analysis, the processor's greater knowledge of demand conditions (information asymmetry) may provide him with such flexibility.

When few buyers are present and there exists uncertainty with respect to packing intentions, buyers can exploit information impactedness (Williamson) to maintain uncertainty above what it need be for sellers. In so doing, processors may negotiate more favorable contract terms.

Organizational slack and X-inefficiency explain why processors may fail to write least-cost contracts. But there is no reason to believe that only collective bargaining could achieve these results. Many forces could lead the firm to reduce slack and move toward its production possibilities surface. But it is not clear that all such pressures would lead the firm to write contracts that foreclose its option to exploit information asymmetries. The firm may, in fact, rely more heavily on such short-run advantages in times of economic stress. Vertical integration or some form of countervailing power may be the only means of eliminating such obstacles to the reduction of joint costs.

Summary and Conclusions

This note examines case studies of contract revisions prompted by collective bargaining, analyzes their resource allocation consequences, and offers an explanation of why those revisions did not come about in the absence of collective bargaining. It

concludes that the revisions led to a reduction in joint costs of production and processing and argues that collective bargaining was one of several factors which may have prompted contract revisions.

These findings support the claim that there are fundamental differences in the resource allocation consequences of alternative vertical coordination mechanisms. They do not permit a conclusion that collective bargaining is necessarily a desirable alternative. They do offer evidence that one dimension of coordination may be improved through collective action.

Relationship between Two Price Quotes for Eggs

David A. Bessler and Lee F. Schrader

Most transfers of shell eggs at all levels of the marketing channel from the production to the retail level are priced by formula based on published market quotations. Most pricing formulas in the U.S. east of the Rocky Mountains are based on prices quoted in *Producers' Price-Current*. West coast egg-pricing formulas most often use quotes by the U.S. Department of Agriculture's *Poultry Market News*.

The pervasive use of formula-pricing results in a thinly traded cash market and focuses attention on the price quotes. The validity and accuracy of quotes are major concerns of the trade. The problems of egg pricing are documented by Rogers and Voss and by Schrader, Larzelere, Rogers and Forker. The desire on the part of the trade for a means to facilitate price discovery and price reporting for eggs motivated the establishment of Egg Clearinghouse, Inc. (ECI). ECI is a cash exchange trading gradable nest-run eggs, where trades are matched by computer with the product moving directly from seller to buyer once a trade has been completed.

Trading on ECI has been thin, representing less than 0.5% of all eggs produced in 1978. Yet trades on ECI and Defense Personnel Support Center purchases represent the only transactions for which quality and delivery are clearly specified and for which prices are available to the public. Other transactions are known to participants and, to some extent, to Urner Barry or USDA reporters. Both Urner Barry and *Market News* report prices paid by retailers for cartoned eggs; however, these prices usually are determined by formula using a prior quotation.

Much of the trading on ECI represents trading among grading and packing firms to correct short-term imbalances. As such, these relatively few trades may represent the marginal price-making transactions. The quality specifications are such that only eggs suitable for cartoning for table use are acceptable for delivery in the gradable nest-run classes.

A committee, the Egg Market Evaluation Committee (EMEC), translates the trades, bids, and offers on ECI into quotes representing the Midwest (delivered Chicago) and East (delivered New York) twice weekly.[1] The EMEC quotes are based primarily upon activity on ECI supplemented by information gathered from telephone contact with members of the egg trade and current *Market News* statistics. This supplementary information is used only when the activity on ECI provides insufficient information for a particular class or location (Stemberger, Grange, Schrader). The Urner Barry reporters place less emphasis on use of ECI information. Urner Barry stated in August 1977: "In the development of the Urner Barry Egg Quotations, we use three broad areas of information as follows: the trading on Egg Clearinghouse, our own telephone canvass, and related information such as purchases by the Defense Department and other government units along with the various statistical information that is available." The UB spot market quote, which represents the base for most pricing formulas, has not been defined as representing a specific market level recently.

Many in the trade believe that prices based on ECI (such as the EMEC quote) should be used as the base for pricing formulas. Others defend present pricing practice, arguing that the added judgment and tempering of the "over reactions" to very short-term or regional imbalances reflected in ECI trading are more appropriate.

We suggest that if one series can be shown to lead the other, the leading series is the more accurate or sensitive indicator of equilibrium value. We assume that, in time, both quotes will change in the same direction as a change in the unobserved equilibrium values at all levels in the market. The two quotes do not represent the same level and one would expect there to be a market for processing services which would determine the difference between nest-run and graded, cartoned eggs. We do not have the data to model that relationship on a daily basis nor does the UB quote represent exactly a cartoned-egg level.

The lead lag relationship is further complicated by the fact that transfer-pricing formulas are based on the UB quote. We suggest that, if UB errs, transaction prices will follow and the resulting misallocation will persist until it becomes clear to the UB reporters that the quote must be changed. That is, if the UB quote is too high, users will take less than suppliers wish to sell, prices on ECI will be

offered down and, before the correction is complete, prices will be lower than otherwise would have been the case. Therefore, in a time period of about two or three weeks, errors in the UB quote may influence the level of prices on ECI.

If both quotes are equally accurate indicators of value change, one would not expect any lead or lag. If one is more sensitive, it would be expected to lead; however, any feedback through pricing formulas would be expected to result in a negative relation from a less accurate UB to a more sensitive EMEC quote. If UB is the more accurate, no negative feedback from EMEC to UB would be expected.

Review of Two Methods to Infer Causal Relations among Economic Time Series

The analysis applied in this paper is that generally discussed under the heading of Granger causality. The method provides a means to infer causal (or at least predictive) relations among two variables reported in a time series.[2] More specifically, we can say a variable X causes another variable Y, with respect to a given universe that includes at least X and Y if current values of Y can be better predicted by using past values of X than by not doing so, all other information in the universe (including past values of Y) being used in either case. The method has been applied in various studies; probably the most well known of these being Sims (1972) and Pierce.

In general, attempting to detect causality by analyzing cross-correlations or regressions of levels of Y on past levels of X and Y can be a difficult problem. In particular, the significance tests (t- and F-statistics) obtained from relating levels of highly autocorrelated series can be grossly overestimated, thus leading us to assert a causal relationship when none may exist. As an alternative to relating levels of series to detect causality, Haugh suggests that we deal with the innovations of each series.[3] That is, he suggests that we first remove all of the time-series properties from each series—i.e., filter both series using procedures of, say, Box and Jenkins. One can then cross-correlate the innovations of each series in order to infer any causal relationships. Pierce and Haugh demonstrate that variable X causes Y if the cross-correlations between the innovations from each transformed series are nonzero at positive lags—that is, current Y can be predicted by past X.

Other causal relationships involving two-way or feedback causality, instantaneous causality, and independence can be analyzed by these same cross-correlations. For example, if nonzero cross-correlations exist at both positive and negative lags, then a two-way or feedback relation exists between X and Y. Or, if no feedback exists, and if the cross-correlation is nonzero at a lag of zero, then there exists instantaneous causality.

The actual test of these cross-correlations must, of course, be carried out with estimated cross-correlations. Such a test can be made using the U-statistic given by Haugh:

$$U_m = n \sum_{k=1}^{m} r_k^2,$$

where n refers to the number of observations on the innovations of X and Y, r_k^2 the squared cross-correlations at lag k, and m is an integer, greater than or equal to one, chosen large enough to include expected nonzero coefficients. Under the null hypothesis of series independence, the U-statistic is distributed chi-square with m degrees of freedom.

In assessing one-way causality using the Haugh approach, there is a bias associated with the U_m-statistic. In particular, once we reject the hypothesis of independence among the innovations of current X and future Y, the test of feedback using U_m is biased toward failing to reject the null hypothesis of independence. The general nature of this problem is discussed in Sims (1977).

As an alternative to Haugh's procedure, we can use the causality test proposed by Sims (1972). He suggests one prefilter each series (using a common prefilter) to remove autocorrelation in both series. The current values of one transformed series (call it y) are then regressed on past and future values of the other transformed series (call it x). If causality runs from x to y only, future values of x in this regression should have coefficients, as a group, insignificantly different from zero. The test of the null hypothesis of no influence can be carried out with the usual procedures—comparing the relative reduction in sums of squared errors with and without the future values of x in the regression. Under the null hypothesis of no influence, the appropriate test is an F-test, (we reject the hypothesis of no influence for large F-values).

This second test can also result in improper inference if the common prefilter is not sufficient to remove substantial autocorrelation in each series. This problem is discussed within the causality context in Pierce and Haugh. A more general description of the problem is given in Granger and Newbold.

Application of the Causality Tests to Empirical Price Quotes by Urner Barry and EMEC

We apply the causality tests to 1977–78 twice-weekly price quote data of Urner Barry and EMEC. Thus, we have 208 observations on each series. It should be noted that the UB series is a price repre-

[2] The word causality in this context is perhaps misused. The word predictability might be better substituted. However, given its widespread acceptance in the literature, we continue to use causality.

[3] Here "innovations" refers to that part of a series which cannot be predicted from its own past.

senting New York wholesale Grade A large eggs but not precisely defined; while the EMEC series represents an estimate of trading level of class I gradeable nest-run eggs delivered to the New York area.

The estimated autocorrelations and partial autocorrelations on each series are given in tables 1 and 2. The behaviors of these estimates are similar for both series. The autocorrelations tail-off; while the partial autocorrelations cut off at lag 2. Two possible options seem appropriate: either we can model the price quotes as a second-order autoregressive process or we can investigate a difference transformation to take into account a possible nonstationarity in the levels. We considered both options and chose the former. The filters applied to UB and EMEC data are given as

$$\text{UB: } (1 - 1.24B + .35B^2)(Y_t - 61) = U_t$$
$$\text{EMEC: } (1 - 1.30B + .40B^2)(X_t - 50) = V_t,$$

where U_t is the innovation of the UB (Y_t) series and V_t is the innovation of the EMEC (X_t) series.[4] Both models give a fairly high degree of fit ($R^2 > .90$). Autocorrelations of the innovations (U_t, V_t) are generally small. These along with the portmanteau "Q"-statistic are given in tables 3 and 4.[5] Under the null hypothesis of no serial correlation, the Q-statistic is distributed chi-square with 22 degrees of freedom. Our calculated Q in both cases is below the critical value of 33.9 at the .05 level of significance.

Following Haugh's procedure, we cross-correlated the innovations from each series. These are given in table 5. Applying the asymptotic standard deviation ($1/\sqrt{n} = .07$) we note individual cross-correlations are significant (using two standard deviations) at lags of −1, 0, +1, and +2. This suggests that there is some evidence of a two-way or feedback causality. That is, there is evidence that the innovations of EMEC explain and are explained by the innovations of UB.

The evidence of instantaneous causality—a significant cross-correlation at lag zero is consistent with our prior beliefs. The quotes represent very closely related concepts. Thus, we should see a positive cross-correlation at lag zero.

Further discussion of the causality patterns can be carried out using the U-statistics reported as test 1 in table 6. Here we have calculated values of U for various leads and lags. Before discussing these however, we should point out that we originally suspected direct leads and lags at low values—say one, two, or three. In addition, we suspected that feedback, if it existed, would be found running from UB to EMEC, at lags of about one month. That is, our suspicions were that the innovations in quotes would be zero if separated by more than eight or nine periods. Thus, we calculated U-statistics with

[4] B is a lag operator such that $(B^n)\, z_t = z_{t-n}$.

[5] The portmanteau statistic indicates overall deviations of a series from a random series. It is described in Box and Jenkins.

lags of three and nine periods in each direction. These statistics indicate rather strongly causality running from EMEC to UB. That is, for lags lasting no longer than a month UB seems to follow EMEC. Going back the other way, we find the evidence more questionable. In testing UB leading EMEC, we cannot reject the hypothesis of series independence at the 1% level; however we do reject this hypothesis at the 5% level.

The causality results based on Haugh's U-statistic should be viewed with caution, since there is a tendency to underestimate the significance level of U given one-way causality. As alternative evidence, we consider the Sims test which was briefly described above. Each price series was first transformed with the common prefilter $(1 - 1.27B + .37B^2)$. This filter ought to be sufficient to nearly prewhiten each series—as it closely resembles the empirical filters obtained above using Box and Jenkins' procedures. We tested causality running both ways (from EMEC to UB and vice versa). Again, leads and lags of three and nine periods were tested. More explicitly, we tested causality running from EMEC to UB in a single-equation ordinary least squares regression by regressing the transformed EMEC series on past and future values of the transformed UB series. We then reran the regression without the future values of the transformed UB series. If causality runs from UB to EMEC only (that is, EMEC does not cause UB) then the future values of UB in the regression will be insignificantly different from zero. The residual sums of squared errors are compared using the usual F-test. An analogous set of regressions was run to test causality from UB to EMEC.

The F-tests from these regressions are summarized in table 6 as test 2-*i* and *ii*. Test 2-*i* considers the null hypothesis that the entire set of regressors (past and future) have coefficients equal to zero, as a group. We reject this hypothesis in all cases—suggesting that there is dependence among the transformed values of the two egg quotes. Test 2-*ii* considers the hypothesis that the coefficients associated with the future values of the causal series are, as a group, not significantly different from zero.[6]

Failure to reject this null hypothesis is inconsistent with causality in the direction indicated in the table. That is, we reject the null hypothesis that the future values of UB have (as a group) no influence on current values of the EMEC quote. Thus, we cannot say that causality runs from UB to EMEC only. Alternatively, we can say causality runs from EMEC to UB. A similar statement cannot be made

[6] Similar statistical results were obtained by applying Sims' regression tests to series prefiltered with the separate empirical filters used in the Haugh procedure. We also investigated the Sims test using current values of the regressor in the Sims regression. That is, regressing y on past, current, and future values of x yields causal orderings similar to those obtained in test 2-*ii*. While Sims (1972, p. 545) did not suggest this alternative test, we investigated it for completeness.

for causality running from UB to EMEC. We do not reject the hypothesis that future values of EMEC have coefficients as a group equal to zero.

The two tests are consistent and allow us to make some general statements. We can firmly reject the hypothesis that EMEC is passive, responding to the UB quote but not influencing it. This follows from the significant chi-square statistic in test 1 and the significant F-statistic in Test 2-*ii* in the EMEC → UB column of table 6. The results are also consistent with the hypothesis that UB is, at best, questionable in its influence on EMEC. That is, coefficients of the future values of EMEC in the regression of UB on past and future values of EMEC are, as a group, not significantly different from zero, at the 1% level. However, test 1, based on the cross-correlations, shows some evidence of feedback at the 5% level, however slight.

Discussion of Results

Our analyses indicate causality running from EMEC price quotes for class I gradable nest-run eggs in the current period to UB spot market quotes for large whites, one, two, and three quote periods into the future. These results are both important and interesting. Recall that EMEC quotes reflect primarily trading activity on the thinly traded ECI while UB quotes are said to be based on ECI trading and upon other information. Our results suggest that this additional information or tempering of price extremes may not serve to improve UB quote as an indicator of changes in the unobserved equilibrium.

The results indicate that the thinly traded ECI is a relatively accurate and sensitive indicator of changes in the equilibrium price of eggs. ECI does represent a residual market. As indicated above, firms offer eggs which have not sold to regular outlets at prevailing prices or bid for eggs needed to supply regular customers in excess of supplies at prevailing prices. Increasing or decreasing price to secure or dispose of the marginal load is the essence of price discovery. ECI gives the marginal load national exposure and quality specifications assure the quality dimension of price information from the exchange. This positive evidence of the relative accuracy and sensitivity of ECI price during the 1977–78 period is encouraging for the ECI concept and one would expect enhanced accuracy and sen-

Table 6. UB–EMEC Causality Detection Tests

	EMEC → UB		UB → EMEC	
	3 periods	9 periods	3 periods	9 periods
Test 1[b]	21.53*[a]	26.14*	8.69	1.751
Test 2: *i*[c]	6.87*	4.85*	9.78*	4.44*
ii[d]	9.75*	3.51*	1.88	1.42

[a] Single asterisk indicates rejection of null hypothesis at 1% level.
[b] Test 1 is the empirical Haugh U-statistic based on the cross-correlations of the innovations from separate empirical refilters. Tabular chi-squared values are $\chi^2_{.01}(3) = 11.3$ $\chi^2_{.01}(9) = 21.7$ $\chi^2_{.05}(3) = 7.81$ and $\chi^2_{.05}(9) = 16.91$. Empirical chi-squared values greater than these tabular values suggest we reject the null hypothesis of independence among the innovations.
[c] Test 2-*i* is the empirical F-statistic associated with the estimated coefficients of the entire regressions of past and future innovations in Sims' causality regression. The tabular F-values are $F_{.01}(6,200) = 2.90$ and $F_{.01}(18,188) = 1.98$. Empirical values of F greater than these tabular values suggest we reject the null hypothesis that the regression coefficients as a group are equal to zero.
[d] Test 2-*ii* is the empirical F-statistic associated with the test that the coefficients on the future innovations in the Sims regression are, as a group, equal to zero. The tabular F values are $F_{.01}(3,200) \approx 3.89$ and $F_{.01}(9,188) \approx 2.52$. Empirical values of F greater than these tabular values suggest we reject the hypothesis that the coefficients on these future innovations are, as a group, equal to zero.

sitivity from increased trading levels in evidence at this writing.

Economic Efficiency and Policy Comparisons

Mahlon George Lang

Empirical studies published in the *Journal* have used the concept of economic efficiency to compare policy alternatives. Hall and LeVeen present an "analysis . . . developed for the current debate over acreage restrictions in reclamation policy." The authors argue "that large farms generally have lower production costs and that restrictive policies may therefore have some impact on overall economic efficiency" (p. 589). Mann and Paulsen assess the "impact of restricting feed additives in livestock and poultry production." They conclude that "health risk reductions may be obtainable at a smaller loss in economic efficiency than previously suggested" (p. 47). The reader will recall colleagues' claims that particular regulations or policy proposals would result in a loss in economic efficiency.

The Meaning of Economic Efficiency in Use

The measures of economic efficiency implied in the cited articles are simply productive efficiency or the private, pecuniary unit cost of production. These measures are quite different from the concept of Pareto optimality, which is the only theoretical definition of economic efficiency. Further, the use of such measures to compare policy alternatives obscures the true nature of the public choice involved.

Any policy which restricts the use of productive factors or establishes conditions on production will, if it is a binding constraint, raise the pecuniary unit cost of production. When this measure is used, it is tautological that, assuming rational decisions, any such policy action will reduce economic efficiency.

In any public choice affecting food additives, pesticides, product safety, and such, the real policy question is: "What factors and products shall be allocated by market exchange?" Explicitly, "shall the cost of health risk resulting from the use of feed additives be considered by livestock producers?"

This question cannot be answered in terms of economic efficiency. As Schmid and Shaffer have said, "Economic theory provides a method of calculating positions of maximum efficiency or optimum advantage. . . . These calculations are valid, however, only within any given set of exchange system rules which defines the qualitative makeup of the inputs and outputs to be included" (p. 29).

Policy choices affecting the use of feed additives, acreage limitations in federal irrigation projects, and others are choices among exchange system rules and the qualitative makeup of inputs and outputs to be counted by the market. In the absence of actual compensation to those injured by policy choices, conclusions that such choices affect economic efficiency positively or negatively are wrong.

Kaldor, Hicks, and Scitovsky (Henderson and Quandt, p. 279) have suggested compensation criteria which accept potential, rather than actual, compensation to losers. But, as Henderson and Quandt point out, "nothing can be said about the social preferability of (allocation) A over (allocation) B in the absence of actual compensation unless one is willing to make additional value judgments" (p. 279).

Economic Efficiency in Theory

Production efficiency and economic efficiency are defined and discussed below. These definitions are used to analyze the concept of economic efficiency used in the articles cited earlier.[1]

Production Efficiency

Hall and LeVeen (pp. 589, 90, 91) claim a loss in "economic efficiency" owing to the 160-acre irrigation limit. But their definition of economic efficiency really corresponds to "the overall efficiency of the firm" (Farrell, p. 255).

For Farrell, production efficiency is the joint occurrence of technical efficiency and price efficiency. Technical efficiency is achieved when the minimum quantities of factors (X_1 and X_2) are used (in fixed proportions) to produce a given level of output (Y). Price efficiency is achieved when the ratio of factor prices is equal to the ratio of factor use.

Mahlon George Lang is an assistant professor of agricultural economics, Purdue University.

Journal Paper No. 7950, Purdue University Agricultural Experiment Station.

The author wishes to thank his colleagues, E. M. Babb, R. D. Boynton, L. F. Schrader, and W. E. Tyner for thoughtful reviews of an earlier draft of this manuscript.

[1] The arguments developed here apply to numerous works in addition to those cited. There is general misuse of the concept of economic efficiency. This analysis does not question the importance, analyses, or value of the work by Hall and LeVeen and Mann and Paulsen. Their work is cited to analyze a term (economic efficiency), the misuse of which has substantive, but inappropriate policy implications.

The effect of enforcing a 160-acre irrigation limit, as measured by Hall and LeVeen, is to restrict each firm's use of a variable factor. If binding, this restriction precludes price efficiency and, therefore, firm efficiency with respect to the production of Y using X_1 and X_2 will not be achieved. Clearly, private pecuniary unit costs of production for Y will be higher when the use of a binding factor is restricted.

But this is not the same as a loss in economic efficiency. It is possible to achieve different economically efficient allocations of resources when different initial endowments of property rights shape market exchange. Under different definitions of property rights affecting factor use, the firm can still achieve overall productive efficiency with respect to the remaining variable factors of production. Each definition will raise or lower private, pecuniary costs of production depending on whether irrigated acreage limitations are enforced or irrigation water is publically subsidized in the first place as, in fact, it is. Thus, given each definition of property rights, productive efficiency would be achievable and consistent with economic efficiency depending on public goals with respect to the output of Y, the size distribution of commercial farms, and the opportunity cost of subsidizing irrigation initially.

For example, in (1) there are not restrictions on irrigated acreage because there is less concern with farm structure than is implied in (2), where irrigated acreage (X_2) is treated as a fixed factor. Given that X_2 is fixed, production efficiency

(1) $$Y = f(X_1, X_2/X_3 \ldots X_n),$$

(2) $$Y = f(X_1/X_2 \ldots X_n),$$

(3) $$Y = f(X_1/X_3 \ldots X_n),$$

with respect to variable factors can be achieved although (if X_2 is binding) at a lower level of Y than in (1). Similarly, if there were no public subsidy of irrigation water and it were simply not available, X_2 would drop out of the equation entirely as in (3). The potential for production efficiency with respect to variable factors would remain and the potential output of Y would be even lower than that suggested by (2).

Farrell's test of production efficiency can therefore be applied to variable factors in the context of any policy affecting the availability of factors. The test can be used to compare private pecuniary unit costs and the level of output Y under each policy. But the test cannot be used to compare these policies in terms of economic efficiency.

Economic Efficiency

As Henderson and Quandt indicate, "Pareto optimality provides a definition of the economic efficiency of allocations that serves as the basis for much of welfare economics" (p. 255). Alternative definitions of economic efficiency cannot be found in the literature. The same authors further observe that "changes which improve the positions of some individuals but cause a deterioration in those of others cannot be evaluated in terms of (economic) efficiency . . ." (p. 256). The studies cited above clearly imply that such changes can be evaluated in terms of economic efficiency.

Economic efficiency (Pareto optimality) in consumption, in production, and in general are clearly defined. Economic efficiency in consumption is defined by the equation of marginal rates of commodity substitution (MRCS) between consumers. Economic efficiency in production is defined by the equation of marginal rates of technical substitution (MRTS) between producers and between factors of production. Economic efficiency in general is defined by the point at which the marginal rate of commodity substitution (MRCS) for all consumers equals the MRTS between factors for all producers. Models of perfect competition define conditions under which producers will select such a point in response to relative prices defined by consumers engaged in the free exchange of commodities.

Two Theoretical Analyses Involving Pareto Efficiency

Two applications of the Pareto efficiency concept can more appropriately be used to analyze the feed additives issue addressed by Mann and Paulsen. The first application is a traditional analysis involving external economies and diseconomies. This approach analyzes the policy choice in a Pareto framework which shows the possibility of moving to a higher level of social welfare when the diseconomy is internalized. While consistent with Pareto efficiency, the first analysis does not frame the policy issue as accurately as does the second approach.

The second analysis involves the redefinition of factors and products. It demonstrates that the decision to restrict feed additives cannot be evaluated in terms of economic efficiency because it involves different combinations of factors and products. It analyzes the decision in a framework which shifts the structure of production possibilities and shows that the policy alternatives are not Pareto-comparable.

External Diseconomies

The use of feed additives by livestock producers is said to be an external diseconomy to the producers and consumers of good health. All costs of livestock production (which include the risk of poor health to meat consumers) are not internalized by livestock producers. This externality holds the price of livestock low relative to the price of good health. The result is a Pareto inefficient allocation of resources. (For proof, see Appendix.)

Mann and Paulsen make assertions about eco-

nomic efficiency consequences of restricting feed additives only with reference to livestock production. They treat health risk resulting from the use of feed additives as something that one trades off against economic efficiency. In fact, in a Pareto-efficiency context, the livestock output-health risk trade-off is an intimate part of the efficiency question. The economic efficiency of livestock production cannot be evaluated independent of the level of health risk.

The Redefinition of Factors and Products

The second approach to analysis of the feed additives issue views the related policy decision as a nonmarginal change affecting the entire structure of production possibilities. Thus, two Pareto-efficient allocations of resources are possible under restricted or unrestricted use of feed additives. Clearly these allocations cannot be compared in terms of economic efficiency.

Each set of market rules affecting factor use defines a production possibilities curve for the economy. Figure 1 depicts two such frontiers. Frontier F represents a simple economy which produces livestock and good health and permits unrestricted use of feed additives for livestock. Frontier F' represents an economy producing the same products under rules forbidding or restricting the use of additives.

As figure 1 indicates, a Pareto-efficient allocation of resources can be achieved under either definition of property rights represented by production possibilities frontiers F and F'. The redefinition of property rights amounts to a change in initial endowments (E_1 and E_2). These lead to different price relatives for factors and products. Social welfare functions SW_1 and SW_2, on which price relatives are presumed to identify at least one point, may be located as suggested in figure 2.

In this illustration, the unrestricted use of feed additives permits one person or group of persons to benefit greatly in terms of livestock (meat) consumption but the other person or group of persons gives up much "good health." Pareto-efficient allocations of resources are possible under either rule. But, in the absence of compensation for those who give up something in terms of health, the decision to restrict the use of feed additives and therefore the resulting resource allocation cannot be evaluated in terms of economic efficiency.

The potential normative burden associated with comparing these policy alternatives is better illustrated by transposing production possibilities frontiers F and F' (figure 1) into utility possibilities frontiers as was done by Mishan (1973, p. 751). Figure 2 shows two such utility frontiers. These define the levels of utility each production possibilities function would provide for two different consumers or two groups of consumers. The horizontal axis measures the utility acquired by consumer (group) A under each policy toward feed additives. This group clearly derives more utility from health relative to livestock than does consumer (group) B for which utility is measured on the vertical axis. A therefore derives more total

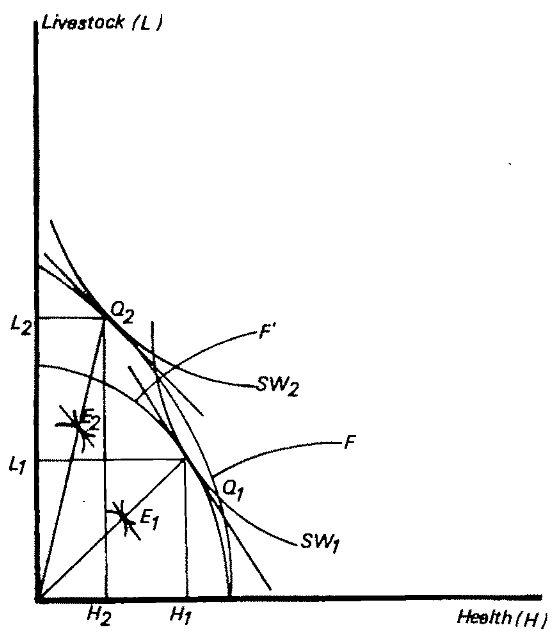

Figure 1. Pareto-efficient allocations under restrictive and nonrestricted policies with respect to feed additives

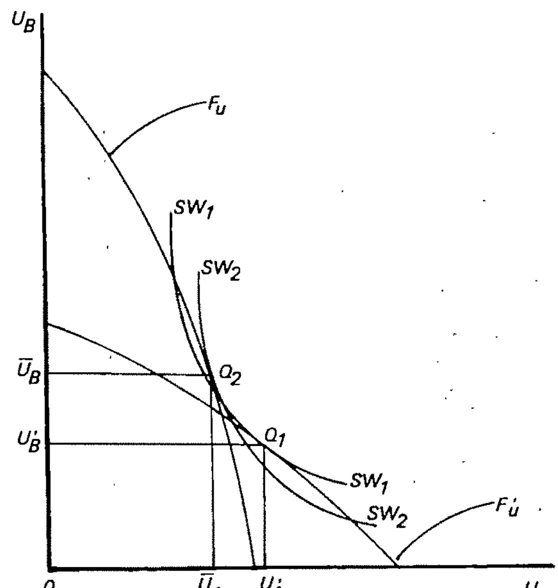

Figure 2. Mishan's two-person utility possibilities frontiers illustrating Scitovsky's Paradox

utility ($U'_A > U_A$) from the policy of restricting feed additives while B derives more total utility ($U_B > U'_B$) from the policy permitting the use of feed additives.

SW_1 is a community indifference curve (also transposed from fig. 1) which defines the Pareto-efficient allocation of resources when feed additives are restricted. SW_2 is the community indifference curve defining the Pareto efficient allocation of resources when feed additives are not restricted. Such curves give rise to Scitovsky's paradox (Mishan 1976, p. 394). The paradox arises as follows. Society can allocate its resources in a Pareto-optimal way at Q_2 in the case where feed additives are not restricted. But it is clear that Q_1, representing the Pareto-efficient solution under the policy which restricts feed additives, lies above the community indifference curve SW_2. However, if society restricts feed additives and if the resulting Pareto allocation is Q_1, it is clear that Q_2 lies above the indifference curve SW_1. The policies are not Pareto-comparable. Mishan's analysis of the paradox leads to a conclusion that "such cases are only resolvable by reducing them to a distributional ranking of the collections in question" (1973, p. 765). He further states, "In light of the above analysis, a conclusion that criteria based on potential Pareto comparability should be used with greater circumspection is hardly necessary" (p. 765).

Different initial endowments lead to different relative prices. These favor different people depending on their personal utility maps. Thus, the policy choice regarding feed additives cannot be unambiguously evaluated in a Pareto framework. A Pareto-efficient allocation of resources is possible given one definition of property rights (policy). But even in unambiguous (nonparadoxical) cases, unless there is compensation by gainers to losers, movement from one policy to the other cannot be compared. In the absence of a normative goal or decision rule, nothing in the training of economists can be used to determine which definition of property rights is best in the first place. There is nothing beyond impact analysis that the economist can contribute to the evaluation of these alternatives. The economist cannot compare policy alternatives in terms of economic efficiency.

This second approach to analysis more accurately reflects the nature of the policy choice than does a comparison of pecuniary price levels or even analysis of external diseconomies. The former is tautological and the latter assumes that relative prices are determined uniquely by consumers' and producers' actions in the market. While consumers' choices directly determine relative prices, policy choices determine the market rules within which those choices will be made. Thus, a different set of price relatives, a different combination of products, and a different income distribution will result under each policy alternative.

Therefore, price is a normative datum. The set of prices arrived at under one definition of property rights is a reflection of values underlying those property rights. Property rights issues arise from different sets of values which, if reflected in policy, lead to different Pareto-efficient allocations of resources.

To analyze a policy issue in the context of external diseconomies is to evaluate the policy choice in the context of one set of values. In fact, the policy choice is: Which set of values shall the market reflect?

Implications for Economists

Economists have drawn extensively on price-based (hence, normative) concepts to compare policy alternatives. These concepts include not only economic efficiency, but also marginal value product (as a measure of a factor's contribution to pecuniary output) and the concepts of producer and consumer surplus (as measures of welfare). The normative content of such concepts limits the ways in which the policy economist can apply analytics to the comparison of policy alternatives. This may leave him/her uneasy. As Boulding has said:

> We are strongly inbued today with the view that science should be *wertfrei*, and we believe that science has achieved its triumph precisely because it has escaped the swaddling clothes of moral judgment; it has only been able to take off into the vast universe of the "is" by escaping the treacherous launching pad of the "ought." Even economics, we learn in the history of thought, only became a science by escaping from the casuistry and moralizing of medieval thought. Who, indeed, would want to exchange the delicate rationality of the theory of an equilibrium price for the unoperational vaporings of a "just price" controversy? In the battle between mechanism and moralism generally mechanism has won hands down. . . . (pp. 117–18)

Economics, insofar as it addresses the fundamental economic (and policy) question of how scarce resources should be allocated among unlimited ends, has not escaped and, by definition, cannot escape the "launching pad of the ought." However methodologically attractive the use of price-based policy evaluation criteria, recognition that these criteria are inappropriate in such use demands adjustments by economists in their efforts to conduct policy analysis. Two possible adjustments are suggested below.

The first, and most logical adjustment is to compare nonmarginal policy changes in terms of their impacts on affected groups. That is, use the tools of economic analysis to identify the incidence of benefits and costs associated with policy alternatives. But it is essential that the analyst avoid the temptation to compare benefits to group A with costs to group B and then to conclude that one policy or the other is superior in terms of economic efficiency.

A second possible adjustment is for economists to give more attention to the design of policies and institutions which will achieve specified social and economic ends. The outlines of such an approach are provided in Lowe's appeal for an "instrumental economics," the nature of which is paraphrased by Heilbroner as

> the deliberate abandonment of economics as a science that reduces its conclusions or predictions from secure premises of behavior and technology, and its replacement by a conception of economics as a policy-oriented instrument whose major theoretical purpose is to discover what 'premises'—what behavioral forces, what technological constraints, what institutions—would be necessary to attain targets or goals. (p. 9)

Specifically, Lowe suggests that we begin policy analysis with the assumption of specified policy goals. One would then "work back" from the goals to identify preconditions to their achievement.

This focus need not draw economists into the debate regarding what policy goals "should" be. These are rightly defined by the body politic. The instrumental analysis of microbehavior is conceptually equivalent to the current approach to macroeconomic policy. Goals regarding inflation and unemployment are specified in the political arena and economists are consulted regarding preconditions to the achievement of these goals.

There is no ground for the charge that such an approach would draw economists far into the realm of the normative. In fact, instrumental economics would subject the economist to fewer such charges than is currently the case than when he argues that one policy alternative is more "economically efficient" than another.

In no way does the approach imply the abandonment of market economics or of price as a resource allocation mechanism. It does recognize that markets are instituted—that the outcome of free exchange through the price mechanism is a function of the institutional setting in which exchange takes place. Further, the existent institutional setting is the product of past public choices. There is never a policy vacuum. The implication is that there is merit in a conscious effort to shape the market to achieve desired resource allocation through the price mechanism. This effort will require multidisciplinary research involving economists, sociologists, psychologists, organization theorists, and legal specialists.

The development and adaption of a policy approach analogous to Lowe's is a major, long-term goal. A more immediate concern is to avoid the use of an economic efficiency criterion to compare policy alternatives.

Appendix

The Analytics of External Diseconomies

Let (4) and (5) be production functions for livestock (L) and health (H). Each product relies on a common factor, V, which is fixed. The quantity of V devoted to the production of L and H are V_1 and V_2, respectively. The output of health is negatively affected by the production of livestock since feed additives used in its production are damaging to health. The partial derivatives are

$$L = l(V_1), \tag{4}$$

$$H = h[V_2,\, l(V_1)], \text{ and} \tag{5}$$

$\dfrac{\partial L}{\partial V_1}$ and $\dfrac{\partial H}{\partial V_2}$ are positive because the common factor contributes to the output of both. But the partial derivative $\dfrac{\partial H}{\partial V_1} = \dfrac{\partial h}{\partial l}\dfrac{\partial l}{\partial V_1}$ is negative.

The achievement of a Pareto-efficient allocation of resources requires that the marginal rate of product transformation (*MRPT*) equal the marginal rate of commodity substitution (*MRCS*). The *MRPT* is equal to the ratio dH/dL, and the *MRCS* is equal to the ratio of product prices in a competitive economy.

The ratio dH/dL can be formed with the total derivatives of (4) and (5), as in (6):

$$\frac{dH}{dL} = \frac{\dfrac{\partial h}{\partial V_2}\,dV_2 + \dfrac{\partial h \partial l}{\partial l \partial V_1}\,dV_1}{\dfrac{\partial l}{\partial V_1}\,dV_1}. \tag{6}$$

Since $V = V_1 + V_2$, $dV = dV_1 + dV_2$. Because $dV = 0$, $dV_1 = -dV_2$ and (6) can be rewritten as (7),

$$(7)\quad \frac{dH}{dL} = -\frac{\frac{\partial h}{\partial V_2} - \frac{\partial h \partial 1}{\partial 1 \partial V_1}}{\frac{\partial 1}{\partial V_1}} = -\frac{\frac{\partial V_2}{\partial h}}{\frac{\partial 1}{\partial V_1}} + \frac{\partial h}{\partial l}$$

$$= -\left[\frac{\frac{\partial h}{\partial V_2}}{\frac{\partial 1}{\partial V_1}} - \frac{\partial h}{\partial 1}\right] = MRPT.$$

In factor-use decisions, firms producing H and L consider only those factors they control. They produce at levels consistent with the ratio of product prices P_H and P_L for H and L. Their profit functions, as defined by (8) and (9), were r is the price of V:

$$(8)\quad \pi_H = P_H\, h(V_2) - rV_2, \text{ and}$$

$$(9)\quad \pi_L = P_L\, 1(V_1) - rV_1.$$

When each firm maximizes its profits, it will allocate resources as indicated in (10), to be consistent with the price ratio ($MRCS$):

$$(10)\quad P_H \frac{\partial h}{\partial V_2} = P_L \frac{\partial l}{\partial V_1}, -\frac{P_L}{P_H} = -\frac{\frac{\partial h}{\partial V_2}}{\frac{\partial l}{\partial V_1}} = MRCS.$$

But under these conditions, $MRCS$ (10) and $MRPT$ (7) are not equal. A Pareto-efficient solution will not be achieved. In (11), $MRPT$ is greater than $MRCS$ because the term $\frac{\partial h}{\partial l}$ is negative:

$$(11)\; MRCS = -\frac{P_L}{P_H} = -\frac{\frac{\partial h}{\partial V_2}}{\frac{\partial l}{\partial V_1}} <$$

$$-\left[\frac{\frac{\partial h}{\partial V_2}}{\frac{\partial l}{\partial V_1}} - \frac{\partial h}{\partial l}\right] = \frac{dH}{dL} = MRPT.$$

This represents a lower price of L relative to H than is consistent with the $MRPT$. Thus, the external diseconomy created by L on the production of H prevents the Pareto-efficient allocation of resources.

Because the external diseconomy is not internalized by livestock producers, they behave as if the $MRPT$ were equal to (10). If livestock producers were to internalize the cost of health risk, they would behave as if the $MRPT$ were (7), thereby producing less L and more H. The effective cost (and equilibrium price) of L relative to H would rise such that society is left with a Pareto-optimal allocation of resources.

Testing for Homogeneity and Habit Formation in a Flexible Demand Specification of U.S. Meat Consumption

Rulon Pope, Richard Green, and Jim Eales

Three common practical problems facing empirical analysts of demand relations are (*a*) the choice of a functional form for econometric estimation, (*b*) the decision whether to deflate price and income data and the related question, "Are demand equations homogenous of degree zero?" and (*c*) the representation of changing preferences.

The purpose of this paper is to test for homogeneity conditions and habit formation in a flexible demand specification. Box-Cox transformations are applied to four meat demand relations in order to allow for more flexible functional forms. Estimators of the demand parameters are obtained by using maximum likelihood techniques, and tests of homogeneity and habit formation are based on the likelihood ratio procedure. The analyses utilize annual U.S. data on beef, pork, poultry, and fish for the years 1950–75, and short-run effects are emphasized.

Many studies have focused on the demand for meat. Fuller and Ladd, Hayenga and Hacklander, and Tryfos and Tryphonopoulos used linear functional forms. The log form was used in Fox and Breimyer. More recently, Chang used the Box-Cox transformation in a dynamic model to investigate aggregate demand for meat in the United States. The linear and logarithmic forms are special cases of this more general functional form.

The above studies make no attempt to test restrictions implied by consumer theory. In contrast, recently, Christensen and Manser applied a translog utility system to meat demand and estimated demand parameters and tested theoretical restrictions. However, most econometric analyses of demand in agricultural economics do not use explicit utility function formulations but use arbitrary reduced forms (one recent exception is the work by Green, Hassan, and Johnson). This study adopts the latter approach because of increased ease of estimation and the ability to incorporate greater complexity in the dynamic formulation. These relations can be made locally (or, in some cases, globally) consistent with utility maximization by imposing restrictions on parameters (Court, Byron). However, homogeneity can be imposed globally as well as locally within a demand equation for many log-linear demand equations—it is noted here that Court assumed, but did not test for, homogeneity; however, Byron and others have tested for homogeneity (and usually rejected it) in more aggregated log-linear static systems. Because all demand specifications (whether a system or single equation) are amenable to homogeneity tests and because of general interest in the deflation issue, this study focuses on homogeneity restrictions.

Model

The transformation developed by Box and Cox and extended in Zarembka is of the functional form,

$$q_t^{(\lambda)} = (q_t^{\lambda} - 1)/\lambda, \tag{1}$$

where q_t is the tth observation of a variable and λ is some real valued parameter. For a single-equation demand specification, and applying the Box-Cox transformation, the static model becomes

$$\begin{aligned} q_{it}^{(\lambda)} = \beta_0 + \beta_1 P_{1t}^{(\lambda)} + \beta_2 P_{2t}^{(\lambda)} + \dots \\ + \beta_n P_{nt}^{(\lambda)} + \beta_{n+1} Y_t^{(\lambda)} + U_t, \\ i = 1, \dots, n \qquad t = 1, \dots, T \end{aligned} \tag{2}$$

where q_{it} is the per capita quantity demanded of the ith commodity in time period t, P_{jt} is the corresponding price of the jth commodity in time period t, Y_t is the per capita disposable income in period t, and U_t is a random error. Equation (2) reduces to the linear form when λ equals one. This can be seen easily by inspection of the equation. As λ approaches zero, the model approaches the double-log demand specification (see Box and Cox). Thus, the above functional form is a more general specification than the typical linear and double-log relations often employed by economists.[1]

The elasticity of q_{it} with respect to one of the explanatory variables, say P_{jt}, can be shown to be

$$\epsilon_{ij} = \beta_j (P_{jt}/q_{it})^{\lambda}. \tag{3}$$

For the linear case, $\lambda = 1$, the elasticity approaches

The authors are, respectively, associate professor of agricultural economics, Texas A&M University, associate professor, and research associate, Department of Agricultural Economics, University of California, Davis.

Giannini Foundation Paper No. 585.

[1] By relaxing the restrictive assumption that all the λ's are the same for each variable the semilog and log-inverse functional forms can be obtained. However, to reduce the computational burdens, only a single λ in each equation is considered.

one as the explanatory variable (P_{jt}) increases (Chang, p. 356). For the double-log case, the elasticities are constant with respect to changes in the explanatory variable. For example, if $\lambda < 0$ and the commodity is a superior good ($0 < \epsilon_{qY}$), then ϵ_{qY} decreases as (Y_t/q_t) increases.

Homogeneity

Theoretically derived demand functions are homogenous of degree zero in all prices and income if and only if

$$(4) \qquad \sum_{j=1}^{n} \epsilon_{ij} + \eta_{iY} = 0 \qquad i = 1, \ldots, n$$

where η_{iY} is the income elasticity associated with the ith commodity. For the Box-Cox functional form, this condition can be expressed as

$$(5) \qquad \sum_{j=1}^{n} \beta_j P_j^{\lambda} + \beta_{n+1} Y^{\lambda} = 0, \qquad i = 1, \ldots, n.$$

Thus, the Box-Cox demand function is globally homogenous; that is, equation (5) holds for all prices and income, if and only if the following conditions are satisfied:

$$(6) \qquad \lambda = 0 \text{ and } \sum_{j=1}^{n} \beta_j + \beta_{n+1} = 0.$$

The Box-Cox functional form is locally homogenous at specified prices and income, $\bar{P}_j$ and $\bar{Y}$, if and only if

$$(7) \qquad \sum_{j=1}^{n} \beta_j \bar{P}_j^{\lambda} + \beta_{n+1} \bar{Y}^{\lambda} = 0.$$

Dynamic Representations

The demand relation in equation (2) does not allow for persistence or inertia in consumption patterns. In order to account explicitly for habit formation, three habit-version demand specifications are considered. However, unlike previous research, we will adopt the Box-Cox transformation for its added generality. The first extension of the static model in (2) assumes that taste changes can be treated by adding a time trend to the original model, t. The second habit specification assumes that adjustment of actual consumption to desired consumption is achieved only partially during any given time period because of habit effects (Houthakker and Taylor). The model, with the Box-Cox transformations, differs from the static model in that transformed lagged consumption, $q_{it-1}^{(\lambda)}$ is added. The third habit-formation version is similar to the state adjustment model, in unrestricted reduced form, of Houthakker and Taylor—discussed, for example, in Phlips (pp. 164–69). In this model the quantity demanded of the ith commodity is assumed to be a function of the psychological stock of habits (S_t), prices, and income. By assuming that the time rate of change in the transformed stock of habits is equal to current transformed purchases minus losses due to depreciation, and substituting for the transformed unobservable psychological stock variable, $S_t^{(\lambda)}$, the model (see, e.g., Phlips, p. 168) differs from the static model by the inclusion of q_{it-1}, P_{jt-1}, and Y_{t-1}, which are lagged values of the quantities, prices, and income, respectively.

The elasticity formulas for the dynamic models are the same as given in (3). However, consider the effects of habits on elasticities. For example, the change in the elasticity with respect to a change in habits (represented by time) for the own-price elasticity in the time trend model is

$$(8) \qquad \frac{\partial \epsilon_{ii}}{\partial t} = -\lambda \epsilon_{q_i P_i} \beta_{n+2} t^{\lambda-1} q_i^{-\lambda},$$

where β_{n+2} is the coefficient of time. For normal goods, sign $\partial\epsilon_{ii}/\partial t$ = sign ($\beta_{n+2}\lambda$). Therefore, habits may increase, decrease, or leave unchanged the elasticities. For example, if $\lambda = 0$, then (8) is zero. Therefore, global homogeneity, (6), implies constant elasticity, and thus, necessarily, changing habits do not alter elasticities. When $\lambda = 1$, from (8), an increase in habits make demands more inelastic when β_{n+2} is positive. Similar results may be obtained for the partial and state adjustment models.

Estimation Methods

For estimating the above models, it is assumed that the error terms are normally and independently distributed with zero means and constant variances, σ^2, for a given λ. Box and Cox and Zarembka show that, given the above stochastic specification, the concentrated log likelihood for fixed λ is, except for a constant,

$$(9) \quad L_{\max}(\lambda) = -n/2 \ln \hat{\sigma}^2(\lambda) + (\lambda - 1) \sum_{i=1}^{n} \ln q_i,$$

where $\hat{\sigma}^2(\lambda)$ may be considered an estimate of σ^2 obtained by regressing $q_t^{(\lambda)}$ on transformed prices and income.[2]

There are two approaches one can take in estimation of (9). One can transform the data so that $q^{(\lambda)}$ is regressed on $P_j^{(\lambda)}$ and $Y^{(\lambda)}$, using ordinary least squares (OLS). Then a search is conducted by varying λ so as to maximize (9). Alternatively, the unconcentrated or concentrated likelihood function could be optimized by gradient methods that con-

[2] The likelihood function in (9) supposes that the optimal λ transforms q to a normally distributed random variable. However, as a number of authors have noted, strictly speaking, $q^{(\lambda)}$ cannot be normally distributed since it is not defined over the negative line (Poirier). Yet, Draper and Cox have shown that if $q^{(\lambda)}$ is reasonably symmetric, then the maximum likelihood estimator is fairly robust to nonnormality.

Table 1. Maximum Likelihood Estimates of the Parameters for the State Adjustment Demand Equation, 1950–75

verge on the value of the optimal λ. The former method is used here: the optimal value of λ is obtained by combining (9) and the OLS package such that the maximum likelihood estimate of λ is obtained to within three significant digits.

Because we are using a single-equation approach, some problems of simultaneity may arise. However, we are considering the demand relation for a "representative" consumer and expressing quantities and income in per capita terms. Thus, prices and income can be taken as exogenous and a single regression is reasonably appropriate. Furthermore, assuming, as Chang and others have, that shifts in the supply function of agricultural products vary much more than the demand for those products, a demand relation can be estimated without serious problems associated with simultaneity. Even when a demand-system approach is taken, strong assumptions on the supply side have to be made even though they are rarely explicitly mentioned or accounted for. However, in principle, endogeneity of prices could be tested (Sims). Yet, these approaches are cumbersome to apply and seldom used. If one assumes endogeneity incorrectly, then biased estimation procedures are used when OLS is "best." However, if prices are endogenous and OLS is applied, then the resulting estimates also are biased, and inconsistent as well. In small samples, it is unclear which approach should be taken. Here, the logical foundations of the representative consumer model imply that OLS is appropriate.

The Empirical Application

The static and dynamic relations presume that all prices enter demand functions. Pragmatically, it is impossible to accommodate theory precisely. Researchers often follow two general approaches: (*a*) include the prices of close substitutes and complements directly and use a price index, e.g., Consumer Price Index (CPI), for all other prices either as a deflator or as a separate independent variable (Stone); and (*b*) exclude all prices other than close complements and substitutes (Hassan and Johnson). The former approach is taken here and

was first used by Stone.[3] Income per capita is deflated by the CPI leaving the homogeneity test:[4]

$$\sum_{j=1}^{n} \epsilon_{ij} = 0 \qquad i = 1, \ldots, n.$$

The data used to obtain parameter estimates and to perform the above homogeneity tests are U.S. time-series observations on beef, pork, poultry, and fish 1950–75. Variables used are per capita food consumption in retail weight equivalents (1970 base), per capita income deflated by the CPI, and implicit price indices (1970 = 100) for the commodity groups (Food Consumption, Prices, and Expenditures).

Empirical Results

Parameter estimates for the three habit-formation models and for each of the four meat commodities were obtained. Based upon likelihood ratio tests, the static and partial adjustment models were rejected in favor of the state adjustment model. For the sake of brevity, only the latter results are given in table 1. (See Pope, Green, Eales for more details.) Results are recorded for the linear, double-log, and the functional form associated with the maximum likelihood value for λ. Though the estimates for the linear and double-log forms are maximum likelihood estimates (MLE's), given λ = 1 and λ = 0, respectively, only the estimates using the value of λ which maximizes (9) will be referred to as the MLE's.

With respect to goodness-of-fit measures, the adjusted R^2 values for all commodities and models indicate high degrees of fit. In most cases, the adjusted R^2 values are in the 80% to 90% range. The Durbin-Watson values do not suggest rejection of the null hypothesis of zero autocorrelation. In general, for the case of lagged dependent variables, the Durbin h-values are not suggestive of autocorrelation problems.

Income and Price Parameter Estimates

All direct own-price coefficients are negative for all commodities and functional forms with few exceptions. For the commodity, fish, in the double-log

[3] All of the results reported in this paper also were obtained using the second approach. Often the results differed substantially; yet the major conclusions of this paper are unaltered. Based upon theoretical and pragmatic reasons and the qualitative results, Stone's approach appeared superior.

[4] Implicitly, this assumes that the CPI is homogenous of degree one. The method used by Stone is attractive because it reduces collinearity as compared to the case where the CPI enters as a separate independent variable.

form and for the static and state adjustment models, and for all of the time-trend models, the own-price coefficient is positive. However, in all such cases, the coefficients are not significantly different from zero using any commonly used significance levels. In addition, all the own-price coefficients for the other commodities are significantly different from zero at the .01 level.

In general, the cross-price effects are positive, indicating gross substitution among commodities: the exceptions involve the commodity fish. The t-values associated with cross-price derivatives are usually smaller than those related to the own-direct-price coefficients. The estimated income effects are positive, indicating superior commodities. In most cases, these coefficients are significantly different from zero at the .05 level. Also, t-values are usually higher for the MLE estimates.

Homogeneity and Functional Form

The estimated λ's varied substantially across commodities and model specifications. They range in value from $\lambda = -.6$ to $\lambda = 2.8$. To determine if the linear and double-log forms differ significantly from the functional form obtained by maximizing the likelihood function, likelihood ratio tests are performed (Theil, pp. 396–97).

The likelihood ratio test results indicate that linear demand functions cannot be rejected for beef regardless of the model specification. However, the double-log form is rejected for both the partial and state adjustment models. For pork demand, the double-log specification is rejected in every case, while the linear formulation is rejected only for the state adjustment model. Almost the reverse is implied for poultry demands: the linear specification is rejected in every model, while the double-log rejected only for the time-trend model. The line and double-log specifications are rejected for fis demands in the partial and state adjustment model

These results provide strong support for the pos tion that more careful consideration needs to b given in the functional forms of demand relatio for meat. The traditional linear and double-lo forms are frequently inadequate.

Tests for global [refer to equation (6)] and loc [refer to equation (7)] homogeneity conditions the Box-Cox demand relations are provided in tab 2. Global homogeneity is rejected for all models an all commodities with the exception of poultry in th state adjustment model. Thus, the hypothesis of n money illusion is rejected in nearly every case. T put these results in perspective, others using th Rotterdam and log-linear demand systems als have rejected the property of homogeneity usin static aggregate systems (Barten, p. 46).

We also imposed local homogeneity conditions the means of prices and income in a manner simil to Byron and Court, who used a static log-linea demand system. Tests for local homogeneity cond tions are presented in table 2. These results a somewhat in contrast to those obtained for glob homogeneity. For example, local homogeneity not rejected in any model for pork; however, loc and global homogeneity is rejected for beef de mand. In general, the frequency of rejection of loc homogeneity is large but less than the frequency rejection of global homogeneity.

In summary, the results of table 2 indicate th homogeneity of meat demands is not a warrante maintained hypothesis. Therefore, our results su gest that a researcher should be cautious whe choosing between regression methodologies usin

Table 2. Results of Local and Global Homogeneity Tests Based on the Likelihood Rati Procedure

Commodity	Static	Time Trend	Partial Adjustment	State Adjustme
	Values of $-2 \ln \hat{\lambda}$			
1. Beef				
a. local	26.429*[a]	22.068*	14.001*	5.082*
b. global	29.475*	22.130*	29.367*	20.973*
2. Pork				
a. local	0.216	0.125	0.180	1.758
b. global	17.489*	16.677*	16.274*	6.953*
3. Poultry				
a. local	10.136*	2.542	9.909*	1.86
b. global	13.788*	15.434*	16.219*	2.022
4. Fish				
a. local	21.273*	8.264*	—[b]	0.749
b. global	21.553*	14.411*	15.874*	17.493*

Note: In every case the models are compared against the unrestricted maximum likelihood forms.

[a] The computed values are to be compared with the critical X^2 values of $X^2_{.05}$ (1) = 3.84 for the local homogeneity tests and $X^2_{.05}$ (2) 5.99 for the global homogeneity tests.

[b] No global maximum of the likelihood function could be obtained for reasonable values of λ.

either deflated or nondeflated data.[5] Because of the broad class of models considered and our choice of flexible functional forms, these results appear of general interest to researchers in demand analysis.

Price and Income Elasticities and Tastes

The price and income elasticities for the state adjustment model are presented in table 3. As can be observed from the entries in the table, generally the elasticities are relatively small (inelastic). Note that though homogeneity was usually rejected, the calculated elasticities, under the unrestricted, local, and global homogeneity restrictions, are similar. The values were computed at the means; however, their behavior generally will differ considerably over time, depending upon the value of λ computed by the maximum likelihood procedure. An exception is when $\lambda = 0$. In this case, elasticities are constant and invariant with respect to taste changes.

Clearly, the static model implies that tastes do not affect the elasticities. For the time-trend model, λ is positive for all commodities except poultry. Further, all of the estimated time coefficients (MLE) are positive except fish. Following (8), the passage of time implies that beef and pork demands are becoming more inelastic, while poultry and fish demands are becoming more elastic. Also, following calculations similar to (8), the results from the time-trend model indicate that beef and pork demands are becoming more income inelastic over time, while poultry and fish are becoming more income elastic.

For the state adjustment model, adapting Houthakker and Taylor's approach, it can be shown that the marginal effects of habits on demands (or elasticities) can be determined from the reduced-form model (see Philips, p. 168). In our case, it was not possible to apply the restrictions on reduced-form parameters as implied by the structure and perform nested hypotheses tests. Hence, these marginal effects cannot be estimated uniquely from the reduced form. However, given the state adjustment rationalization of (6), the estimated marginal effects of habits on the quantities demanded are positive for all commodities with the exception of fish.[6] This corresponds to the results derived from the time-trend model. Further, the marginal effects of habits on own-price elasticities is given by (8), where t is replaced by the stock of habits, S_t, and α is its associated coefficient in the structural state adjustment model. Hence, beef and pork demands become more price inelastic as the stock of habits increases.

Policy Implications and Conclusions

Theoretically, there is a direct linkage between demand relations which are homogenous and flexible. Our results indicate overwhelming evidence for rejection of homogeneity when a flexible functional form is used to model meat demand. These results, though at variance with the theory of individual choice are consistent with the findings of other researchers who tested homogeneity in demand systems with more restrictive functional forms and representations of changing tastes (see, e.g., Bar-

[5] If global homogeneity holds, then elasticity estimates should not be sensitive to the deflator used. However, if it does not hold, then parameter estimates will depend upon the deflator used, and regressions using nominal and deflated data will give different elasticity estimates. Hence, when homogeneity does not hold, a non-nested testing procedure must be used in order to find the "best" model. It should also be noted that local homogeneity is not a nested model of a globally homogenous model.

[6] The estimates for α, the habit coefficient, are approximately $\hat{\alpha} =$ 1.7, 0.4, 1.1, −1.4, respectively, for beef, pork, poultry, and fish.

Table 3. Price and Income Elasticities for the State Adjustment Model under Unrestricted, Global, and Local Homogeneity

c. local	0.468	0.115	−0.268	−0.314	0.810

[a] The unrestricted model refers to the Box-Cox functional forms without the homogeneity conditions imposed.

ten). Therefore, the many varied ways of deflating data may lead to substantially different results.

Intimately linked to the homogeneity issue is that of functional form. The results reported here suggest that the linear and double-log functional forms are inappropriate as maintained hypotheses. The best functional form, however, is sensitive to the manner in which changing tastes are represented and to the commodity studied. Yet, for pork demands, the often used double-log form was rejected for every model considered. We conclude on the basis of likelihood ratio tests, that Box-Cox transformations may be a useful tool for analysts of meat demand because the double-log and linear functional forms were rejected in many of our cases.

Finally, the Box-Cox demand functions allow flexibility in the way habits affect demand elasticities. Suppose an increase in habits implies that the own-price demand elasticity increases (becomes more inelastic), then the double-log form would measure this phenomena incorrectly because elasticities do not change. Our results indicate that the impact of a future policy aimed at raising price may have a much lower effect on beef and pork demands (and larger impact on expenditures) than predicted from a double-log model (*ceteris paribus*).

)pen-Loop Stochastic Control of Grain Sorghum rrigation Levels and Timing

,uis R. Zavaleta, Ronald D. Lacewell, and C. Robert Taylor

rop growth simulation models that consider the oil-plant-atmosphere continuum recently have be- ome an important research tool. Examples of rowth simulation models include those for corn Curry and Chen), cotton (Baker, Hesketh, Dun- an), alfalfa (Miles et al.), barley (Kallis and Toom- ıg), wheat (Trenbath), and grain sorghum (Arkin, 'anderlip, Ritchie). This article investigates the tility of the grain-sorghum-growth simulation ıodel of Arkin, Vanderlip, and Ritchie as an irriga- on management tool on the Texas High Plains ith economic criteria guiding decisions.

Most water-use studies (e.g., Swanson and Thax- on; Jensen and Musick; Shipley, Regier, Wehrly) mphasize the need for coordinating irrigation with vater requirements of the plant during critical tages of plant development. Yield response attrib- ted to a specific irrigation depends upon several ictors, including: (*a*) amount of soil moisture vailable at the time of irrigation; (*b*) stage of the lant development; and (*c*) interaction effect from revious or subsequent irrigations, or both, which educe or eliminate moisture stress conditions. Iormally, three or four irrigations are applied to rain sorghum in the Texas High Plains to meet vater use requirements during the growing season. pplications may vary from only one preplant to as ıany as six postplant waterings (Shipley and Re- ier).

Increasing concern for the declining groundwater upply and energy costs along with potential energy urtailments in the region emphasize the impor- ance of improved irrigation planning and manage- ıent. Potential fuel curtailments magnify the already existing degree of risk and uncertainty of farming in areas with low and unstable rainfall. This uncertainty results in production practices that depart from the optimal deterministic input-output combinations, even for risk-averse producers. Previous estimates of economically optimal irrigation water application rates, and estimates of the impact of rising energy costs were primarily based on the assumption that the producer knew in advance the state of the different future environments that would surround him (Casey, Jones and Lacewell; Lacewell; Condra and Lacewell). Climatic, institutional, and economic conditions throughout the production year were considered as known at the beginning of the year.

To overcome these limitations, the computerized grain sorghum growth model was modified to consider stochastic situations in weather and/or institutional factors, and allow irrigation timing and quantity decisions to be based on an expected profit-maximizing criterion. The model was used to address two basic issues: (*a*) irrigation strategies that maximize net returns per acre of sorghum; and (*b*) the expected effects that irrigation fuel curtailments would have on the distribution of optimum amounts of irrigation water among the remaining irrigation periods and associated impact on grain sorghum yield and net returns.

The analysis of optimum irrigation strategies and effect of fuel curtailment were addressed under weather scenarios of (*a*) perfect knowledge, and (*b*) stochastic events. Throughout this analysis it is implicitly assumed that sophisticated irrigation technologies exist. This technology is loosely defined as that which would allow the application of up to eight postplant irrigations in a timely sense and would permit application of specific as well as small amounts of water.

Optimal Allocation in a Dynamic and Stochastic Environment

The problem of optimal allocation of irrigation water in a production process over one growing season can be represented by the following set of equations:

$$(1) \quad J(\mathbf{X}_t, \mathbf{U}_t, t) = \sum_{t=0}^{T-1} I(\mathbf{X}_t, \mathbf{U}_t, t) + F(\mathbf{X}_T),$$

where J is a function made up of the summation of the net returns from a T-stage system operating under a deterministic environment; the intermediate function $I(. . .)$ represents the values for each period up to $T-1$; $F(.)$ is the gross revenue or terminal state function. The vector of state variables, $\mathbf{X}$, represents the values obtained by the system at each period t, while $\mathbf{U}_t$ is the control vector.

Maximization of the objective function (1) is subject to

$$(2) \qquad X_{t+1} = f_t(X_t, \mathbf{U}_t, t),$$

$$(3) \qquad g(X_t, \mathbf{U}_t) \leq b_t,$$

where the planting date, (t_0), the state of the system at planting time, (X_0), and the date at which the physiological maturity of the plant is reached, (T) are characteristics determined within the system. Equation (2) represents the dynamic behavior of a deterministic system indicating that the change in the level of the state variable at any instant is a function of its present state, the decision taken, and the time period; equation (3) represents the constraints imposed on the control variables.

Similar to the deterministic case, the problem of optimal allocation of irrigation water in a production process when stochastic conditions exist can be modeled as a control problem. In those cases where uncertainties can be adequately described as stochastic processes, the state of the system at time t is presumed to evolve according to

$$(4) \qquad \mathbf{X}_{t+1} = f(\mathbf{X}_t, \mathbf{U}_t, \mathbf{V}_t, t), \quad t = 0, 1, \ldots, T-1$$

with $\mathbf{X}_t$ and $\mathbf{U}_t$ being vectors of the state and control variables at time t, and $\mathbf{V}_t$ being the vector of stochastic factors. In this case, the choice of controls, which is a multistage decision process, constitutes a stochastic problem, and the way of choosing $\mathbf{U}_t$ determines the class of control policies to be applied. These classes of stochastic control policies are defined according to the information on past and anticipated future observations available to the controller. Knowledge about the probabilities of future observations allows the controller to anticipate statistically the information to be obtained from subsequent observations, with the anticipated information used in deciding the most desirable present action.

According to the amount of information used, four classes of stochastic control policies—as defined by Bar-Shalom and Tse—can be distinguished: open-loop (OL), open-loop feedback (F), m-measurement feedback (mF), and closed-loop (CL). It should be noted that F, mF, and CL have the same information about the past. The only difference among them resides in the anticipation of future knowledge. Of these four policies, the optimal stochastic control belongs, in general, to the closed-loop class (Bar-Shalom and Tse; Intriligator; Rausser).

Inherent analytical difficulties in deriving the closed-loop control rule suggest other policy classes should be used as an approximation. Analytical hardships can be reduced by decreasing the amount of information anticipated by the decision maker. Because of the complexity involved in modeling and analytical solution of the stochastic closed-loop policy, the stochastic open-loop feedback control was considered as an alternative for this study. Although the limitation of finding an analytical solution could not be overcome for this control, the possibility of being modeled so as to obtain a numerical solution leaves it as a viable alternative.

Model Description and Procedure

The basis of this study is the computerized grain sorghum growth model developed by Arkin, Vanderlip, and Ritchie. The core model is a system representation of the soil-plant-atmosphere continuum. Because a detailed description of the model is available, this discussion is limited to a brief account of the relevant components.

The model is based on a set of physiological efficiency functions that reflect effects of all (nonoptimal as well as optimal) weather and irrigation conditions. At the heart of the model is a net photosynthesis efficiency function. Potential net photosynthesis (Po) is defined as the net CO_2 fixed on a ground area basis for nonlimiting water and temperature conditions. When limiting factors exist, the potential value is reduced by some fraction that reflects the stress imposed on the plant due to the presence of a nonoptimum environment; i.e., extremely high or low temperatures and/or lack of water availability. Whenever water or temperature conditions are limiting, net photosynthesis is considered given by

$$(5) \qquad P = (Po\, \xi_1\, \xi_2) - N,$$

where P is the net photosynthetic rate of the crop; Po remains as defined before; ξ_1 and ξ_2 are efficiency parameters corresponding to temperature and soil water; and N is the value of the nighttime respiration losses. The parameters ξ_1 and ξ_2 are dimensionless fractions whose values vary between 0 and 1, depending on stress. Expression (5) was based on the assumption that limiting variables in the environment proportionately reduce the photosynthetic rate regardless of the value of the other limiting variables. Each efficiency parameter represents a particular environmental constraint on the photosynthetic rate.

The temperature efficiency parameter, ξ_1, forces a complete inactivity in photosynthesis for values below 5°.centigrade (C) and above 45°.C. An optimal range is considered to be between 25° C and 40° C. Limitation in soil moisture is reflected by the coefficient ξ_2. Reductions in net photosynthesis

re considered to be proportional to the reduction ı plant evaporation resulting from a limited supply f water. As reported by the study, plant evapora- on is not affected until a threshold of extractable oil water is reached. When approximately 80% of ıe extractable soil water is depleted by evapo- anspiration, the value of the soil water parameter, ,, becomes less than one indicating net photosyn- ıesis is affected. This relationship is somewhat peculative, and net photosynthesis may be af- cted to a larger degree if it is limited more by plant ater status than it is by evapotranspiration (Arkin, anderlip, and Ritchie).

Model application requires specification of the umber of leaves produced by the plant, the maxi- ıum area capable of being developed by each leaf, lant population, row spacing, planting date, titude, extractable soil water content on planting ate, and extractable soil water capacity. The plant sed in the simulation model was considered to ave seventeen leaves—each one with a maximum rea of 0.88, 2.30, 7.60, 12.30, 22.80, 42.50, 69.50, 13.00, 170.80, 248.80, 287.00, 357.50, 336.50, 40.80, 272.30, 209.30, and 116.00 centimeters cm.), respectively (Arkin). A row spacing of 68.60 m. was used in equipopulated plantings of grain orghum together with a population level of 148,200 lants per hectare (ha.). Latitude is also required ecause the sun's altitude and azimuth determine ıading of leaves. The soil water content was con- dered to have a maximum capacity of 15 cm. xtractable soil water content on planting date was onsidered to be 10 cm. to reflect a preplant irriga- on of approximately 4 inches.

Although the grain sorghum model simulates aily conditions, determination of optimum irriga- on levels on a daily basis would be computation- lly prohibitive. Consequently irrigation was con- dered in only eight periods, which were the twen- eth day after plant emergence and every tenth day ıereafter until harvest.

he Feedback Model

he approach to simulating the performance of pen-loop stochastic control for the problem at and is to first solve a deterministic optimization roblem for all eight irrigation periods within a crop ear. The deterministic model is formed by replac- g all stochastic variables with their expected val- es which are conditioned on weather prior to the rst irrigation period. Then the irrigation level ob- ined for the first period is applied, with the solu- on for all other periods ignored. Actual weather etween the first and second irrigation periods is ıen used to update the system and also to revise ıe conditional expectations for the remaining fu- ıre periods. With the revised conditional expecta- ons, a deterministic optimization model for the econd through the eighth period is solved, with nly the solution for the second period used in the mulation. This updating and repeated solution process continues in the above manner until a solution for the eighth period (i.e., a solution to a one-period optimization model) is applied to the system. Finally, actual weather throughout the growing season is simulated with the irrigation levels for the eight periods to obtain actual crop yield and net returns.

Generation of Conditional Expectations

Generation of conditional expectations was based on research by Rockwell, who concluded that the presence of rainfall could be treated as a binomial random variate, with the amount of rainfall determined by an empirical distribution modeled for each month. The distribution obtained was assumed to satisfy

$$(6) \qquad X = (e^{F(X)n/\hat{b}} - 1)/\hat{a},$$

where $\hat{a}$ and $\hat{b}$ are the parameters estimated by the nonlinear regression

$$(7) \qquad RANK = b \ln[a(X) + 1],$$

where $RANK$ is the number of observations for each level of rainfall, X is the amount of rainfall observed, and n is the maximum value for $RANK$. If the occurrence of rain was determined, the amount in which it happened was estimated by equation (6).

The probability distribution for solar radiation was based on a three-way empirical frequency table conditioned by both precipitation and maximum temperature for the day. A three-way empirical frequency table was also built for maximum temperature (*TEMPMX*). The value of *TEMPMX* was conditioned on that day's amount of rainfall and the maximum temperature during the previous day. Finally, once maximum temperature was determined, minimal temperature was estimated by means of a transformation under the assumption that these two variables were approximately bivariate normal distributed.

Based on these conditional expected values for all future periods, the amount of irrigation water to be applied during specified periods of the production process to maximize expected per acre profit were computed. A quasi-Newton method was used to numerically search for the profit-maximizing control vector.

Results

Analysis of optimum irrigation strategies and effect of fuel curtailment were addressed under scenarios of (*a*) perfect knowledge case (known weather pattern) for which the open-loop feedback control yields the optimal closed-loop solution; and (*b*) the stochastic case (random climatic values as well as uncertain energy curtailments) for which the open-loop feedback control is used as an approximation

to the optimal closed-loop control. The analysis was extended over thirty simulated sets of weather patterns, based on daily weather records obtained from the Texas A&M Experiment Station near Lubbock for the 1945–77 period.

For the analysis, the price of natural gas was assumed to be $2.50 per one thousand feet (mcf). Well characteristics were assumed to be a lift of 250 feet and a yield of 800 gallons per minute at 30 pounds pressure per square inch. Other costs of production were taken from enterprise budgets applicable to the region (Extension Economists-Management). The price of grain sorghum was set at the 1978 target price of $4.07 per hundredweight.

Perfectly Known Environments

For this case, all environments (economic, climatic, and institutional) are assumed to be known at the beginning of the simulation process. As contrasted to the stochastic case, values of the control variable can be, and in fact are, established in the first period. This is because in all subsequent periods, the expected values are identical to the realized or actual values, hence, no adjustments are needed during the growing season. These results provide the optimal or profit maximizing irrigation strategies in the absence of weather risk and, hence, a benchmark for determining the performance of the stochastic open-loop control policies.

Table 1 summarizes results obtained for thirty different weather patterns. Amounts of water used in the eight irrigation periods within a specific year differed as well as the levels applied in each period across the years. These results indicated that frequent irrigations with small application rates produce, *ceteris paribus*, higher net returns than a strategy of applying the same total amount of irriga tion water on a less frequent basis. Of course, practical constraint to several small irrigation appli cations is the limited number of wells on a typica farm. Irrigation application numbers and rates ar sensitive to acres irrigated and the type of distribu tion system.

The total amount of growing season water to b applied could be expected to be in the range of 10. to 11.5 inches 95% of the time. This is irrigatio water applied to the plant and does not includ distribution system or environmental losses asso ciated with applications. In addition, preplant irri gation water is not included. It is assumed that soi moisture is available at planting. Thus, to obtai total irrigation needed, the preplant applicatio (about 4 inches net to the plant), would have to b added. An average amount of 1.1 to 1.4 inche would be required in all periods but the first, whic needs an average amount of 2.6 inches.

Of particular importance are the maximum an minimum values of irrigation water required at eac period and especially the minimum values. Thes quantities of irrigation water, over the thirty year of weather patterns, indicate that a profit maximizing producer should irrigate in at least fou periods in all years; i.e., the first, sixth, seventh and eighth. In the first period, a minimum amoun of about 1.5 inches can be expected in any year.

Under the assumed economic, institutional, an climatic conditions, average yield and net return that could be expected are about 90 cwt. and $110 respectively, as shown in table 2. Values for thes two variables would be expected to fall in the rang of approximately 87–91 cwt. and $102–$116, 95% o the time. This provides an indication of the op timum allocation of water under perfect knowledg and a good indication of the true optimum, aver aged over time.

Stochastic Environments

The complete knowledge assumption was relaxed to reflect two cases: (*a*) stochastic weather environments, and (*b*) stochastic weather with energy curtailments. In the first case, results obtained from using the open-loop feedback control are compared to the results obtained from the perfect knowledge case to provide implications of the effect of uncertainty on overall performance of the model.

Results of the open-loop stochastic control strategy without energy curtailments are summarized in table 3 for thirty simulations. Compared to the perfect knowledge case (table 1), the mean values for irrigation water applied were always slightly higher for the stochastic case. For periods 3 through 8, the increase in irrigation level is from .3 to .5 of an inch or a 20% to 30% increase. For the stochastic weather case, some irrigation water is always applied in every period contrary to the perfect knowledge case.

Thus, general interpretations are that with the open-loop feedback control, results obtained for yields did not differ from those obtained in the perfect knowledge case. However, differences between the two cases were found in the optimal amount of water to be applied and therefore in cost and net returns. In the stochastic case, the use of irrigation water had a mean value of 13.80 inches, approximately 25% more than in the case of complete knowledge. Because of the higher amount of water used per acre, net returns were diminished by 10% (from $110 in the deterministic case to $99 in the stochastic case). This could be considered to be the cost of not possessing complete information.

Stochastic Energy Curtailments

To evaluate the effects that potential energy curtailments may have on producer's net revenues, yields, and water used, fuel curtailments were incorporated by blocking any irrigation for a predetermined period or periods. For this analysis, stochastic weather patterns also were used. Different sets of shocks (curtailments) were introduced to the system as random events. Three arbitrarily defined time spans of curtailments were examined (ten, twenty, and thirty days in duration). In all cases analyzed, it was assumed that the producer

[a] Irrigation water applied to the plant excluding a pre-plant irrigation.

could not foresee the future existence of energy restrictions, so optimal allocations of irrigation water were sought assuming complete availability of water. For those periods where curtailments had been defined to take place, the initial decision to irrigate was overriden, forcing the model to consider rain as the only source of water. In the present context, curtailments should be considered as the number of days by which planned irrigation is delayed.

For ten-day curtailments, there were no changes in yields or total amounts of irrigation water as compared to the stochastic situation presented in table 2. Only the distribution of the water used per period changed. The analysis suggests that to obtain maximum net returns, the best action to follow after a ten-day curtailment is to supply the plants with the moisture required so that no major stress is imposed in growth. This alternative is subject to the condition that optimal amounts of water had been supplied in the previous periods, and that water will be delivered immediately after the curtailment has ceased.

Net revenues for the three different twenty-day curtailments analyzed reflected a decline in their mean value as shown in table 4. Net returns are more severely affected when curtailment takes place during the period of forty to sixty days after emergence. During this period, the head is developing and sunlight interception approaches its maximum. In this period, growth and nutrient uptake occur rapidly, necessitating adequate supplies of nutrients and water.

In the case of curtailments during the forty to sixty days after emergence period, net returns decreased 28% with respect to the no-curtailment case. What is even more significant, though, is the increase in the coefficient of variation: from approximately 18% (for the no-curtailment stochastic case of table 2) to 42%. The minimum value of net returns dropped from $62 to $12, while maximum net returns declined from $132 to $119. The same trend was observed for yields; for a mean of 90 cwt. without curtailment to 80 cwt. (approximately 11% less).

Similar consequences were observed for curtailments during the half-bloom and soft-dough stage of the plant (approximately sixty through eighty days after emergence). In these periods, grain formation begins. Any reduction in plant size and leaf area occurring in this period cannot be completely overcome in later periods. Net returns for curtailments during these stages were observed to decrease about 16% (from $99 for the no-curtailment case to $83), and their variation increased from 18% to 30%. Yields for these periods also experienced a decline of 7%.

Impacts similar to the twenty-day curtailment are obtained for the thirty-day case except the effects are greater (table 5). Periods where curtailment was imposed were twenty to fifty and forty to seventy days after plant emergence. Of the two instances, the latter reflected more severe impacts. During these periods, and different to the cases analyzed before, negative net returns are present in the solutions obtained for some years.

Average net returns and yields for the twenty to fifty and forty to seventy day after plant emergence curtailment are $67 and $50 and 77 cwt. and 73 cwt., respectively, representing a decrease of almost 50% and 19% with respect to the noncurtailment case.

In summary, the primary effects of irrigation curtailments are to reduce net revenues and increase their relative spectrum of fluctuation. The amounts in which they are reduced is dependent upon the stage of growth of the plant and the time span of the curtailment.

These estimates should be taken as being conservative. To obtain them, the model—using the assumption of immediate delivery of water—

[a] Irrigation water applied to the plant excluding a pre-plant irrigation.

optimizes the amount of irrigation water needed at the time that it is required. However, with the given state of the arts, this may not be the case. The twenty- or thirty-day curtailment period might be applicable to much shorter actual fuel curtailment periods. Producers lose not only the time of fuel curtailments but, also, they must cover many acres with a limited number of wells. As a result, a ten-day fuel curtailment could easily result in a twenty- to thirty-day delayed irrigation on some fields.

Concluding Remarks

As a last word of caution it should be pointed out that this study could not cover and evaluate all possible alternatives that might arise; therefore, certain needed constraints and limitations were adopted: to determine the optimal time trajectory for the control variable, the assumption of profit maximization was made. However, this goal may not reflect the objective of each producer. Other goals could be alternatively specified, i.e., secure some minimum net return or produce to the extent that minimum variations in net returns are obtained. Which specification is chosen may alter the value of the control variable.

The process of numerical search to maximize the value of the objective functional by no means assures a global rather than a local maximum. Though parametric analyses were made to assure that no other higher values exist at least in the vicinity, the possibility of finding higher values is still open. The main reason for this resides in the highly nonlinear shape of the objective functional.

Optimization of net revenue was made under the assumption that water was available at the time needed and in the amounts required. However, as mentioned before, a limited number of wells imposes the restriction of a limited amount of water that can be obtained in a given period of time while typically there are approximately 80 acres to be irrigated from each well.

Optimization was made with respect to the use of water and assumes the plant is affected exclusively by the climate. Inclusion of fertilizer and insect interaction would help on the predictive ability of the model.

Lastly, grain sorghum is considered to be the only crop under production. Most farmers grow more than one irrigated crop; consequently, in cases where water is a limiting factor, other crops would compete for the supply of the resource determining a possible different allocation for the control variable.

Empirical Estimates of Interregional Feedback in Input-Output Models and Model Approximations

Dean F. Schreiner and James C. Chang

.egional input-output models have been used idely to analyze impacts of exogenous changes to region's economy or the effects of economic rowth on a region. In addition, regional input-utput models have had application in energy and nvironmental planning. Richardson's book gives a seful summary of input-output models, their appli-ation and their limitations.

What has not been covered adequately in the terature is the importance of "interregional feed-ack" when using a regional rather than an interre-ional input-output model. Interregional feedback defined as the secondary trade effects in the out-ut of one region from an increase in that same egion's final demand. An increase in output in re-ion *m* will lead to an increase in *m*'s imports from ome or all of the other *r*-1 regions in the system, nd the induced expansion in those regions' exports ill have a multiplier effect on levels of output. These higher output levels will be associated with sing imports, some of which will take the form, ither directly or indirectly, of expanded exports om region *m* (Richardson, p. 78).

How important are interregional feedbacks? Vhat can be done about estimating feedbacks short f constructing a complete interregional model ithin a relatively closed system? This study esti-nates the interregional feedback effects for the tate of Oklahoma utilizing the data sets developed y the Harvard Economics Research Project HERP) and contained in the Multi-Regional nput-Output (MRIO) analysis studies (Polenske et l. 1972b, 1974; Rogers 1972, 1974; Scheppach 972). Second, an approximation model is tested to etermine the accuracy of an interregional model onstructed by "nesting" a subset of regions within larger closed system. Estimates of interregional rade are required for the approximation model.

Interregional Feedback

Interdependence arises not only among sectors within a region but also among sectors between regions (Moses, Richardson). For example, an increase in demand for fed beef increases feedlot output in Oklahoma. Expansion in feedlot output increases the demand for feed grains from the Midwest, which, in turn, increases the demand for petroleum products produced in Oklahoma. Interregional feedback is this secondary trade effect in Oklahoma from an increase in final demand for fed beef. The first comprehensive accounting of commodity flows among states is recorded in Rodgers (1974). For the present study a three-region model is used. It is composed of separate regions for the states of Oklahoma and Texas and a third region, Rest of U.S. (RUS). The three-region trade model permits estimation of interregional feedbacks.

The principal data source is the MRIO model. The model affords both industrial and regional disaggregation, providing data for seventy-nine industry sectors and fifty-one regions. The data source covers the years 1947, 1958, 1963, 1970, and 1980. It is presented and documented in the five previously mentioned published volumes. A sixth publication, *A Guide for Users of the U.S. Multiregional Input-Output Model,* is also useful (Polenske 1972a). The model is flexible because of the level of disaggregation. The data are accessible and well-documented. Consistency with national aggregates in employment, output, final demand, and trade is maintained throughout. These features make it a useful model for the present study.

The authors have applied an aggregated version of the MRIO model to determine regional dimensions of U.S. agricultural growth and policy (Schreiner, Chang, Flood). In particular, the regional dimensions were the employment and income impacts on the southwestern states of Oklahoma and Texas of alternative growth and policy assumptions for U.S. agriculture. The National Economic Analysis Division (NEAD) of Economics, Statistics, and Cooperatives Service (ESCS) provided projections of alternative futures to 1980 and 1985 for U.S. agriculture based on different scenarios of growth in U.S. exports, population, and income (Smith et al.). The results of that study

(Schreiner, Chang, Flood) are not the focal point of this presentation. However, that study provides the model for testing interregional feedback and the results of an interregional approximation method.

The Model and Its Application

Regional input-output data are available in the format presented in Polenske (1972a). Total regional consumption (row total) for each sector is the sum of interindustry inputs, service industries residual, final demand, and secondary product transfer-out. The interindustry matrix is a seventy-nine-sector model. Service industries residual are the result of balancing total regional consumption with total regional output for those service sectors where regional trade was not estimated. The present study has used the regional trade data for sixty-one of the seventy-nine sectors.

Total regional consumption does not identify where products were produced. Hence, the row totals for each of the seventy-nine industry sectors are not necessarily equal to the corresponding column totals of regional output except for the nontraded service sectors.

Columns in the input-output table represent the regional input structure for each of the seventy-nine industry sectors. Total regional output (column total) is equal to regional production plus transferred imports, secondary product transfer-in, inventory depletion, and scrap production. Components of regional production are available in Rodgers (1972).

The columns of the regional input-output tables are defined on an establishment basis. The inputs purchased by a particular industry, therefore, consist of the amounts required to produce its primary and secondary outputs. Secondary products are double-counted to obtain an accounting balance, but with only a single column of transfer-out and a single row of transfer-in added to each regional input-output table (Polenske et al. 1974, p. 26). To balance the regional input-output tables with the regional trade matrices, the inventory depletion component of net inventory change is subtracted from final demand and added as a positive row. This adjustment is required to account for all shipments of a given commodity, regardless of the year in which it was produced (Polenske et al. 1972a, p. 29).

The technical coefficients are calculated from the regional input-output tables containing double counting of the secondary products. Each column of the regional input-output table is divided by the column total, adjusted to exclude inventory depletion, to obtain regional technical coefficients. The inventory depletion figures are not included in the column total since the technical coefficients should reflect inputs required to produce output of the current year. Thus, for the three regions of Oklahoma, Texas, and Rest of U.S., technology is represented as a partitioned matrix with the technical input-output coefficients for each region co tained on the diagonal:[1]

$$(1)\qquad \begin{bmatrix} A^{OK} & 0 & 0 \\ 0 & A^{TX} & 0 \\ 0 & 0 & A^{RUS} \end{bmatrix}.$$

A^{OK} thus represents the technical input-outp coefficients for Oklahoma with similar interpret tions of A^{TX} and A^{RUS} for Texas and Rest of U.S respectively. Each of these is a 79×79 submatri

Interregional commodity trade data are availabl on a region-by-commodity basis for each state an are published in Rodgers (1963). To maintain th balance between the regional input-output tabl and the regional trade tables, regional transfer-o is added to the respective control totals of the r gional trade tables. As employed here, region transfer-out is added to intraregional shipment Total regional consumption in the trade tables i then consistent with regional consumption in th input-output tables.

Trade coefficients, t_j^{km}, are computed by dividin the jth commodity flow from region k to region m r_j^{km}, by total regional consumption of commodity in region m, R_j^m. The trade coefficients includ intraregional flows. For the three-region model, total of nine trade matrices were computed an arranged in the following partitioned form:

$$(2)\qquad \begin{array}{r} \\ OK \\ TX \\ RUS \end{array} \begin{array}{c} \begin{array}{ccc} OK & TX & RUS \end{array} \\ \begin{bmatrix} T^{11} & T^{12} & T^{13} \\ T^{21} & T^{22} & T^{23} \\ T^{31} & T^{32} & T^{33} \end{bmatrix} \end{array}.$$

Each of the T^{km} matrices is a seventy-nine-secto diagonal matrix with the components equal t r_j^{km}/R_j^m. The matrices forming the princip diagonal identify intraregional shipments. Thu nontraded commodities are accounted for in thes matrices. In the off-diagonal matrices, nontrade commodities (sectors 61–79) receive a zero valu The Rest of U.S. region trade coefficients we aggregated from individual state commodity trad data. The interregional input-output coefficient m trix is computed as the product of the interregion trade matrix and the regional technology matrix:

$$(3)\qquad \begin{bmatrix} T^{11}T^{12}T^{13} \\ T^{21}T^{22}T^{23} \\ T^{31}T^{32}T^{33} \end{bmatrix} \begin{bmatrix} A^{OK} & 0 & 0 \\ 0 & A^{TX} & 0 \\ 0 & 0 & A^{RUS} \end{bmatrix} = \begin{bmatrix} B^{11}B^{12}B^{13} \\ B^{21}B^{22}B^{23} \\ B^{31}B^{32}B^{33} \end{bmatrix}$$

The B^{km} matrices give the regional source of th inputs described by the technical input-outpu coefficients. Hence, B^{21} shows the amount of input by sector coming from region two (Texas) per uni of sector output in region one (Oklahoma).

The complete interregional input-output model i expressed as

[1] The technology matrix A^{RUS} was not estimated directly. Se the next section on an interregional input-output approximatio model.

$$(4)\quad \begin{bmatrix} B^{11} & B^{12} & B^{13} \\ B^{21} & B^{22} & B^{23} \\ B^{31} & B^{32} & B^{33} \end{bmatrix} \begin{bmatrix} X^{OK} \\ X^{TX} \\ X^{RUS} \end{bmatrix} + \begin{bmatrix} T^{11} & T^{12} & T^{13} \\ T^{21} & T^{22} & T^{23} \\ T^{31} & T^{32} & T^{33} \end{bmatrix} \cdot \begin{bmatrix} Y^{OK} \\ Y^{TX} \\ Y^{RUS} \end{bmatrix} = \begin{bmatrix} X^{OK} \\ X^{TX} \\ X^{RUS} \end{bmatrix}.$$

Elements B and T are as previously defined. Final demand by region is represented by Y^{OK}, Y^{TX}, and Y^{RUS}. Multiplying the vector of regional final demands by the interregional trade coefficient matrix gives those portions of final demand coming from each region. Output by region is represented by X^{OK}, X^{TX}, and X^{RUS}. The output projection equation, suppressing regional identification, becomes:

$$(5)\quad (I - B)^{-1}TY = X,$$

where I is a unit matrix.

Richardson used a two-region, input-output model to illustrate the procedures of estimating interregional feedback. He excluded, however, the interregional feedback effects of final demand by using only Y rather than TY in (5). Expanding (5) to the two-region case gives

$$(6)\quad (I - B^{11})\Delta X^1 - B^{12}\Delta X^2 = T^{11}\Delta Y^1 + T^{12}\Delta Y^2$$

and

$$(7)\quad (I - B^{22})\Delta X^2 - B^{21}\Delta X^1 = T^{21}\Delta Y^1 + T^{22}\Delta Y^2,$$

where ΔX^k and ΔY^k refer to the change in total output and final demand in region k, respectively. Hence,

$$(8)\quad \Delta X^1 = [(I - B^{11}) - B^{12}(I - B^{22})^{-1}B^{21}]^{-1}[B^{12}(I - B^{22})^{-1}T^{21} + T^{11}]\Delta Y^1 + [(I - B^{11}) - B^{12}(I - B^{22})^{-1}B^{21}]^{-1}[B^{12}(I - B^{22})^{-1}T^{22} + T^{12}]\Delta Y^2.$$

Equation (8) gives the change in output of region one due to the change in final demand for both regions. Regional models assume $T^{km} = 0$ for all $k \neq m$. Under this assumption, equation (8) can be rewritten as

$$(9)\quad \Delta X^1 = (I - B^{11})^{-1}T^{11}\Delta Y^1.$$

Effects of feedback as proposed by Richardson are estimated by the difference between the first term of equation (8) (set $\Delta Y^2 = 0$) and equation (9).

In a closed interregional model the feedback effect of ΔY^2 on ΔX^1 must also be considered. If we assume a change in final demand for region two increases exports from region one (which is part of final demand for region one in a regional model) but do not allow for interregional feedback, then equation (9) is replaced by

$$(10)\quad \Delta X^1 = (I - B^{11})^{-1}T^{11}\Delta Y^1 + (I - B^{11})^{-1}T^{12}\Delta Y^2.$$

Total interregional feedback on ΔX^1 from ΔY^1 and ΔY^2 is then the difference between all of equation (8) and equation (10). It is this total interregional feedback that has been measured for Oklahoma in the three region model.

The difference in 1980 baseline output for selected sectors between the regional solution and the interregional solution for Oklahoma is shown in table 1.[2] This difference is attributed to interre-

[2] Sectors one and two (agricultural crops and livestock) have been excluded because in the original study these two sectors entered as predetermined output with interregional feedback already included in regional estimates of output (see Schreiner, Chang, Flood, pp. 26–31). The purpose of this study is to show the effects of interregional feedback using input-output models and exogenously determined agricultural output resulting from alternative assumptions concerning U.S. policy and growth in agriculture.

Table 1. Measurement of Interregional Feedback for Projected 1980 Baseline Output, Oklahoma, Selected Sectors ($1,000 in 1963)

Selected Sectors	Regional Output Solution	Interregional Output Solution	Interregional Feedback (2) − (1)	Percent (3) ÷ (1)
	(1)	(2)	(3)	(4)
59 Wholesale retail trade	2,468,177	2,500,142	31,965	1.3
71 Real estate, rental	2,214,945	2,305,599	90,654	4.1
11 New construction	1,497,345	1,497,345	0	0.0
31 Petro. related indus.	1,190,543	1,398,234	207,691	17.4
8 Crude petro. nat. gas	996,503	1,351,467	354,963	35.6
14 Food, kindred prodts.	927,924	997,355	69,430	7.5
65 Transp. warehousing	842,319	872,710	30,390	3.6

gional feedback. Interregional feedback as a percentage of the regional solution is given in column (4) of table 1. The weighted average of interregional feedback for the ten nonagricultural sectors with the highest state output is 7.2%. Underestimation of sector output using the regional solution ranged from 0.0% in MRIO-11, new construction, to 35.6% in MRIO-8, crude petroleum and natural gas. The weighted average of interregional feedback for the remaining sixty-five nonagricultural sectors of the Oklahoma economy is 11.3%. The overall weighted average for the nonagricultural sectors is 8.6%. These results show that a regional input-output model for Oklahoma could underestimate sector outputs, and subsequent employment and income estimates, to a significant degree by not including interregional feedback.

Interregional Input-Output Approximation Model

The previous section has shown the importance of interregional feedback for the state of Oklahoma. Not many state and local research and planning agencies have the resources to finance a regional input-output model, let alone an interregional model. However, if an input-output model is available for the relatively closed system, i.e., the United States, and if trade estimates are available, a simplified model can be constructed. The simplified model assumes the region(s) of interest is (are) a small part of the overall closed system. Further, it is assumed that technology for the large remaining part of the closed system can be approximated by the technology of the entire closed system.

For the three region model described in the previous sections, an approximation model is tested that substitutes U.S. technology coefficients for A^{RUS}. All other data sets for Rest of U.S. region are aggregated from state data. That is, trade coefficients are built up from regional trade data, and final demand is calculated by subtracting Oklahoma and Texas data from national data. The purpose of the model is to approximate the structure of the remaining portion of the closed system as closely as possible without actually having to estimate the system.

The three region model is empirically tested using the 1963 MRIO base-year data.[3] If Oklahoma and Texas output accounts for a small share of U.S. output, the approximation model is expected to reproduce the original 1963 base-year output results fairly closely. Data for selected sectors on regional shares of national output and the percentage of error in reproducing regional output using the approximation model are presented in table 2. One sector in Oklahoma and seventeen sectors in Texas account for more than 5% of national output. Most of these sectors relate to petroleum mining and processing industries. Seven sectors in Oklahoma, ten sectors in Texas, and five sectors in Rest of U.S. region show an error of 5% or more in reproducing base-year output. Almost all of these sectors in Oklahoma and Texas include, or are highly interrelated with, petroleum mining and processing (MRIO-8, crude petroleum and natural gas; MRIO-27, chemicals and selected chemical products; MRIO-28, plastics and synthetic materials; MRIO-31, petroleum refining and related industries; MRIO-45, construction, mining, and oil field machinery and equipment).

Errors in reproducing both Oklahoma and Texas data are almost exclusively in the direction of overestimation of regional output. This would be ex-

[3] The MRIO model is a complete system with fifty-one regions. Hence, the need for an approximation model does not exist if all fifty-one regions are used. However, if analysis of but one or two regions in the MRIO system is needed or if such complete systems are not available, then the approximation model as proposed here becomes a feasible alternative.

Table 2. Validation Data of the Interregional Input-Output Approximation Model for Selected Sectors, 1963

	Regional Share of National Output (%)			Percentage of Error in Estimation of Base-Year Output Using Interregional Input-Output Approximation Model		
Selected Sectors	Oklahoma	Texas	Rest of U.S.	Oklahoma	Texas	Rest of U.S
69 Wholesale retail trade	1.03	5.02	93.95	0.68	1.05	−0.06
71 Real estate, rental	1.06	4.02	94.92	4.34	0.69	−0.14
11 New construction	1.48	6.17	92.35	0.0	0.0	0.0
31 Petro. related indus.	3.70	27.06	68.35	14.82	18.42	−8.32
8 Crude petro. nat. gas.	7.16	37.33	55.51	20.96	21.31	−19.60
14 Food, kindred prodts.	0.81	4.44	94.75	2.84	1.74	0.34
65 Transp. warehousing	1.25	5.81	92.93	1.95	3.81	1.70
77 Med. educ. services	0.63	3.02	96.35	0.15	0.21	0.01
68 Elect. gas. san. serv.	1.27	5.47	93.26	1.91	4.16	−1.89
60 Aircraft, parts	3.54	4.83	91.63	4.68	0.29	−0.93

Source: Schreiner, Chang, and Flood, p. 27.

pected, however, because the basic petroleum mining and processing sectors (MRIO-8 and 31) are overestimated and these two sectors are important components of the two state economies. Excluding results of petroleum-based sectors, the interregional input-output approximation model appears to be able to reproduce regional output data rather closely for the present regional delineation. However, the results also show that for regions with shares in excess of 5% of national output for any sector, a more critical evaluation should be made of the approximation model. In particular, the Rest of U.S. region technology should be adjusted to exclude the influence of the sector output accounted for in the study region(s).

Conclusions

The Multi-Regional Input-Output studies have been an asset to economists doing regional impact analyses. As similar national studies and updates occur, data will be improved and refined leading to increased confidence and usage of the data base by state and regional analysts.

Regional scientists realize that practically all national policies have differential impacts on states and regions. National policies and programs are evaluated on the basis of national benefits to achieve maximum social welfare. And this involves both equity and efficiency considerations. However, questions of economic efficiency and equity cannot be fully evaluated until the regional dimensions of national policy are specified. The regional dimensions of U.S. agricultural growth and policy are part of this overall evaluation. Beyond this, it is important to realize that planning is an ongoing process for regionally oriented public and private organizations. Thus the regional implications of national policies merit study if for no other reason than to provide these organizations the information necessary to anticipate needed adjustments and plan future investments. It is hoped that solid information of the regional impacts of national policy can act as a counterweight to the tendency to view regional differences as regional divisions (as may be the case in the discussion of national energy policy) by stressing the interrelatedness of regional economies.

Specification of regional impact models contribute to generation of solid information for policy evaluation. This study provides further evidence on the importance of interregional feedback in estimating regional impacts. But the cost of constructing the better specified interregional model may be too great. This study provides an approximation to the fully specified, interregional, input-output model utilizing available data bases from the MRIO studies. The state regional scientist can concentrate more on interpreting the issues facing his clientele group(s) and how best to integrate those issues into the interregional impact models.

Specification Errors and Inference in Recreation Demand Models

Michael E. Wetzstein and John G. McNeely, Jr.

Recreation demand models are normally developed either for forecasting future demand or measurement of primary economic benefits of recreation facilities. A fundamental problem with the application of recreation demand models, based on the travel cost approach, is the difficulty of capturing effectively the price of a recreation experience. Distance, travel cost, monetary cost (travel cost plus other variable cost), and travel time have been incorporated into various demand functions (Cesario, Gum and Martin, and Sinden). The present paper discusses a number of proposed demand specifications and investigates alternatives for incorporating price surrogates. Specifically, ski data collected over California and Nevada ski resorts were applied to alternative model specifications.

Demand Specification

Three multiplicative model specifications generally have been employed to estimate recreation demand models (Cesario; Cicchetti, Fisher, Smith; McConnell; Wilson):

(1) $$v_{ij} = A x_{1ij}^{\beta_1} \exp^{\mu_{ij}},$$

(2) $$v_{ij} = A x_{2ij}^{\beta_2} \exp^{\mu_{ij}},$$

(3) $$v_{ij} = A x_{1ij}^{\beta_1} x_{2ij}^{\beta_2} \exp^{\mu_{ij}},$$

for $i = 1, \ldots, I$, $j = 1, \ldots, J$, and where v_{ij} is the number of visits incurred by individual or origin "i" to area "j";[1] x_{1ij} is the total monetary cost, travel cost plus other variable cost, for individual or origin "i" to participate at area "j"; and x_{2ij} is the distance between an individual's residence or origin "i" and area "j."[2]

Distance or cost have been employed in various recreation models as price surrogates in the form of specifications (1) and (2). Theory suggests, however, that disutility of overcoming distance is not cost alone but also time involved in making the trip (Cesario and Knetsch; McConnell). Thus, both variables have been incorporated into a single model where cost and distance are surrogates for price and time allocation, respectively, specification (3). This would then allow the effects of time and cost to be separated and the impact of cost on use could be evaluated. Cost and time are, however, normally highly correlated for most outdoor recreation observations, and thus, the variables have been combined into a single interacting variable (Cesario; Cesario and Knetsch).

A disadvantage of the single interacting variable, as stated by Brown and Nawas, is the implicit assumption that one or more specific trade-offs exist between cost and time. Thus, researchers are confronted by multicollinearity if they incorporate both cost and time in a model specification (3), and specification error if they only incorporate either cost or time, specification (1) or (2). In addressing this problem Brown and Nawas increase sample size by employing observations across individuals rather than origin or county zones. This allows distance traveled to be used as a surrogate variable for travel time. Another problem with employing aggregated data is the loss of efficiency in the cost coefficient by aggregating over distance instead of cost. Past empirical estimates of outdoor recreation demand are usually based on data aggregated in distance zones which is a highly efficient grouping scheme for distance but not for monetary cost.

Efficient Method of Grouping

Brown and Nawas provide one solution, disaggregation, that may solve the dilemma of multicollinearity and specification error. In a case where aggregation is necessary to avoid large-scale computations, however a researcher is still confronted with the problem of multicollinearity and specification error. Efficient grouping of the cost variable, by aggregating observations by cost instead of time (distance), will provide a more efficient estimate of the coefficient associated with cost and thus improve the confidence in the value of the coefficient. In addition, grouping observations by cost may reduce the bias from errors in the explanatory variable (Johnston).

Michael E. Wetzstein is an assistant professor in the Department of Agricultural Economics, University of Georgia. John G. McNeely, Jr., is an associate professor in the Division of Agricultural and Resource Economics, University of Nevada, Reno.

[1] Number of visits is specified as the dependent variable instead of visitor days. For a discussion of which specification is appropriate, see McConnell.

[2] For a complete specification of the model, variables accounting for income allocated to recreational activities and prices of substitutes would be required. These variables were not introduced into the model because the focus of this paper is a discussion of the relationship between cost and time, not the development of a full demand model. Exclusion of these variables are not expected to alter results and conclusions.

Prais and Aitchison present an extensive discussion of grouping units which are as homogenous as possible in order to obtain more efficient estimators. Recent research has provided various criteria for grouping data into homogenous units. (For examples, see Cox; Friedman and Rubin; O'Neill and Wells; Ward.) All the criteria for efficient grouping of data attempt to minimize the variable sum of squares within groups. Aggregating over costs versus distance would minimize the sum of squares of the cost variable within groups compared to aggregating over distance. Therefore, aggregating observations over cost leads to more efficient estimates of the cost coefficient, as illustrated below.

Results of Analysis

A logarithmic transformation of the three demand models were estimated employing ski survey data collected over the 1976–77 ski season for eleven California and Nevada ski areas. A total of 784 individual observations, disaggregated data, collected over the eleven ski resorts, were used to estimate (by ordinary least-squares) the parameters of specifications (1), (2), and (3). Observations were then aggregated into fixed-interval groups over both cost and distance. The aggregated data were estimated by applying weighed least-squares to specification (3). Weighted least-squares was applied in this case because heteroskedasticity is present in the aggregated data. Heteroskedasticity results when the number of observations is not identical in every group (Kmenta, pp. 322–28).

Results of estimating the specifications employing individual and aggregated observations are presented in table 1. The overall goodness of fit $\bar{R}^2$ between aggregated and individual observations reflects the situation that aggregated means tend to be less dispersed around the fitted regression line than the individual observations (Cramer).

The monetary cost and distance coefficients are negative in every case which is consistent with a priori expectations. Furthermore, the t-values indicate that all coefficients are highly significant except those associated with monetary cost for equations (3) and (3′). The coefficients associated with cost in equation (3) and (3′) are significantly different from zero at the 0.32 and 0.45 level, respectively.

The large standard errors associated with the monetary cost coefficients in equations (3) and (3′) are due to the relatively high intercorrelation between monetary cost and distance in these two equations. The correlations between monetary cost and distance in equations (3) and (3′) are 0.59 and 0.83, respectively.

When the data are aggregated by monetary cost both monetary cost and distance coefficients are significantly different from zero at the .05 level (see table 1). The standard errors associated with the coefficients in equations (3′) and (3″) are, however, in all cases greater than those associated with the disaggregated estimates. In fact this is always the case. That is, the variances of the estimators based on grouped data can not be less than those of the estimators based on the disaggregated observations (Prais and Aitchison). The results presented in table 1 do indicate that the estimates of the coefficients are more efficient in equation (3″) than in equations (3) and (3′). This result is of particular importance when the modeling objective is for measurement of primary economic benefits.

Table 1. Estimated Demand Models for Disaggregate and Aggregate Specifications

[e] $\bar{R}^2$ is the adjusted R^2 value.

Summary and Implications

Aggregating over cost versus distance provides an alternative model specification where disaggregation is not feasible or does not elevate a problem of multicollinearity. This paper illustrates that a model specification incorporating aggregated data over cost does result in more efficient estimates of the coefficients, as suggested by previous research in grouping of observations. Simulation results performed on the estimated equations indicated that aggregating data over cost generally provided a more efficient estimate of the cost coefficient compared to aggregating by distance. The cost coefficient was significantly different from zero in all these simulations when the data are aggregated by cost; however, only 84% of the coefficients are significantly different from zero when the data are aggregated by distance. Although this method may not be suitable in all cases it is an alternative specification worth investigating.

Expected Benefits from Nonchemical Methods of Alfalfa Weevil Control

Luis R. Zavaleta and William G. Ruesink

The problem of managing insect pests has been receiving increased interest as a part of the technological revolution that has dramatically increased agricultural output.[1] During the past few decades, several biological and cultural methods of pest control have been conceived and/or implemented, e.g., DeBach, Huffaker (1971, 1980), Huffaker and Messenger, Metcalf and Luckmann, Reichelderfer and Bender. However, contemporary technology has analyzed and relied heavily on the use of synthetic chemical pesticides (Hall and Norgaard; Regev Gutierrez, Feder; Talpaz and Borosh; Talpaz et al.). The preference for chemical control is derived, in most cases, from its achievement of satisfactory control at relatively low costs.

However, the intensive, as well as extensive, uses of synthetic organic pesticides, in particular a few persistant insecticides such as DDT and BHC, have had detrimental effects on the quality of the environment. Prolific use of chemical pesticides develops genetic pest resistance, changes pest complexes by affecting nontarget populations and allowing outbreaks of secondary pests, and affects the ecosystem with its residues in feeds, foods, and organisms (Shoemaker). Policymakers have reflected the concern of society for environmental contamination by legislation restricting pesticides, suggesting that future pest control cannot solely depend upon routine applications of insecticides.

This note investigates the potential gains that may be derived from the use of biological means of control as well as the introduction of a host plant with added resistance (antibiosis) against the alfalfa weevil (*Hypera postica*). This insect contitutes one of the more important insect pests of alfalfa and can cause large losses in yield or even death of the crop if uncontrolled (Armbrust and Gyrisco).

Luis R. Zavaleta is an assistant professor, Section of Economic Entomology and Department of Agricultural Economics, University of Illinois; William G. Ruesink is an associate professor, Section of Economic Entomology and Office of Agricultural Entomology, Illinois Natural History Survey and University of Illinois.

The authors are thankful for the constructive comments provided by three anonymous reviewers.

[1] The term "pest" is a rational abstraction with no ecological inference. Its existence, however, indicates that the insects are regarded as destructive or noxious in proportion to the number present and that it is in direct competition with man for a set of limited resources (Headley and Lewis; Metcalf and Luckmann).

Model Description and Procedure

Our study used the computerized models developed for the alfalfa crop (Fick) and for the alfalfa weevil (Ruesink). More complete versions of these models have been provided by the authors; therefore, this presentation is limited to a brief discussion of the relevant components and those elements not explicitly addressed in available descriptions.

The dynamic computer model of the alfalfa crop mimicked the daily time path of state variables such as the biomass of leaves, stems, buds, and total nonstructural carbohydrates (TNC) as a function of environmental conditions. To simulate other conditions, such as the harvesting of the crop, the state variables for leaves and stems were set to zero, following which regrowth was achieved by a flow of materials from buds and TNC into leaves and stems. New material was generated by photosynthesis. The rates of flow between components and the rate of photosynthesis were modeled as functions of light intensity, day lengths, temperatures, and the values of the state variables. The model assumed adequate soil moisture, high levels of fertility, and absence of pest problems other than the *Hypera postica*. In actual field conditions, more than one pest may be found; however, to keep the problem computationally manageable attention was directed to the alfalfa weevil.

The alfalfa weevil system was modeled using thirteen components, while the parasite system used three. For example, in figure 1, the alfalfa weevil has components for egg (E), four larval instars (L_1 through L_4), pupa (P), and adult stages (A_0, A_{f1}, A_{f2}, A_d). The parasite was modeled as having a cocoon (C), diapausing (D), and adult (A) stages. In this model, the state variables describe the number of individuals present in that life stage. Flows were unidirectional in that an individual could only become more mature in its lifetime. For each of the components of this system, there are response functions in difference equation form using a one-day time step. The rates of flow between components and the rates of reproduction were modeled as functions of temperature, day length, and the values of other key state variables.

Both models, the alfalfa plant growth and the insect component, are interfaced through a trophic process (*FEEDING*, in fig. 1). The potential rate of feeding by the weevil was modeled as proportional

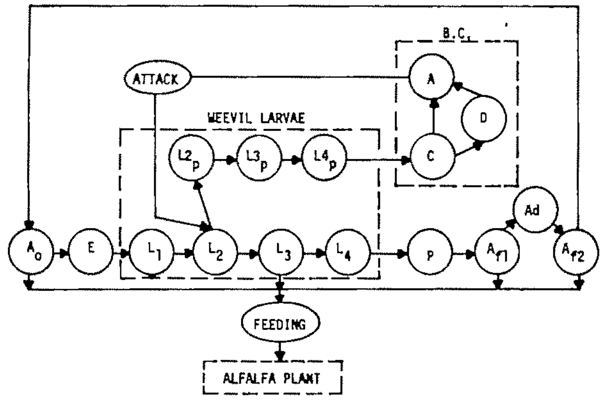

Figure 1. Diagrammatic model of the alfalfa weevil and *B. curculionis* life systems. (From Ruesink, copyright 1976, Board of Trustees, Michigan State University. Reprinted by permission.)

to the average developmental rate per instar, but this rate was allowed to vary from day to day with temperature variations. The actual feeding rate for each instar and the adult stages at time *t* was assumed a function of the ratio between available biomass and the estimated potential feeding rate. The interaction between *B. curculionis* and the weevil larvae was modeled through the trophic process denoted *ATTACK* (fig. 1). Through this process, a certain percentage of the larval population in the second stage is parasitized ($L2_p$) and remains as such during the third and fourth stages ($L3_p$ and $L4_p$, respectively), reaching death during the latter instar.[2] The beneficial effects of the parasite were obtained through an induced reduction on feeding rates for the larval stages and through an increase in the mortality rate of the weevil.

For the present analysis, records of ten years were used for each of four weather stations, selected as representative of major alfalfa growing regions in the eastern United States. They were Ithaca, New York; Bedford, Virginia; Rochester, Minnesota; and Nashville, Illinois. For the period of analysis, daily maximum and minimum temperatures and solar radiation were required. It was also necessary to indicate which biotype of the alfalfa weevil was being simulated, because the eastern and western population of this species do have a few differences that are not explainable by differences in climate.

The model was initialized on 1 September, because at that time most of the alfalfa weevil are diapausing adults. Hence the insect portion of the model could be initialized by assigning nonzero densities to these state variables and setting the remaining at zero. Therefore, in the simulation runs for each locality, the initial weevil density was set at $10/m^2$, which is typical of a moderately heavy infestation. In those cases where parasities were included, their initial density was set at $2/m^2$, which is a rather low population level for that species. These initial conditions were used in the simulation models to provide results that may be considered as conservative values to be expected from these control actions.

Finally, the model recorded an insecticide application whenever the density of third and fourth instar weevil larvae exceed $400/m^2$, which corresponds approximately to the economic injury level recommended in Illinois (Wedberg et al.).[3]

Changes in yield, insecticide use, and their monetary values were computed by comparing ten-year averages for a normative benchmark solution to averages obtained for different elements integrated in pest management methods. Specifically, the normative benchmark solution considered the application of chemicals as the only means of pest control. The results thus obtained were used to measure the benefits that may have been derived from integrating (*a*) biological and chemical controls, and (*b*) biological, cultural, and chemical practices.

Value of the Parasite

This analysis examined the impact of *B. curculionis* at an initial density of $2/m^2$. From this initial density, the population was allowed to develop naturally for the following ten years. The effects that the parasite may have on the weevil population were, among other factors, dependent on the levels as well as on the synchrony of the cyclical fluctuations on population. Therefore, when the parasite did not perform an adequate job in controlling the weevil, the use of an insecticide was simulated at the time the economic injury level was achieved by the *Hypera postica* population. In this case it was considered that the insecticide affected only the mortality rates of the two insect species but did not interfere with the efficiency or behavioral attack of the parasite. The assumption of noninterference was made since at the present time there are no data that will contradict it.

As a result, it was found that the use of this integrated approach improved the yields obtained by reducing the damage, compared to those values reached by means of chemical control only. These values, however, varied among regions (table 1). For Illinois and Virginia, alfalfa yields were increased by 130 and 230 kilograms per hectare (kg./ha.), respectively; while in the northern states of Minnesota and New York, the increase was of 100

[2] The *B. curculionis* also attacks the third instar weevil larvae; however, its effects compared to the attack on the second instar were found to be of relative insignificance. Therefore, it was not explicitly modeled.

[3] The economic injury level is considered to be the lowest population level capable of creating a crop damage that will equate or exceed the cost of taking a control measure.

Table 1. Value of the Parasite, *Bathyplectes curculionis*, in Reducing Losses to Alfalfa Weevil in the Eastern United States

Annual Average[a]	Ithaca, New York	Bedford, Virginia	Nashville. Illinois	Rochester, Minnesota
Increased yield (T/ha)	.10	.23	.13	.10
Reduced insecticide use (no. applications)	.20	.90	.75	.10
Value of increased yield ($/ha)	5.00	11.50	6.50	5.00
Value of saved insecticide ($/ha)	3.00	13.50	11.25	1.50
Total economic value	8.00	25.00	17.75	6.50

[a] Alfalfa hay is valued at $50/T and insecticide is estimated to cost $15/application/ha.

kg./ha. The data presented in table 1 show that the introduction of the parasite not only had the effect of reducing the amount of yield damaged by the weevil (or to increase yield), but it also reduced the amount of insecticide applications required.

For the latter, the southern areas were the most benefited by the existence of the parasite. This improvement could be attributed to more favorable climatic conditions for the development of the *B. curculionis* than those existing in the northern states. As a result, the value of the saved insecticide in these areas exceeded the value of increased yield; while in the northern areas, the major benefits are derived from increased yields. When these data are evaluated for the eastern United States, they suggest that the parasite could save about $44 million per year as compared to the benchmark case. It should be pointed out that the predicted increase in production represents less than 1% of the total crop, and this increase would not be expected to influence the market price for alfalfa hay. In addition to its economic impact, this approach could account for a great reduction in pesticide use. About 1,100 tons per year less insecticide would be necessary than in the case where only chemical control is employed. This reduction in pesticide input to the environment deserves attention beyond its economic value.

Value of Host Plant Resistance

Another method of pest management is the use of cultural practices. These practices may involve, among others, adjusting the date of harvest as well as introducing the use of plants that are genetically resistant to the weevil. As described by Kogan, "Resistance to insects is the property that enables a plant to avoid, tolerate, or recover from injury by insect populations that would cause greater damage to other plants of the same species under similar environmental conditions. This property generally derives from certain biochemical and/or morphological characteristics of plants which so affect the behavior and/or the metabolism of insects as to influence the relative degree of damage caused by these insects" (p. 103).

At the present time, there are no commercially available alfalfa varieties that have resistance to the alfalfa weevil. Plant breeders have had little success at finding genetic material that carries the level of resistance they seek. The following analysis was performed to quantify the value of partial resistance, and the results should provide the breeders with incentive to develop varieties with even a small amount of resistance.

The particular type of resistance considered here is known as antibiosis, in which some characteristic of the plant causes a reduction in survival of the pest population. This analysis assumes the development of a variety that causes mortality to the first larval instar of the weevil but that has no other direct impact on either the weevil or its parasite. Specifically, 20, 40, 60, and 100% additional mortality levels were evaluated. The data presented in table 2 consider the presence of *B. curculionis* and *Hypera postica* at the same initial population densities described previously.

The use of a truly resistant plant—one on which the pest cannot (or will not) live, represented here by the 100% added mortality case—would increase average yields about .35 tons per hectare. This increase corresponds to a total value of $89 million per year. At the same time, insecticide use would be reduced to zero. These savings are not spread equally over the four regions. The south-central area would benefit only $13.50 per hectare, while in the other areas the benefits range from $16 to $18.50 per hectare. The primary reason for the smaller benefit from plants with added mortality in the south-central region is that the parasite, according to these simulations, is already doing a good job of controlling the weevil.

If, instead of total resistance, the breeders only achieved 60% added larval mortality, insecticide use still would decline to zero, but a small amount of damage to alfalfa would continue to occur. Under these conditions the damage is too small to justify the expense of insecticide application. Thus, 60% added mortality is nearly as beneficial as 100%.

Table. 2. Value of Host Plant Resistance in Reducing Losses to Alfalfa Weevil in the Eastern United States

Annual Average[a]	Benchmark	Level of Added Mortality (%) 20	40	60	100
	Northeast U.S. (0.8 million ha.)				
Yield (T./ha.)	14.07	14.22	14.35	14.38	14.39
Insecticide used (kg./ha.)	.70	.20	0	0	0
Reduced damage ($mil./region)		6.00	11.20	12.40	12.80
Reduced insecticide (T./region)		400.00	560.00	560.00	560.00
	Southeast U.S. (0.1 million ha.)				
Yield (T./ha.)	19.43	19.61	19.68	19.75	19.77
Insecticide used (kg./ha.)	1.20	.10	0	0	0
Reduced damage ($mil./region)		.90	1.25	1.60	1.70
Reduced insecticide (T./region)		110.00	120.00	120.00	120.00
	North Central U.S. (3.5 million ha.)				
Yield (T./ha.)	13.72	13.83	13.97	14.04	14.09
Insecticide used (kg./ha.)	.70	.40	.10	0	0
Reduced damage ($mil./region)		19.25	43.75	56.00	64.75
Reduced insecticide (T./region)		1,050.00	2,100.00	2,450.00	2,450.00
	South Central U.S. (0.7 million ha.)				
Yield (T./ha.)	18.31	18.42	18.45	18.57	18.58
Insecticide used (kg./ha.)	1.625	.625	.25	0	0
Reduced damage ($mil./region)		3.85	4.90	9.10	9.45
Reduced insecticide (T./region)		700.00	963.00	1,138.00	1,138.00
	Total for Eastern Half of the U.S. (5.1 million ha.)				
Reduced damage ($ million)		30.00	61.10	79.10	88.70
Reduced insecticide (T.)		2,260.00	3,743.00	4,268.00	4,268.00

[a] Alfalfa hay is valued at $50/T. and insecticide is estimated to cost $15 application/ha.

In the cases where 40% added mortality were attained, the value of production would increase by $61 million per year, and insecticide use would decrease by 3,743 tons per year. In this case, some insecticide still would be used in the Midwest each year, but it would be 85% below the present use rate. East of the Allegheny Mountains, no insecticide would be needed.

Finally, if only 20% mortality were added to the first larval instar, the value of production in the eastern United States could be increased by $30 million per year, and insecticide use could decrease by 2,260 tons a year. Although these figures are far inferior to the 40% case, producers and environmentalists would welcome this improvement.

A Proposal to Further Increase the Stability of the American Grain Sector

J. R. Groenewegen and W. W. Cochrane

This paper presents a policy proposal which is designed to complement current agricultural legislation in its attempt to stabilize the United States grain sector. Price and income stability is important to commercial agriculture and consumers (e.g., see Brandow), has been of central concern in past agricultural legislation (Cochrane and Ryan), and will, in all likelihood, continue to be on the legislative agenda in one form or another. The proposal advanced in this paper is predicated on the following statements:

First, the programs and instruments contained in the 1977 Food and Agriculture Act are adequate for stabilizing prices between the loan rate and the farmer-held reserve release rates when global production does not significantly veer below trend for grain crops. The target price deficiency payment scheme is also deemed adequate for protecting income levels. (For details and discussion on the 1977 Act, see U.S. Department of Agriculture, Spitze.) But it is our assertion that the existing programs in their present form are not adequate for protecting the long-run interests of American consumers and producers in periods when global production does drastically veer below trend (e.g., the production shortfalls as witnessed in 1972/73).

Second, major importers of grains, such as the EEC, Japan, the USSR, and China, insulate their agricultural sectors from the world grain market. These insulation policies exaggerate the price adjustments required by countries openly linked to the world market. (See Johnson, Grennes, Thursby; and Nelson for a discussion of these operational instruments for Japan and the EEC. D. G. Johnson provides a description of agriculture and agricultural policies in the Soviet Union.)

Third, prices for agricultural products in the United States, especially grain products, would not have reached the high levels of the early seventies if the major importers, instead of maintaining their protective and insulating policies, had adjusted internal prices in accordance with world conditions at that time.

Fourth, in this same era price advances also would have been more moderate if a system of national grain reserve stocks had been in operation with the objective of stabilizing world grain prices.

Fifth, the theoretically appealing concept of free trade, as a means to stabilize international grain markets, is not proposed as the means to stability because most nations control their agricultural sectors and thereby insulate those sectors from world conditions, and those nations are not willing to forfeit that control.

Sixth, the United States is the predominate supplier of grains to the world market; it is openly linked to the world grain market while the major grain importers (and some exporters) insulate their agricultural sectors from this market; and, as a result, it assumes a disproportionate share of the stock and price adjustment when world grain conditions change.

Seventh, the viability of present-day American agriculture depends heavily on the exportation of grain and its products. A policy of domestic agriculture maintaining a direct open link with the world grain market (i.e., export competitiveness) benefits domestic agriculture by maintaining and expanding grain exports; but when taking into consideration the five previous statements, then this policy conflicts with the objective of stable grain prices.

Eighth, therefore, if it is in the national interest to avoid repercussions of global grain shortages which are beyond the boundaries of protection provided by current legislation, then the United States could if it wished, stabilize its domestic agriculture by (*a*) insulating its grain sector from abnormal world conditions and (*b*) inducing grain importers to undertake some of the required adjustment in world grain utilization.

With these statements as a background setting to the stability problem under consideration, the policy proposal is presented in the next section. The subsequent section focuses on implications of this proposal and also highlights some empirical questions that should be addressed before implementation of this proposal is considered.

Policy Proposal

It is proposed in this paper that the United States insulate in a certain price range and to a reasonable degree its domestic grain sector from extreme destabilizing world market forces but, at the same

Scientific Journal Series No. 10,891, of the Agricultural Experiment Station, University of Minnesota.

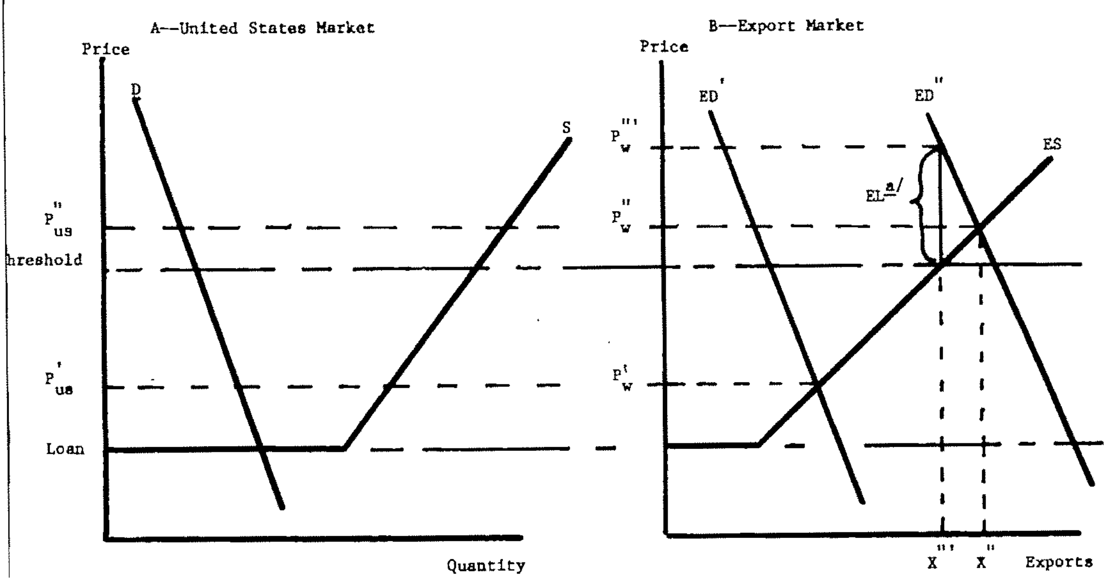
The authors acknowledge the assistance of B. Oleson, L. Geyer, and an anonymous referee.

time, maintain its position as a dependable supplier of grains. The achievement of these two procedural objectives can be achieved, it is argued here and throughout the paper, without seriously compromising either of the seemingly conflicting goals of market stability and export competitiveness. This proposal, it must be repeated, does not completely insulate U.S. agriculture; it is designed only to insulate this sector when world shortages are so acute that the stabilizing instruments of the 1977 Food and Agriculture Act are ineffective. Granted this acute global shortage may never again occur; but if this did occur, then U.S. agriculture would again be required to make unnecessary and undesired adjustments. When price is close to its equilibrium value, then the proposal does not restrict price from performing its various functions in the world grain market that it does most efficiently.

For the proposal under consideration here to be effective, policy instruments, in addition to those contained in the current program, are required for the American grain sector to insulate itself from extremely high prices, to maintain the position as a dependable supplier, and to be responsive to a long-term trend. These additional instruments, which are discussed below, are variable export levies, bilateral agreements with importers, a global allocation system, and a domestic grain reserve.

Variable Export Levy

The variable export levy is included to ensure that domestic prices never will exceed a threshold level. A system of variable export levies serves to insulate American consumers and producers from extreme external price rises in the same manner as loan rates give downward price protection. Given existing legislation the maximum domestic price (the threshold price) allowed could be set, for example, 150% of loan at the discretion of the Secretary of Agriculture. This threshold value must exceed the equilibrium price level. Also, consistency with the farm reserve program requires that the threshold price be at least as great as the level at which the secretary can call the loan. Threshold prices for grain products would be determined by establishing grain equivalents for these products. Grain prices would be stabilized in a band between the loan rate and the threshold price. Corn prices, therefore, could vary between \$2.00 (loan) and \$3.00 (150% of loan) per bushel. Domestic prices would remain at the threshold price whenever the world price rose above the threshold level, as a consequence of the operation of the variable export levy in conjunction with an allocation system and a bilateral trade agreement system, both of which are discussed in the next section. In this case, the export levy would be the difference between the world price and the threshold price. Figure 1 illustrates just the influence of the levy on domestic and world prices. Panel A in figure 1 represents a hypothetical supply (S) and demand (D) condition for the United States. Panel B shows the excess supply (export) function for the United States (ES) and the net import demand function for the rest of the world (ED). (For a discussion on excess supply and demand functions, see Bressler and King.) When import demand is ED', the world price (P_w') and the U.S. price (P_{us}') are identical. Without an export levy, an increase in world demand to ED'' increases the world price and the domestic price to P_w'' and P_{us}'', respectively. Implementation of an export levy (EL) whenever



a/ Export levy.

Figure 1. Export levy on United States grain exports

price is above threshold maintains the domestic price at the threshold price and for the above example increases the world price P_w^{m}. In this case U.S. export volume decreases from X^{n} to X^{m}.

When world price is above threshold, exporters could purchase grain at threshold and sell at the world market price, so long as the domestic and bilateral agreement allocations were not infringed upon. Export companies would submit levy proceeds to a government agency, such as the Commodity Credit Corporation (CCC), which would also monitor export sales. These funds would be used to finance CCC operations or other farm programs. The export levy would need to be adjusted continuously in accordance with world market developments because, if the levy is too small, export companies would gain windfall profits since supplies are purchased at threshold; if the levy is too large, exporters would be losing money on export sales. The propensity for internal prices to rise above the threshold price would be moderated because exporters would not bid more than the threshold price for grain, unless they were willing to encounter a loss when submitting levy receipts. The global allocation system which is discussed in a subsequent section also prevents this type of price rise.

This program, while designed to insulate the domestic economy, would be flexible enough to respond to price trend between crop years. The Secretary of Agriculture could increase the threshold price by 10% whenever domestic price is 95% of threshold, or more. If the threshold price is increased, but domestic price is less than 95% of the former threshold value, then the subsequent threshold price could decrease to its former value.

Variable export levies, it can be argued, are not compatible with American food and agricultural goals in two respects. First, total world trade declines with an effective levy, since by insulating itself, the American grain sector does not adjust consumption and production, and hence, exports to world developments. Second, this reduction in world trade results in a higher world price when the levy is in force, as illustrated in figure 1. Both of these side effects of the proposed policy run counter to the goal of a dependable supplier of grains. But a system of bilateral agreements and domestic reserve programs could be employed to circumvent these disadvantages.

Bilateral Agreements

Bilateral agreements with importers of U.S. grains would serve to undergird the goal of maintaining and expanding exports of grain and their products. The agreements would contain the following considerations: (*a*) each importer would be required to purchase a minimum prespecified volume of grain each year from the United States (plus some growth factor), and each importer would be guaranteed this amount at the threshold price whenever the export levy was in effect; (*b*) each importer would be required to build and operate a grain reserve stock program in which the stock levels are related to, or determined by, the nation's average volume of grain imports; (*c*) the importer would be required to release and acquire stocks in its reserve program in accordance with the same rules as those employed in the management of the U.S. reserve stock; and (*d*) the last two conditions are waived for low income, developing countries.

The establishment of a system of bilateral agreement emanating from the United States should accomplish three important things: (*a*) expand and regularize the export of grains from the United States, (*b*) assure importers of grain from the United States of their regular supply in years of world shortages, and (*c*) greatly increase the probability of holding the world price of grain within the agreed upon price stabilization range.

As a consequence of the above set of results, the probability of the variable export levy becoming operational is greatly reduced. This consequence fits into the overall design of this proposal. The variable export levy is not viewed as a revenue generator; it is viewed as a control mechanism for stabilizing the domestic price of grain. And when the world price of grain is stabilized within an acceptable range by the operations of a system of coordinated national grain reserve programs, the variable export levy need not come into operation.

Global Allocations

It is conceivable that exports to nonagreement countries would be sufficiently brisk in the first part of a marketing year, at prices below the threshold price, that domestic demand plus the bilateral agreement commitments in the latter part of the marketing year would push the domestic market price above the threshold price. The operation of an effective system of national grain reserve programs in conjunction with the variable export levy makes such a development unlikely, but it remains a possibility. Thus, it is proposed here the United States establish a global allocation for each major category of grain each marketing year that is equal to the expected domestic demand for each category of grain at the stabilization target price, plus the export quantities fixed in the bilateral agreements plus whatever food aid commitments that the government may have made. Private exporters would be free to export grain to any nonagreement country, with or without the export levy in operation, to that point where the global allocation was being infringed upon. At this point, sales to nonagreement countries would cease. The remaining supplies would be sufficient to meet bilateral agreement and domestic commitments.

Domestic Grain Reserves

To fulfill the U.S. obligation of assured supplies to signatories, the CCC, it is proposed, should be re

quired to purchase and maintain an adequate level of stocks labeled as grain reserves. A study by Cochrane and Danin on maintaining world prices in a plus 10% and minus 5% of trend band, required reserve stocks that averaged 50 to 75 million tons over the 1975–85 period. With this proposal, such a large stock level is not required to help stabilize U.S. grain prices since the link between the U.S. grain price and the world grain price is broken whenever the world price exceeds the threshold price of U.S. grains. However, in this proposal the United States is committed to providing minimum supplies to signatories and is committed to providing grain supplies during a global shortage, and therefore, the United States must maintain an adequate level of reserves to meet these obligations. If the United States does not follow this course, then its role of a dependable supplier of grains is in jeopardy.

Currently, domestic grain stocks are composed of farmer-held reserves, CCC stocks, and private stocks. At present, these stocks are not directly accessible to serve as part of a reserve system. The reasons are as follows: First, farmers are not required to market the farmer-held reserves when the Secretary of Agriculture calls the loan. The producer pays only the loan, and hence, can speculate with these stocks. Second, there are no well-defined rules regarding the marketing of CCC stocks. At present, the resale price is set at not less than a certain percentage of loan. Third, the majority of stocks are private and the government has no direct control over the marketing of these stocks. Therefore, these stocks should become more accessible so that they can be considered part of the reserve system. This could be accomplished by changing the rules governing the release of farmer-held reserves and by expanding the role of the CCC with regard to purchasing and selling grain in the market.

Implications of the Proposal

The consequences of this proposal are different from the effects of an export embargo, which also protects domestic agriculture. An export embargo has a surprise element, whereas the operation of the levy system and the global allocation scheme is known and obvious to all. Also, since the operation of the levy and the global allocation scheme is plainly incorporated into agricultural legislation, this proposal minimizes many of the moral and political problems associated with controlling exports in periods of extreme food shortage.

When world price is above threshold, then signatory importers are at a relative advantage to nonsignatory importers. This relative advantage is the difference in prices paid for grain imports. An outcome of this proposal is that if enough importers comply with the agreements, then free-riders benefit from the stability of these agreements. However, the free-rider is at a disadvantage if and when there is a global production shortage because these importers are not guaranteed supplies in accordance with the bilateral agreements and the global allocation. Thus, these nations are forced to adjust to changing world conditions. Consequently, the onus is shifted from the United States to the rest of the world to stabilize world grain markets. The easiest course would be for them to sign bilateral agreements with the United States or other major exporters (e.g., Canada, Australia). Thus, it may be to the advantage of all grain exporters to consort on elements of this proposal.

The distinct advantage of this proposal is that there does not have to be an international agreement on decision rules, such as when prices or quantities trigger acquisition or release of stocks, and who should carry these stocks. A multilateral agreement on these regulations is virtually impossible (Cochrane). Instead, the United States takes the initiative in setting price stabilization ranges and formulating grain operating rules. These rules would govern the size of country reserve stocks, the acquisition and release of stocks based on world prices, and the provision of food aid. Agreement to these operating rules would be given by participating countries in return for guaranteed supplies and purchase price limits.

Export levies are a form of export tax and the latter are considered unconstitutional. Article 1, Section 9, Clause 5 of the U.S. Constitution states that "No Tax or Duty shall be laid on Articles Exported from any State" U.S. Code, Annotated). Where there was a proper exercise by Congress of its power to regulate commerce, it has been held that the export clause did not limit such power (*American Law Reports*). The case of *Moon (Appellent)* v. *Freeman* (*Secretary of Agriculture*) *et al.*, exemplifies the point. Moon contended that the purchase of export wheat marketing certificates (under the Agricultural Act of 1964) was analogous to an export tax and prohibited by the Constitution. "Overruling Moon's contention, the court interpreted the Statute (Agriculture Act of 1964) as an exercise by Congress of its power to regulate commerce under the Constitution, which is not to be limited by the constitutional prohibition against taxation of exports. The court stated that the purpose of the statute was to induce producers to comply with crop controls and to regulate the price of wheat reaching both the domestic and foreign markets" (*American Law Reports*). Export controls which have a similar effect as export taxes on prices and amounts exported are not prohibited by the Consitution. Under the auspices of the Export Administration Act of 1969 the Congress declared that it is "the policy of the United States to use export controls to the extent necessary to protect the domestic economy from the excessive drain of scarce materials and to reduce the inflationary impact of abnormal foreign demand" (U.S. Code Service). The purpose of the export levy in this proposal is to regulate domestic price and to reduce the inflationary impact of abnormal foreign demand.

The ruling on the case of *Moon* v. *Freeman* and the legality of export controls to protect domestic interests serves as a precedent for arguing that the export levies in this proposal should not be considered unconstitutional.

Another effect of this proposal is that if the United States is in a situation where the export tax must be applied then the resulting world price would not convey the same exact information as when world grain price is in the stabilized band (i.e., between the loan and threshold levels). The world price in this situation would be artificially higher than before, but other supplemental information, such as the value of the export tax, world stock levels, and the percentage of world imports that are under the umbrella of the bilateral agreements, could be used by the grain market. When world price is above threshold, then world price plus the above data should reflect as much information as price by itself when world price is below threshold.

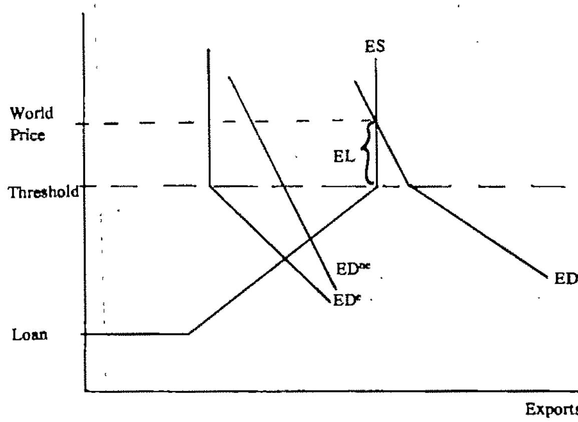
World price is a function of the proportion of imports valued at the threshold price when world price is above the threshold. Specifically, the larger the percentage of imports that are sold at threshold, the higher the world price. The structure of the world grain market in this situation is illustrated in figure 2. In this figure, the U.S. export supply function (ES) and the import demand function for complying countries (ED^c) are unresponsive to world price levels above threshold. Only the net import demand for noncomplying countries (ED^{nc}) is responsive to world price above the threshold level. The elasticity of the total net import demand function can be represented by

$$E_{ED}t = E_{ED}c\ E_Pc\ S + E_{ED}nc\ E_Pnc\ (1 - S),$$

where $S = \frac{ED^c}{ED^t}$ is the complying import share; $E_{ED}i$ are import demand elasticities with respect to world price, $i = t,\ c,\ nc;$ and E_Pj are price transmission elasticities, $j = c,\ nc$. This elasticity is used to show the effect of import share on world price. To do this, assume that U.S. exports had to be curtailed by 5% in one period to maintain domestic prices at threshold, and restrict $E_Pc = 0$ since above threshold a signatory's domestic price is insulated from the world price. Hence,

$$\%\Delta P = \frac{5}{E_{ED}nc\ E_Pnc\ (1 - S)},$$

where $\%\Delta P$ is the percentage change in world price. Thus, holding everything else constant, world price increases as the import share to complying countries increases. As a consequence of this result, the cost associated with not complying increases dramatically as more nations sign the bilateral agreements. Thus, if the United States can induce a few large importers to enter into this agreement, then it would be to the advantage of all other importers to become signatories. Therefore,



Note: Where ES is U.S. export function; ED^c is import demand function for compliers; ED^{nc} is net import demand for the rest of the world; ED^t is total net import demand; and EL is export levy.

Figure 2. An export levy, import shares, and world price

the free-rider problem mentioned above should be minimal.

This proposal is supplementary to the provisions of the 1977 Food and Agriculture Act and the proposals should be implemented such that the instrument of this proposal do not dominate the 1977 Act. Most particularly, the threshold levels for grain should be set above equilibrium values to enable price to perform its functions around the equilibrium value. This draws attention to what is the intermediate to long-run equilibrium level of price, and this should be on the research agenda before the proposal is implemented.

Another important implication of this proposal for future research consideration is a concern that domestic price may automatically tend toward threshold if this proposal is implemented. This policy proposal is directed at the marketing and trade level of the grain sector and this sector may respond to the policy by removing supplies from the market until price moves to the threshold level. This will not occur because this increase in price cannot be realized on the removed supplies, for if these supplies were added to marketable supplies then price would drop to its former level. The trade's main function is to provide services, such as transportation and brokering, and hence the removal of supplies to enhance price does not benefit the grain trade. If this is not the case, then the trade would be engaged currently in this type of activity.

This proposal involves an export levy and a global allocation scheme for grains. For operational purposes this requires an institution to oversee and coordinate these instruments. A research question that follows concerns the desired structure of the grain trade. The grain trade need not be nationalized, because the CCC could administer the allocation system and export levy system when they need to be operational. This does require closer

communication between the grain trade and the CCC for example.

A final research consideration involves the empirical question of what size of reserve stocks is optimal for the United States if this proposal is implemented. Because the link between the U.S. price and world price is broken above threshold, the stock level should be smaller than indicated by the Cochrane and Danin study, for example. The separation of working stocks and reserve stocks, and their substitutability under different structures should also be investigated for effective operation of this proposal.

Concluding Comments

The viability of United States food and agriculture is dependent on exports to the world grain market. Insulating policies by importers and variable import demands contribute to the instability of the world grain market. As a means to reduce the American grain sector's vulnerability to this instability, this paper proposes that American food and agriculture policy should move in the direction of insulating domestic food and agriculture from world instability and at the same time maintain its position as a dependable supplier of world grains. Existing programs which currently insulate U.S. agriculture from weak foreign demand are included in the proposal. Export levies in conjunction with the global allocation system are proposed because they can insulate domestic agriculture from transitory surges in foreign demand. As a result, domestic price is stabilized between the loan rate and the threshold price, and the American grain sector is open to the world market when world price is in the price stabilization band.

Also included in the proposal are bilateral agreements which require importers to maintain reserve programs. These agreements and the global allocation system ensure complying importers their import requirements at, or below, the threshold price. The bilateral agreements augment stability in the world grain market by requiring importers to increase their reserve stock holdings as world price declines and to decrease these holdings as world price increases. American reserve grain stocks would operate in the same manner. The export levy would rarely be operational because the deployment of reserve stocks held under the bilateral agreements, the domestic reserve stock held by the United States, and the global allocation scheme in all likelihood would hold the world price within the defined price stabilization band.

Producer-Consumer Trade-Offs in Export Cartels: The Wheat Cartel Case

Colin Carter, Nancy Gallini, and Andrew Schmitz

Since the formation of the Organization of Petroleum Exporting Countries (OPEC), several models of cartel-competitive fringe markets for an exhaustible resource have been developed. Derivations of Nash-Cournot equilibrium price paths under such a regime and insightful behavioral descriptions of limit pricing by monopolists facing potential competition have enriched the literature concerning this market structure (Salant and Gilbert and Goldman). In addition, the gains to producers from cartelization in the oil, copper, and bauxite industries have been derived empirically (Pindyck).

Largely in reaction to OPEC, numerous discussions have focused on an important but different commodity than those mentioned above. Several proposals (supported by many producers and consumers) have been put forth to form a cartel in wheat among the major exporters: the United States, Canada, Australia, and Argentina.[1] If such a cartel were organized, which group or groups have the most to gain? The above studies on exhaustible resources do not distinguish between producer and consumer effects in the exporting countries largely because domestic demand for this type of good is small relative to the total amount exported. In oil, for example, there is little need to distinguish between a producer export cartel, which maximizes producer returns, and a government cartel which maximizes the welfare of all groups since the solutions would be very similar. However, this is not necessarily the case for other commodities where domestic demand is an important component of market structure (e.g., in wheat the domestic demand is large relative to total wheat exports).[2]

The purpose of this paper is to consider a market in which the commodity in question has a relatively large domestic demand component and to demonstrate that a sharp distinction has to be made between a producer export cartel and a government export cartel. This paper shows (abstracting from implementation issues raised by Caves, Pindyck, and McCalla and Schmitz) that producers actually may lose from a government cartel. The conditions under which this can happen are derived theoretically. The model is then applied to the world wheat economy; and, interestingly, the empirical results suggest that there is a strong possibility that producers would, in fact, lose from a government wheat cartel if there are decreasing returns in production unless compensated by a tax on consumers. This result raises several important policy issues.

Government and Producer Cartels

The model in figure 1 gives the maximum gains from a government export cartel under the initial condition of free trade, perfect competition in the production and consumption sectors, and no retaliation on the part of importers. The demand and supply curves for the exporter of good X are D_C and S_C while, for the importer, the corresponding schedules are D_D and S_D. The excess demand curve for the importer is ED, and the excess supply curve for the exporter is ES. The free-trade price is P_F. The government cartel solution for the exporting country is computed by determining where the ES schedule crosses the marginal revenue curve (MR) pertaining to ED. The price in the importing country becomes P_C (for both consumers and producers), and the price in the exporting country for both producers and consumers becomes P_D. The tax revenue is *abcd*.

Unless consumers are effectively taxed by producers, the latter could well lose from the optimal government export tax shown in figure 1. Their alternative is the formation of a producer export cartel with the objective of maximizing producer welfare (recall that the government export cartel maximized the welfare of society). Under the producer cartel arrangement, the producers would always gain because the cartel would discriminate against domestic as well as foreign consumers. The producer cartel takes surplus from both the importer and the domestic consumer, whereas the gov-

Giannini Foundation Paper No. 570, University of California, Berkeley.

The authors acknowledge the usual insightful comments from Alex F. McCalla on world grain trade issues, and helpful comments from Bob Thompson and Bob Chambers.

[1] For instance, H.R. 3042 was introduced by Congressman Weaver on 15 March 1972 (Terpstra). The bill proposed the creation of a National Grain Board to yield the highest possible prices in foreign markets for American agricultural producers.

[2] In the 1977–78 crop year, for example, the consumption of wheat in the major exporting nations was approximately 34.7 million metric tons (mmt), while exports were 56.4 mmt and production was 89.6 mmt.

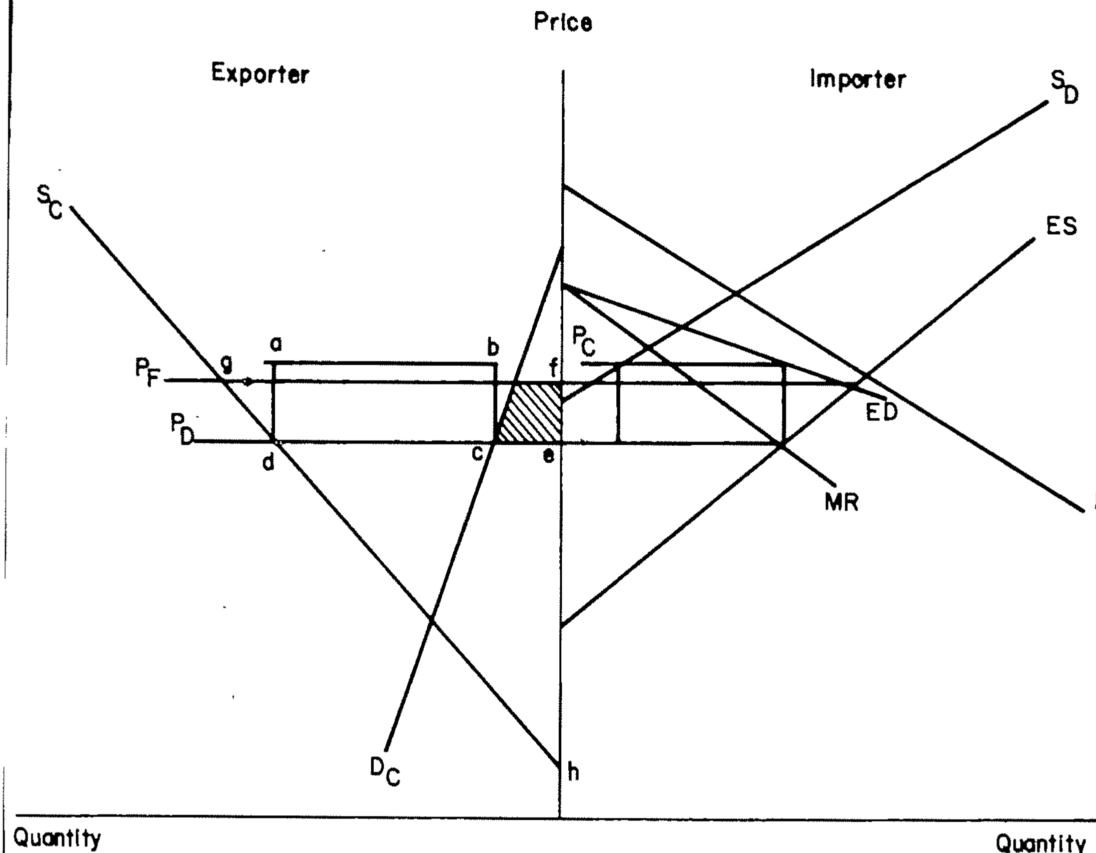

Figure 1. Optimal export cartel: with domestic demand

ernment cartel (discussed above) takes economic surplus only from the importing country.

Figure 2 represents the case where demand is absent in the exporting country. The free-trade price is P_F. Under a cartel solution, producer prices in the exporting country drop to P_D, but they increase to P_C in the importing contry. Clearly, the producer cartel solution and the government cartel solution are identical; and producers would always gain from a cartel. Their net gain in rents is $P_c abd - efg$. It is now clear why for wheat, unlike oil, a distinction has to be made between a government export cartel and a producer export cartel. In wheat, the schedule, D_C, is relatively much more important than in oil.

In the model in figure 1, the government cartel solution maximizes the welfare of both producers and consumers jointly. As a result, the government export cartel solution has to result, in the absence of retaliation, in a net welfare gain for the exporting country. However, what about specific groups in the exporting country? From figure 1, clearly the consumers gain from an export cartel by an amount of the crosshatched area. But what about producers? There is a loss to producers in the form of economic rent of *defg* and a gain in tax revenue of *abcd* (assuming that the tax revenue is given to producers).[3] Interestingly, producers can actually lose from the cartel. In figure 1, the loss in economic rent exceeds the gain in tax revenue. This will not always be the case, however, as will be shown later. Note that the reason the producers can lose from a government export cartel while society as a whole can gain is that consumers gain in the exporting country as a result of the cartel.

Producer Welfare and Government Cartels

In the following section, the conditions are derived under which producers are made worse off by a government cartel. The following notation is employed: P_C (cartel price to importing countries), P_D (domestic price in exporting countries under the cartel), P_F (free-trade price), and Q_i^j (output corresponding to the jth price on the ith curve), where $j = D$ (domestic price), F (free-trade price), or C (cartel price) and $i = ES$ (excess supply), ED (ex-

[3] In the case where the revenue is given to producers, acreage controls, or whatever will be needed to restrict output since the true producer price is no longer P_D if the tax revenue is viewed as a return on output.

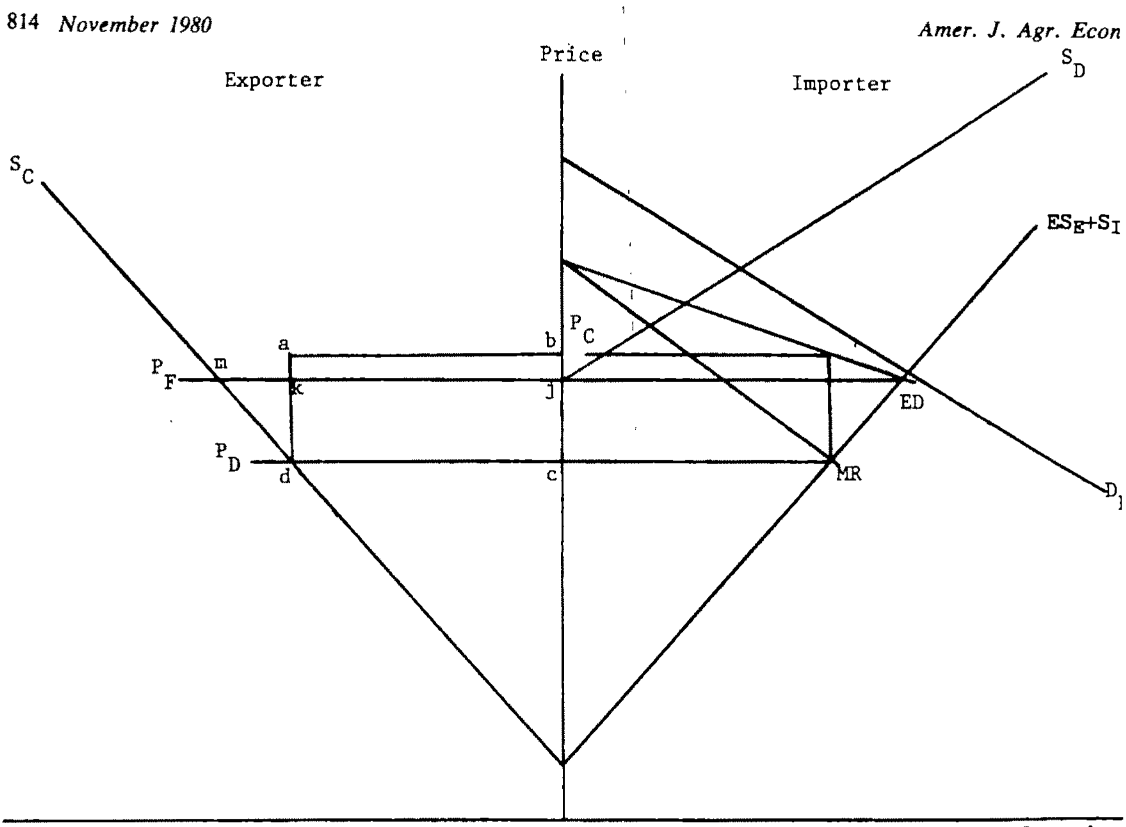

Figure 2. Optimal export cartel: without domestic demand

cess demand), S (supply of the exporting country), or D (demand of the exporting country). For linear excess supply and demand curves,[4] the net benefits to the producers in the exporting countries from a government cartel can be written as

$$(1)\quad B_P = (P_C - P_F)Q_{ES}^D - (P_F - P_D)\left[Q_D^D + \frac{1}{2}(Q_S^F - Q_S^D)\right].$$

The domestic price resulting from the government cartel is expressed in terms of the cartel price and the elasticity of excess demand at P_C—ϵ_{ED}^C—by the well-known relationship,

$$(2)\qquad P_D = P_C\left(1 - \frac{1}{\epsilon_{ED}^C}\right).$$

Then the producer benefits are negative when moving from a free-trade position to a government-formed cartel market structure if

$$(3)\qquad \frac{1}{\epsilon_{ED}^C}[(Q_{ES}^D - Q_{ES}^F) - (Q_D^F + Q_D^D)] < \frac{P_F - P_C}{P_C}(Q_S^F + Q_S^D).$$

To gain more insight into the inequality in (3), the excess demand and supply prices are specified, respectively, as

$$(4)\qquad P = \alpha - \beta Q_{ED},$$

$$(5)\qquad P = \gamma + \delta Q_{ES},$$

where α, β, and $\delta > 0$.

Expressions for the equilibrium prices and quantities under free trade and cartelization are determined in terms of the parameters in (4) and (5) and substituted into expression (3). The free-trade price, P_F, is the result of equating Q_{ES} with Q_{ED}. That is,

$$(6)\qquad P_F = \frac{\alpha\delta + \beta\gamma}{\beta + \delta}.$$

The cartel price in the importing countries (inclusive of the export tax) is that price for which the corresponding quantity of excess demand equals the quantity of excess supply at P_D, where P_D is defined in (2). That is, P_C is given by

$$(7)\qquad P_C = \frac{\alpha\delta + \beta\gamma}{\delta + \beta\,(1 - /\epsilon_{ED}^C)}.$$

Substituting $(P_F - P_C)/P_C$ for $-\beta/(\beta + \delta)\epsilon_{ED}^C$ and deriving the expressions for Q_{ES}^F and Q_{ES}^D obtains

$$(8)\qquad \frac{\beta\,(\alpha - \gamma)}{(\delta + \beta)} - \delta\,(Q_D^F + Q_D^D) < 0.$$

Inequality (8) suggests the impact of domestic demand on the change in producers' rents due to a change in market structure. If domestic demand equals zero at both the free-trade and cartel prices, the producers are always made better off from a

[4] Linear demand and supply curves are used to correspond to the empirical model in Section 3.

government cartel. Because it is assumed that the producers receive the entire export tax revenue, this corresponds to the single-market monopoly solution. However, if there is a domestic demand, there is a loss in producer surplus in the domestic market. The imposition of the export tax by the government (i.e., the government export cartel solution) has the effect of shifting the excess demand faced by the producers downward by the amount of the tax, thus resulting in a constrained competitive equilibrium price for the commodity less than that under free trade.

Further insight into the condition in (8) can be gained by formulating it for the exogenous parameters. Let $P = a - bq$ be the domestic demand for the commodity, then the condition can be rewritten as

$$(9)\quad \frac{\beta(\alpha-\gamma)}{(\delta+\beta)} - \frac{\delta}{b}\left(2a - \frac{\alpha\delta+\beta\gamma}{\beta+\delta} - \frac{\delta\alpha+2\beta\gamma}{\delta+2\beta}\right) < 0.$$

Algebraic manipulation transforms the left-hand side of (9) into a quadratic in β and is given by:

$$(10)\quad \beta^2[2b(\alpha-\gamma) - 4\delta(a-\gamma)] + \beta[b\delta(\alpha-\gamma) - 3\delta^2(2a-\gamma-\alpha)] - 2\delta^3(a-\alpha) < 0.$$

Let $F(\beta, \cdot)$ describe the function on the left-hand side of the inequality in (10) for given values of all the parameters except β. Differentiation of $F(\beta, \cdot)$ reveals that the function has a minimum at β^*, where

$$(11)\quad \beta^* \gtreqless 0 \quad \text{if} \quad b \lesseqgtr \frac{3\delta(2a-\gamma-\alpha)}{(\alpha-\gamma)}$$

$$b > \frac{2\delta(a-\gamma)}{(\alpha-\gamma)}$$

and a maximum at

$$\beta^* < 0 \quad \text{if} \quad b < \frac{2\delta(a-\gamma)}{(\alpha-\gamma)}.$$

Furthermore, if the intercept of the domestic demand exceeds that of the excess demand curve (i.e., $a > \alpha$), the value of the function evaluated at $\beta = 0$ is less than zero. The solid curves in figure 3A and 3B, respectively, illustrate the cases in which $F(\beta,\cdot)$ has a maximum and $b = \underline{b}$ where $\underline{b} < 2\delta(a-\gamma)/(\alpha-\gamma)$, and one of the cases in which the function has a minimum and $b = \bar{b}$ where $2\delta(\alpha-\gamma)/(\alpha-\gamma) < \bar{b} < 3\delta(2a-\gamma-\alpha)/(\alpha-\gamma)$. Note that only the positive orthants in figure 3A and 3B are of interest since a downward sloping demand curve has been assumed. Thus, if the slope of the domestic demand, b, is small relative to the slope of the excess supply, δ, the producers will always lose from a cartel (fig. 3A); if the domestic demand is fairly steep, there will be a critical β, β_1 in figure 3B above which there is a welfare gain to producers of the commodity.

As the value of a changes, there will be a shift and change in the functions shown in figure 3 by the dotted line. In particular, if $a = \alpha$, $F(\beta, \cdot)$ is linear; and it can be shown that the condition under which producers lose from a cartel is

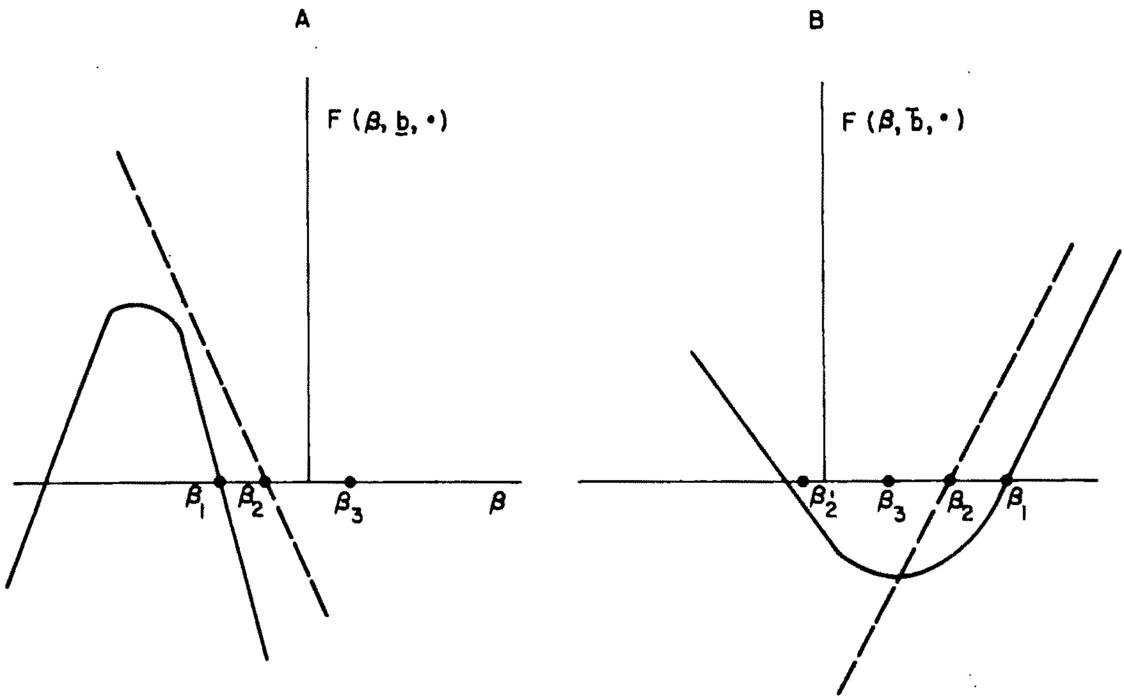

Figure 3. Critical values of excess demand slope

$$\beta < \frac{\delta\,(3\delta - b)}{2\,(b - 2\delta)} = \beta_2$$

for $2\delta < b < 3\delta$. Evaluating $F(\beta, \cdot)$ at β_2 in (12), given a is some value greater than α, indicates that the shift in the function due to a change in a places β_2 to the right of β_1 in figure 3A and to the left of β_1 in figure 3B. Note that producers lose from the cartel in the case of a relatively flat domestic demand (fig. 3A). However, unlike the previous case, if $b > 3\delta$, the critical value for β, β'_2, above which the producers are made better off from the cartel, lies in the negative orthant (fig. 3B). Thus, the producers should favor the development of the cartel regardless of the values of the other parameters. Finally, if $a < \alpha$, it can be shown that the critical β, β_3 for figure 3B lies further to the left of β_2 but still in the positive orthant. However, for the case of the small slope of domestic demand described in figure 3A, producers are better off from the cartel formation for $\beta \in (0, \beta_3)$.

These results are quite intuitive since they suggest that, as the intercept of the domestic demand falls below that of the excess demand curve (that is, as the domestic demand becomes more insignificant), the range of values which the slope of the excess demand curve can take on to insure a gain to producers under the cartel market structure gets larger. Also, as the slope of the demand gets larger, holding all else constant, the producers will more likely benefit from the cartel.

To summarize the results:

Result 1. If there is no domestic demand, producers always gain.

Result 2. If there is a domestic demand, then producers

(a) always gain, if $b > 3\delta\,(2a - \gamma - \alpha)/(\alpha - \gamma)$ and $a \leq \alpha$. If $a > \alpha$, there exists a β_1 above which producers gain from the cartel;

(b) always lose if $b < 2\delta\,(a - \gamma)/(\alpha - \gamma)$ and $a \geq \alpha$. If $a < \alpha$, there exists a β_3, below which producers will gain from the cartel;

(c) will gain if $2\delta\,(a - \gamma)/(\alpha - \gamma) < b < 3\delta\,(2a - \gamma - \alpha)/(\alpha - \gamma)$ and the slope of the excess demand is greater than some critical $\beta > 0$ which is a function of a, α, γ.

Empirical Results: The Wheat Cartel Case

The highly aggregate market model, described in figure 1, has never been estimated empirically for the wheat market, at least not to the authors' knowledge. Less aggregate empirical studies do exist, however. For the purpose of this paper, the most relevant of these is the one by Rojko, Urban, and Naive (hereinafter referred to as the ERS study).

The ERS study divides the world into twenty-two regions, and it has estimated linear supply and demand equations for wheat in each region. Average data for 1964–66 provide the base for the model. The parameters of the supply and demand equations are not all econometrically estimated. Some of the parameters are synthesized from economic theory and statistical findings.

From the estimates of the ERS study, aggregate supply and demand functions were computed for the major wheat exporters and importers. The aggregate supply and demand curves were obtained by a horizontal summation of the countries' individual supply and demand curves. Because of time constraints, these estimates are likely as good as one can realistically derive for the world wheat market given the purpose at hand which is only to show that producers may actually lose from a government export cartel. It must also be recognized that it is very difficult to "statistically fit" supply and demand functions for the world wheat market.

The export sector in our aggregation process is made up of the United States, Canada, Australia and Argentina (these countries account for over 80% of world wheat exports). The importing bloc includes the United Kingdom, Japan, western and eastern Europe, South America, Asia, etc. (ERS study).

By substituting 1978–79 average data for the coarse grains and rice price and quantity variables, the intercept terms of the ERS supply and demand equations were adjusted and expressed as functions of own-price and quantity only. The adjusted aggregate equations serve as the basis for the empirical estimates of the welfare effects of a wheat cartel in table 1. The annual net trade of the Soviet Union and China is treated exogenously by increasing the intercept of the importers' excess demand function for wheat by 15 million metric tons (mmt) per annum to approximately correspond to 1980 net imports.[5]

The aggregate equations of the wheat model are

Exporters:

$$Q_{Sd_t} = 90{,}757.4 + 380.4\,P_t \tag{13}$$

$$Q_{Dd_t} = 45{,}285.0 - 54.4\,P_t \tag{14}$$

$$Q_{ESd_t} = 45{,}472.4 + 434.8\,P_t \tag{15}$$

Importers:

$$Q_{Sf_t} = 165{,}912.9 + 288.9\,P_t \tag{16}$$

$$Q_{Df_t} = 355{,}676.1 - 395.9\,P_t \tag{17}$$

$$Q_{EDf_t} = 189{,}763.2 - 684.8\,P_t, \tag{18}$$

where Q_{Sd_t} is total annual supply of wheat in the exporting bloc (× 1,000 tonnes), Q_{Dd_t} is total annual demand for wheat in the exporting bloc (× 1,000 tonnes), Q_{ESd_t} is total annual excess supply of wheat in the exporting bloc (× 1,000 tonnes), Q_{Sf_t} is total annual supply of wheat in the importing bloc

[5] A 10-year (1965–75) average of net imports of wheat by the USSR and China is nearly 10 million tons per annum; for exact figures, see International Wheat Council.

Table 1. Welfare Effects of the Formation of a Wheat Cartel by the Major Exporters, 1980

Major Exporters	Welfare Effects[a]	Major Importers	Welfare Effects
	(U.S. $mill.)		(U.S. $mill.)
1. Gain in consumers' surplus	5,361	1. Loss in consumers' surplus	25,202
2. Loss in producers' surplus	17,049	2. Gain in producers' surplus	17,780
3. Export tax revenue	16,003	3. Net loss (1 minus 2)	7,422
4. Net gain (1 plus 3 minus 2)	4,315		
5. Loss to producers including tax revenue (2 minus 3)	1,046		

Source: Own estimations.
[a] The values are estimated for a single time period only.

($\times$ 1,000 tonnes), Q_{Df_t} is total annual demand for wheat in the importing bloc ($\times$ 1,000 tonnes), Q_{EDf_t} is total annual excess demand for wheat in the importing bloc ($\times$ 1,000 tonnes), and P_t is price of wheat (dollars per tonne) in 1979 dollars.

Table 1 gives the welfare gains and losses resulting from an optimal government-controlled cartel. The estimates are based on equations (13) through (18). Interpretation of the estimates of gains and losses presented in table 1 should be done with some caution. The empirical results rest on the assumption that the market was in competitive equilibrium when the ERS parameter estimates were made and, more important, that the formation of a wheat cartel is done *vis à vis* an initial competitive situation.

The estimates show that, even if producers receive the entire export tax revenue, they are worse off with a government wheat cartel. Their loss is estimated at roughly $1 billion per year. The welfare gain accruing to consumers in the exporting nations is $5.4 billion per annum. This interesting empirical result makes it clear that consumers in the exporting countries have the most to gain from an optimal export tax because the domestic price falls substantially under such an arrangement.

In relating the empirical findings to the specifications in the previous section, the following suggestions are offered as the major determinants of the net loss accruing to the wheat producers in the domestic market:

The estimated quantity demanded domestically [from (13) through (18)] at the free-trade and cartel-constrained prices is 30.9 mmt and 38.2 mmt, respectively, while the estimated domestic supplies at these prices are 191.2 mmt and 140.3 mmt. Thus, domestic demand comprises a significant 16% and 27% of the total domestic supply under the two market structures.

For the estimated equations (13) through (18), $a = 832$, $\alpha = 277$, $b = .02$, $2\delta\ (a - \gamma)/(\alpha - \gamma) = .01$, and $3\delta\ (2a - \gamma - \alpha)/(\alpha - \gamma) = .03$. Therefore, $a > \alpha$ and b lies in the interval bounded by .01 and .03.

Relating these estimates to expression (10) leads to the conclusion that the critical β below which producers will lose from the formation of a cartel is .0028. Because the estimated slope of the excess demand function is .0015, there is a loss to producers.

Thus, the relatively large demand for wheat by domestic consumers and the relatively flat importers' excess demand are the indicators of a possible loss to producers from a government-formed cartel.

Conclusions

Theoretically, it has been shown that the formation of a government export cartel, in which the government takes into account the welfare of producers and consumers, does not necessarily result in a welfare gain to producers unless consumers are taxed. In the world wheat economy, the results show that the producers in the exporting countries would lose from such an arrangement in the wheat market. However, it should be kept firmly in mind that the results are compared to a situation of free trade, and no retaliation is assumed on the part of importers. Both of these assumptions should be relaxed in future research. Concerning the free-trade assumption, this may be highly restrictive in view of the optimal tariff thesis recently proposed by Carter and Schmitz. In this case, a cartel threat may result in the EEC moving to freer trade. Also, if, for example—in reaction to the cartel price—technological change occurs, the cartel may create disincentives in the form of limit pricing. It should be noted that, while the producers in the importing country always gain from the cartel arrangement, it is conceivable that they may improve their position by increasing their production at home, even at the expense of a lower cartel price.

A policy issue raised by the analysis (not clearly pointed out previously) is that, even though governments, producers, and many consumers in the major wheat exporting countries seem to support some type of wheat cartel arrangement, there may be a conflict of interest among these groups once specific proposals are examined in detail. The results of this paper show that, if a government cartel is formed, consumers have the most to gain and

producers in the exporting countries may, in fact, lose unless appropriate redistribution policies are introduced. The issue of current redistribution policies that now exist in the wheat versus nonagricultural sectors is not addressed in this paper.

Import Tariffs and Price Formation in the World Wheat Market: Comment

Thomas Grennes and Paul R. Johnson

One of the well-known results of orthodox trade theory concerns the ability of exporters and importers to take advantage of less than perfectly elastic demand and supply functions. It is possible to tax imports or exports so that foreign suppliers or foreign demanders pay some of the tax. In this way, it is possible that the national income of a buyer or seller nation can be increased relative to a free-trade position. In fact, with sufficient information on supply and demand functions, one can find the tax that maximizes welfare, the so-called optimum tariff.

Most tariffs are not of this nature. Typically, tariffs have been imposed for revenue purposes or for protection of domestic producers of a good. For the United States, where export taxes are unconstitutional, the opposite case of an optimum export levy is even less discussed. (For an exception, see Johnson 1964). Since motivations are not easily analyzed, one must go to the market evidence for inferences about putative monopoly or monopsony behavior. Recently Carter and Schmitz (CS) have done this for the international wheat market. They test the hypothesis that for certain periods two of the major importers of wheat, Japan and the European Economic Community (EC), have wielded market power in such a way that their tariffs are close to optimum. In our judgment this analysis seems to gloss over some relevant information, and hence it could be misleading. Our concern is not with the proposition that Japan and the EC may individually or collectively be large enough importers to affect the price. Rather, we are concerned with the conclusion that the EC and Japanese import tariffs on wheat, in practice, have not only been welfare increasing (for EC and Japan) but have been close to optimal.

The Carter-Schmitz Optimum Tariff

The standard formula for deriving the optimal tariff in a partial equilibrium setting for a particular product is that the percentage tariff be equal to $1/E$, where E is the elasticity of excess supply that the country in question faces. CS do not present estimates for elasticities. They deal with linear demand and supply functions, and the reader can obtain elasticity estimates by reading off numbers from their figure 2. Our calculations based on figure 2 lead to the following estimates: (*a*) the elasticity of supply of the major exporters at the equilibrium price of \$147/ton (their estimate) is .54; (*b*) the elasticity of excess supply facing the two importers is .75; (*c*) the elasticity of the total supply function facing the importers (excess supply plus supply in the importing countries) is .49.[1]

The implied optimum tariff (by $1/E$) associated with the elasticity in (*c*) is 2.04. This estimate is roughly consistent with some other arithmetic they produce. The market price (in 1964–66 dollars according to figure 2) associated with the optimum tariff is \$198/ton. The price to the exporters from this price and the tariff is \$72. The implied tariff, then, is \$126. This tariff is approximately 180% of \$70. The implied elasticity of excess supply is then 1/1.80 or .55. So, we conclude that CS are calculating optima from a supply elasticity in the neighborhood of .5. Such an elasticity implies a great deal of market power.

The optimum tariff is a function of the elasticity of supply of imports facing a nation. The import supply elasticity can be expressed in terms of the supply and demand elasticities in the rest of the world:

$$E = \frac{S}{M}\epsilon_w - \frac{D}{M}\eta_w,$$

where S is supply in the rest of the world, D is demand in the rest of the world, M is imports, ϵ_w and η_w are the respective supply and demand elasticities in the rest of the world. Underlying this expression is the assumption that price changes occurring in the importing country are transmitted to the exporting country. If, instead, suppliers of imports in the rest of the world are insulated from price changes in the importing country, their supplies will be less responsive than this expression indicates (see Bredahl, Meyers, Collins). In the extreme case of complete insulation,[2] the observed

The authors are associate professor and professor of Economics and Business, respectively, at North Carolina State University.

[1] This elasticity is taken at point A in figure 2 of CS. It is not clear from the diagram how or why domestic supply was added to excess supply to calculate the tariff. We are trying to generate the numbers that are only implicit in their article. The correct elasticity to use would seem to be the excess supply elasticity. The implied optimum tariff is then 150%, still larger than observed in the EC.

[2] When insulation occurs, it is necessary to distinguish between prices in the importing country (P^*) and prices in the exporting

import supply elasticity will be zero regardless of the values of ϵ_w and η_w. This problem of insulating trade policies has been empirically important for grain, and it has been discussed extensively in this *Journal* (D. G. Johnson; P. Johnson, Grennes, Thursby; Shei and Thompson; Josling; and Zwart and Meilke). The issue of the variability of trade barriers is important, but at this point let us follow CS and ignore it. The problem of insulation is addressed separately below.

Consider the optimum tariff level implied by conventional values of supply and demand parameters. Let the elasticity of supply in the rest of the world lie between +.2 and +.5 and the demand elasticity between −.1 and −.3. We have calculated weights for *S/M* and *D/M* for four periods. The first is a four-year average 1965–69, and the others are the crop years ending 1972, 1976, and 1977. Following CS, the USSR and China are omitted, although this biases the import elasticity downward and the optimum tariff upward.

Weights of 16 and 15 and extreme values of the above elasticities result in an implied value of the import supply elasticity of +4.7 to +12.5. The associated optimal tariff should lie between 8% and 21%. The discrepancy between these numbers and the CS optimum tariff is large, indeed. We do not claim great precision for these import supply elasticities; but if they are in error, they are likely to understate the true elasticities. Japan and the EEC have taken less than 20% of world wheat imports, and this leaves a large residual market to respond to price fluctuations. For example in the crop year 1976, India imported more wheat than Japan. Since we do not expect complete agreement on the elasticity estimates, we offer additional evidence on the world wheat market concerning the CS thesis.

The Actual EEC Tariff and the Carter-Schmitz Optimum Tariff

The optimum tariff for the CS model is approximately 180%. The most damaging evidence facing the model is that the actual tariff has been far below this level. Of course, the actual levy varies continuously, but for the period 1966–73, the CS optimum tariff, as they recognize, was more than twice as high as the actual EEC tariff.[3] Even when one excludes the years most embarrassing to the mode (1973–76), the actual tariff rates ranged from 68%–87%. From the middle of 1973 to the end of 1974 the EEC wheat levy was zero. Japan does not impose an explicit tariff, but an implicit rate can b calculated from the difference between the sellin and buying prices of the Japan Food Agency. I 1973–74 this implicit wheat tariff was negative.

The Variable Levy As an Optimum Tariff

The salient characteristic of the EEC grain tariff i its continuous variability, but CS do not discuss thi feature. Because the optimum tariff rate is equal t the inverse of the import supply elasticity, the EE levy is optimal only if it moves inversely with ϵ_w The levy has systematically deviated from that pattern, and evidence can be found in the recent literature on insulating trade policies. When foreign grai suppliers prevent price changes from being transmitted to their domestic economies (transmissio elasticities decline), ϵ_w is diminished and the optimal EEC tariff should increase. In 1973–74, man of the major grain-trading countries carried out insulating trade policies. Instead of raising the tarif to exploit a less elastic import supply, the EE reduced the levy all the way to zero. The collectiv monopsony power of EEC countries was used t worsen the terms of trade of the customs union The nature of the variability of the EEC grain lev guarantees its suboptimality.

U.S. Export Policy and USSR–China Import Policy

CS deal with two periods, one prior to 1972–74 an one subsequent to those years. Their price data an diagrams refer to the earlier period. They observ an export price in the neighborhood of $72/ton. Thi price is approximately one-half of their estimate equilibrium price and is attributed to importer exercising their monopsony power. An alternativ explanation of low world prices is the export pro motion policies of major sellers. Both the Unite States and Canada used foreign markets to try t reduce wheat inventories that accumulated as a re sult of domestic intervention policy. At one poin Public Law 480 programs were involved in 85% o U.S. wheat exports, and before 1972 subsidies wer also paid on commercial exports. Thus even if al importers behaved competitively, there have bee important price-depressing forces coming from ex port suppliers.

A discussion of monopsony in the world whea market is incomplete without considering the rol

country (P). The elasticity of supply of imports with respect to price in importing country is

$$E^* = \eta_{P^*P}\left(\frac{S}{M}\epsilon_w - \frac{D}{M}\eta_w\right),$$

where $\eta_{P^*P} = \dfrac{dP^*}{dP}\dfrac{P}{P^*}$ is the transmission elasticity with respect to prices in the exporting and importing (P) countries. With complete insulation $\eta_{P^*P} = 0$ and $E^* = 0$ for any ϵ_w and η_w.

[3] The dollar tariff is the same for all varieties of wheat, but because wheat is a differentiated product, the tariff rate depends on the variety and price chosen. The rough figures reported above refer to U.S. no. 2 Hard Winter and 13.5% at Rotterdam a reported by the U.S. Department of Agriculture in *Foreign Agriculture* before 1976.

of the USSR and China. Both have abandoned earlier attempts at self-sufficiency, and in the 1970s, they have been major wheat importers. Indeed, in the last three crop years both the USSR and China imported more wheat than either Japan or Western Europe (U.S. Department of Agriculture 1979, p. 21). An interesting empirical question is whether the price-depressing effect of EEC-Japan protectionism has been greater than the price-increasing effect of Soviet-China trade expansion. To the extent that tariffs in the EEC and Japan permitted buyers in those countries to obtain wheat at lower prices than they otherwise would, these same consumer benefits were shared by Soviet and Chinese buyers. This free-rider problem is one of the main reasons why most historical monopsonies have broken down.

Changes in Market Power

CS present their monopsony model as an alternative to the earlier view of the world wheat market as an oligopoly (see Alaouze, Watson, Sturgess; McCalla). One of the puzzling aspects of the oligopoly model is how frequently competitive price wars break out. Producer country market power seems to appear and disappear without a warning. CS assert that the wheat market has usually been a buyers market, but they concede that the monopsonistic importers lost power in the high price years of the 1970s. It is curious the way this alleged market power shifts so frequently from one group to another. Finding the welfare-maximizing tariff must be difficult for the interested governments.

Monopsony, Oligopoly, and the Theory of Regulation

The CS monopsony model and the oligopoly model of the world wheat market are incompatible with each other; but they share the same implicit theory of government regulation.[4] Both views represent the public interest theory of regulation (see Stigler; Posner; Abrams and Settle) which implies that governments choose policies that will maximize national income. In this context the monopsony view says that governments adjust tariff rates so as to maximize national income rather than domestic producer income. The oligopoly view says that exports will be restricted to achieve the highest national income even if domestic producer income suffers. According to the alternative economic theory of regulation those private groups most affected by trade policy will try to influence policy so as to promote their private interests even if national income falls. In this context, the economic theory implies that wheat policy would be determined by the interests of domestic wheat producers of the trading countries. Because producer interests sometimes conflict with rules necessary to achieve a cohesive national oligopoly or monopsony, the collusive arrangements break down. The economic theory of regulation rejects both monopsony and oligopoly models as useful representations of world wheat markets. Because there is much evidence that wheat policy in the EEC, and the United States is more strongly influenced by wheat producers than wheat consumers, we find the economic theory more convincing than the public interest theory. In spite of tariffs the world wheat market is not simply a buyers market, and in spite of attempted collusion by exporters the market is not simply a sellers market. As in most other markets it is the interaction of both supply and demand that determines wheat prices. A proper analysis of wheat trade cannot ignore barriers or export controls, but these important institutions can be and have been incorporated into competitive trade models.

[*Received October 1979; revision accepted February 1980.*]

[4] CS state (p. 517) that both views of the market may be compatible. However, all of the calculations in their paper are based on competitive import supply curves which are irrelevant if the suppliers are oligopolists. Similarly, Alaouze, Watson, and Sturgess confronted their triopolists with competitive demand curves (p. 181). One could represent the wheat market as a bilateral monopoly but this has not been done in the literature, and it presents problems for the notion of an optimum tariff.

Import Tariffs and Price Formation in the World Wheat Market: Reply

Colin Carter and Andrew Schmitz

The purpose of our paper was to put forth and empirically test the alternate viewpoint to the generally accepted notion that price formation in the world wheat market is determined largely by the major exporters. We emphasized that the market power on the part of importers of wheat is perhaps greater than the power attributed to exporters by previous researchers. This hypothesis was motivated by the observation that the major importers of wheat (especially Japan and the European Economic Community [EEC]) practice trade restriction. This phenomenon is true for other agricultural commodities as well (e.g., feed grains, beef, and dairy products); and perhaps our hypothesis would also receive strong empirical support for some of these other markets.

Grennes and Johnson (GJ) suggest that our analysis could be misleading to the reader. Our conclusion that the EEC and Japanese trade barriers have enhanced their own economic welfare is challenged. GJ imply these import barriers are used for noneconomic reasons. They also express concern over our findings that the import tariffs (or equivalent quotas) are optimal. Nowhere in our paper do we argue that the import tariffs and quotas are exactly optimal. We argue that these barriers seem to approach optimality. As GJ rightly suggest, an optimal tariff would be next to impossible to calculate at each moment in time largely because of the stochastic nature of supply of agricultural products.

The analysis of optimum tariffs in our paper draws on the graphical exposition in figure 1. The optimum tariff solution can easily be shown algebraically as well. Suppose we have a one commodity-two country world or a two good-two country world with a numeraire commodity. Let $p_s(q)$ be the (inverse) excess supply curve of the commodity which faces the importing country and assume $p'_s(q) > 0$. To maximize national welfare, the importing nation equates its excess demand price, $p_d(q)$, to the marginal cost of importing the commodity. Hence, the optimizing condition is

$$(1) \qquad p_d(q^*) = p_s(q^*) + p'_s(q^*)q^*, \text{ or}$$

$$(2) \qquad p_d(q^*) = p_s(q^*)\left(1 + \frac{1}{\epsilon_s}\right),$$

where ϵ_s is the elasticity of excess supply and is > 0.

Condition (1) states that the marginal benefit of an additional unit of the imported good $p_d(q^*)$ is equal to the marginal cost of obtaining it. However, the exporting nation is paid less for the commodity than the marginal benefit that it confers on the importing nation. The wedge driven between the price in the importing nation, $p_d(q^*)$, and the price in the exporting nation, $p_s(q^*)$, can be defined as the optimal import tariff (τ). Defining τ in percentage terms, we find

$$(3) \qquad \tau = \frac{p_d(q^*) - p_s(q^*)}{p_s(q^*)} = \frac{1}{\epsilon_s}.$$

This condition states that the percentage change in the import tariff rate is inversely related to the elasticity of excess supply. It is obvious from (3) that, as $\epsilon_s \rightarrow \infty$, the behavior of the importer approaches free trade.

GJ use condition (3) to infer the elasticities associated with our linear supply and demand functions. They conclude that our implied estimate of ϵ_s is in the neighborhood of .5 and is far too low. Their smallest estimate of ϵ_s is at least ten times this magnitude. This discrepancy arises for one major reason. Our calculations are made correctly because we take into account all major importers, including the centrally planned economies; GJ's calculations are for the EEC and Japan only. This is the reason they estimate the large weights of sixteen and fifteen for S/M and D/M, respectively. In our original paper we argued that Japan and the EEC may be acting as price leaders in setting a near optimal import tariff (for the group of importers) and thus depressing the world price of wheat. The other major importers (e.g., USSR, China, India, Brazil, Korea, Pakistan, Egypt, etc.) also benefit from the lowered world price and, in addition, may be using tariffs and quotas to their advantage. This is somewhat analogous to the benefit accruing to fringe oil suppliers (e.g., Mexico and Canada) from the export tax placed on oil by OPEC.

The 1973–75 period is not as embarrassing to our simple model as GJ suggest. They mention that the EEC levy was near zero in the 1973–74 period. The levies were low during this period as the EEC was not in a position to exert power in the market during the "commodity boom" at the time. We recognized in our paper that this was an atypical period. Bar-

Helpful discussions and comments from Alex McCalla are gratefully acknowledged.

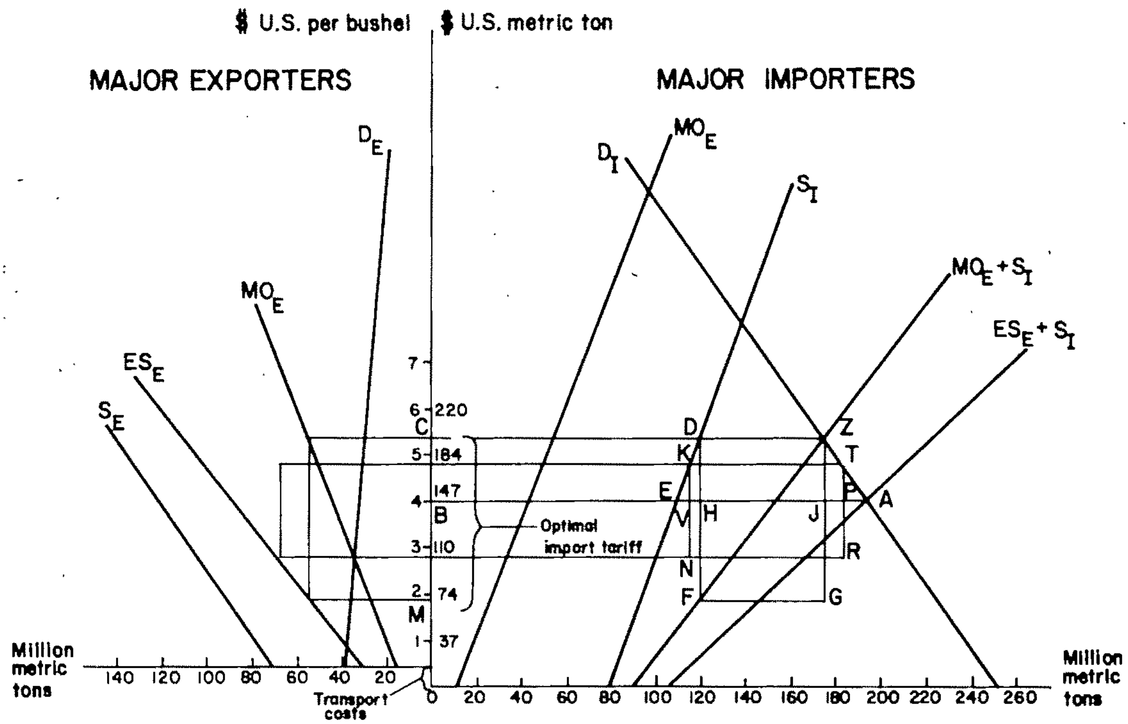

Figure 1. Empirical estimate of the optimal import tariff solution (1964–66 prices)

ring periodical exceptions, our model seeks to explain the general phenomena in the market of importers exerting power. In this context, our model includes a tariff which has a probability distribution associated with it.

GJ suggest that the EEC tariff has been historically below our optimal calculated level of 180%. This fact we cannot deny. The Atlantic Council of the United States has projected the probable level of the tariff-equivalent of the EEC variable levy on wheat, during normal times, to equilibrate at 120%. Cline et al. estimate the tariff equivalent of the Japanese quota to be approximately 145%.

Japan is a much more important importer of wheat than is the EEC, and GJ have much less to say about the Japanese import barriers except for a passing comment that their implicit tariff on wheat was negative during the commodity boom period. The statistics in table 1 of Carter and Schmitz do not support this comment even during the period of high world prices. In any event, the restrictive policies of Japan seem to fit our hypothesis better than do those of the EEC.

In this discussion it is important to recognize that the tariff need not be optimal to be welfare improving. This can be seen clearly in figure 1. Suppose that the importers set a tariff that is somewhat less than the optimal *CM* and is equal to *KN*. This suboptimal tariff is still welfare increasing for the importers *vis-à-vis* free trade. The net gain is equal to the area *NRPV* − (*KEV* and *TAP*).

GJ argue that the EEC tariff rates are normally 68% to 87%. We have drawn the tariff *KN* in figure 1 to correspond roughly to an import tariff of 70%. Even though this lower tariff is not optimal, it is still beneficial to the importing nations. The tariff revenue associated with *KN* is estimated to be approximately $5.2 billion. Consumers in the importing country would lose an estimated $6.0 billion and producers would gain $3.3 billion under this tariff. The net gain to the importing nations, therefore, would be an estimated $2.5 billion (1964–66 dollars). The requirement that the import tariff be optimal is not, therefore, crucial for the major results of our analysis to hold. The wheat importing nations benefit from restricted trade and the magnitude of the benefits depend on how close their restrictive policies are to being optimal.

Earlier price wars in the wheat market are coined "competitive" by GJ. However, McCalla has shown that price wars do not imply a competitive market. GJ discount the relevance of the studies by Carter and Schmitz; Alaouze, Watson and Sturgess; McCalla; and Taplin because they reject the notion that governments choose policies with the aim of maximizing national welfare. We fail to see the trade-off between import tariffs (quotas) and high domestic producer incomes in the EEC and Japan. Quite the contrary, we believe that the producers in these countries support trade barriers and so may consumers because governments can use the tariff revenues to offset the negative consumption effect of the tariff. If one could assume that the economic theory of regulation applies (as GJ do), then it is puzzling why consumers in Japan and the EEC do not lobby for freer trade in agricul-

tural commodities and why the governments do not give in to their demands. The consumers obviously have more to lose from restricted trade than the producers have to gain if tariffs are welfare decreasing in an aggregate sense. But if they are not, consumers may favor tariffs depending on how the tariff revenue is distributed.

The Structure and Changes of Technology in Prewar Japanese Agriculture: Comment

Timothy L. Hunt

In a recent issue of this *Journal*, Nghiep presents an explanation of the structure and changes of technology in Japanese agriculture, 1903–38, using a translog cost-function approach. The interesting and unique feature of Nghiep's work is the application of a distributed lag scheme (Nerlove) to each of the derived cost share equations. The article relates the desired cost shares (S^*) and actual cost shares (S) for factor input i at time period t as,

$$(1) \qquad (S_{it} - S_{it-1}) = \alpha_i(S^*_{it} - S_{it-1}),$$

where Nghiep shows that the adjustment parameter is a constant across the input cost shares, i.e., $\alpha_i = \alpha$, because the real or desired cost shares must add up to one in the translog case. That leads directly to the input share equations,

$$(2) \quad S_{it} = \alpha\gamma_i + \Sigma_j\alpha\gamma_{ij}\ln P_j + \alpha\gamma_{it}\ln T + (1 - \alpha)S_{it-1}.$$

Nghiep's development and application of (2), a dynamic version of the translog cost function, is a valuable contribution. However, there are two major deficiencies.

First, no economic rationale or empirical evidence in support of the assumed lag structure, which implies that farmers adjust all factor inputs—land, labor, machinery, fertilizer, and other—to their desired cost shares at the same rate, α, is offered. Nghiep's proof that $\alpha_i = \alpha$ in the translog case is correct, but the plausibility of economic agents behaving as postulated in the model is not discussed. Even Nerlove has examined the possibility of an equality in the lag parameter between factor inputs and dismissed it as "grossly unreasonable" (p. 141).

Nevertheless, given Nghiep's assumed lag structure, it is possible to evaluate the restriction empirically. Individual R^2 and t-values are of little help because the system of equations in (2) is simultaneous with constraints across equations in which the assumed lag structure itself involves an additional constraint. Therefore, the parameter estimate on the lagged value of the dependent variable, and through it the assumed lag structure, must be evaluated as part of a simultaneous system.

It is disappointing that Nghiep did not carry out a statistical test of his assumed lag structure. First, the null hypothesis of $\alpha = 1$ versus the alternative hypothesis of $\alpha_i = \alpha$ can be tested, in which case failure to reject the null hypothesis means there is no overall support for the distributed lag scheme in (1), i.e., the translog cost function is static. Second, the null hypothesis of $\alpha_i = \alpha$ versus the alternative hypothesis of $\alpha_i \neq \alpha$ can be tested, in which case failure to reject the null hypothesis implies support for Nghiep's model specification. This second test is possible because, in general, the actual sample estimates of the adjustment parameter will not be the same across the input cost shares even though the model specification implies such equality. For more detailed exposition of these tests, see Christensen, Jorgenson, and Lau, and others.

The second deficiency of the article is that the translog functional form itself may be inappropriate in this case. In general, due to its quadratic nature, the translog functional form will not satisfy the conditions for a well-behaved (regular) cost function globally; it is a local approximation only. However, for most applied econometrics situations, this is not a hindrance to the utilization of translog because it is possible to test the estimated translog cost function for regularity in the observed range of input prices. In brief, the translog cost function is monotonic if the fitted cost shares are positive at each data point; it is concave if the matrix of estimated Allen elasticities is negative semidefinite at each data point; and it is symmetric if the restrictions $\gamma_{ij} = \gamma_{ji}$ cannot be rejected.

Keeping in mind that the regularity conditions are minimal conditions implied by economic theory and that the regularity tests are standard in the translog cost literature including Binswanger (1974b), Berndt and Wood, and Halvorsen, it is unfortunate that these tests were not carried out (or at least not reported) and instead the restraints implied by regularity were simply imposed on the estimating model.

Even so, there is some indication that the cost function estimated by Nghiep is not regular because two of the five direct price elasticities are positive, specifically those for land and machinery. Nghiep, however, suggests support for these results by arguing that an aggregate cost function for agriculture need not be well-behaved, or that farmers "utilize their labor force to develop new land and to produce farm implements in slack seasons when the prices of these items rose" (p. 691). While the existence of aggregation problems in macro studies is well-known, many such studies have found the

regularity conditions satisfied using a translog framework including Binswanger (1974a) for U.S. agriculture and Kako for Japanese rice production. Furthermore, the possibility of upward-sloping factor demand curves appears remote and without support in the literature.

The fundamental problem with both of Nghiep's suggestions, however, is that they involve a denial of the very theory on which his estimating model is based. Specifically, Nghiep's suggestions imply either that a meaningful aggregate cost function does not exist, or that if one exists, it is not regular. However, if the true production and cost structure is not regular, then the Shephard duality theorem cannot be used to relate the first derivative of the translog cost function with respect to the log of the factor prices to the cost shares, because regularity is a condition of the theorem itself as indicated by Shephard (pp. 169–71) and amplified in Diewert (p. 112). Furthermore, it is inappropriate to impose the constraints suggested by regularity on estimating equations of a cost structure which itself is not regular. Allen (pp. 503–09) clearly pointed out that imposition of regularity on a cost structure restrains the constant output price (E_{ij}) and Allen (σ_{ij}) elasticities such that $\Sigma_j E_{ij} = \Sigma_j S^*{}_j \sigma_{ij} = 0$. Thus, if the estimated own-price elasticity is positive, indicating irregularity, then some or all of the cross elasticities must be biased because the zero sum requirement remains.

There is an alternative explanation of the lack of regularity in the estimated model; namely, the problem lies within the estimated function only. For example, the domain of the sample may be such that a local approximation of the underlying cost function is not meaningful, or the estimating model itself may be misspecified, possibly because of a left-out exogenous policy variable or because of the imposition of a highly restrictive (and untested) lag structure. Regardless, the estimates remain biased and of little value because now the lack of regularity in the estimated model is indicative of a failure to estimate the true, regular cost function.

Thus, Nghiep's suggestions indicating the true cost function need not be regular are misguided, particularly in the translog case, because the estimating model itself is derived on the basis of regularity. The alternative is to ascribe the lack of regularity to the estimated function only. In both cases, however, the parameter estimates and derived elasticities are biased and therefore of little value in explaining the structure and changes of technology in prewar Japanese agriculture.

The Structure and Changes of Technology in Prewar Japanese Agriculture: Reply

Le Thanh Nghiep

Hunt's first comment is on the assumption that the share adjustment parameters are equal across inputs and across time. This assumption, according to the commentator, is intuitively unrealistic and needs empirical justification. In what follows I will use some numerical examples to show that (*a*) the across-input equality of the adjustment parameters, as proved in my paper, is an unavoidable identity, and that (*b*) the across-time equality of the parameters is a plausible assumption.

Consider the following three distributed lag schemes:

$$(1) \qquad (S_{it} - S_{it-1}) = \alpha(S^*_{it} - S_{it-1}),$$

$$(2) \qquad (X_{it} - X_{it-1}) = \beta_i(X^*_{it} - X_{it-1}),$$

$$(3) \qquad (X_{it} - X_{it-1}) = \frac{X^*_i - X_{i0}}{n_i},$$

where $i = 1, 2$; S stands for factor share, X for input quantity, and $*$ indicates the corresponding desirable level. Equation (1) is the adjustment scheme used in my paper (hereafter, NG adjustment). Equation (2) is the well-known Nerlovian adjustment scheme (hereafter, NE adjustment). Equation (3) presents a lag scheme in which the adjustment path of input quantity is a straight line (hereafter, SI adjustment). Table 1 and table 2 present the corre sponding share adjustment parameters compute from an NE-adjustment case with $\beta_1 = 0.5$, and $\beta_2 =$ 0.2, and an SL-adjustment case with $n_1 = 2$, and $n_2 =$ 5. It is observed that the resulting adjustment pa rameters are always identical across inputs how ever different are the input-adjustment parameters The resulting share adjustment parameters, how ever, tend to decrease in case of NE adjustmen (table 1) and increase in case of SL adjustmen (table 2). Thus, the NG adjustment is not consisten with both NE and SL schemes. However, fron these computation results we can conjecture tha the corresponding input adjustment path falls ir somewhere between those of NE and SL schemes Therefore, the assumed across-time equality o share adjustment parameters is not implausible.

Hunt's second comment well depicts the prob lems of my paper. I do not have much to say excep the following three points, for the readers to rightl understand my paper. First, the paper hypothesize and empirically showed that in the period 1900–4(the Japanese agricultural sector was locked int extremely narrow regions of factor substitution and large parts of changes in the input levels o production factors were due to biased technica changes. It is not whether a substitution or demanc

	Factor Two			$\frac{.651163 - .75}{.5 - .75} = .395$	$\frac{.565217 - .651163}{.5 - .651163} = .569$

elasticity is 0.1 or −0.1. The problem is that most of elasticities are not significantly different from zero. Second, as irregularity arose for land and machinery, the two rather fixed factors, it is likely that the apparent irregularity was due to inappropriate treatment of effective prices and farmers' decision making with respect to investment in fixed factors. My quotation that farmers might use their labor force in slack seasons to develop new land and to produce farm implements when the prices of these items rose was on this line.[1] Third, from various farm surveys and direct interviews with farmers in contemporary developing countries, the rational behavior of farmers with respect to price changes has achieved universal recognition. However, this does not necessarily indicate that those estimated functions which satisfy the regularity conditions are free from fault. By empirical studies we economists are searching for farmers' true but unknown technical structure, and all our estimated results are more or less subject to errors. My view is that the appraisal and discussion of an empirical study should not be focussed only on its estimated results. Instead, the appraisal and discussion should be made on the relationships between these results and the setting of hypotheses, the analysis framework, and the data treatment.

Finally, I appreciate Hunt's detailed comments. Although I cannot agree with him entirely, I believe that his comments brought about insights into the related issues.

[*Received March 1980.*]

[1] Although Hunt mentioned that Japanese studies proved that prewar Japanese farmers responded to normal incentives, I am still not aware of any research on land and machinery markets in the concerned period.

Inflation and Farm Tractor Replacement in the U.S.: A Simulation Model: Comment

R. B. Bartholomew

In a recent article in this *Journal,* Bates, Rayner, and Custance argued for the incorporation of inflation in replacement decisions and stated that the effect of inflation is to increase the optimal replacement age of farm tractors (p. 333). While I agree with the authors on the justifications of treating inflation in replacement decisions, I believe that under one condition their conclusion is incorrect and the effect of inflation could well be to lower the optimal replacement age. This occurs when the discount rate declines as inflation increases.

Inflation and Taxation

The effect of inflation in Bates, Rayner and Custance's model is to increase the optimal replacement age, because (*a*) tax credits for depreciation are based on historic costs, and in real terms are thus lower under inflation; (*b*) tax credits are lagged and in real terms are lower under inflation; (*c*) the difference between resale price and unexpired depreciation is likely to increase dramatically during periods of inflation. As this difference is taxable when the item is sold, the effect of this increase in tax payable is to increase the after-tax cost of the new tractor in real terms.

All of the above considerations are valid; and, other things being equal, the net effect is an increase in the optimal replacement age of the tractor. But, under inflation, do other things remain equal, particularly the discount rate?

Discount Rate

As the authors treat all cost items in real terms, i.e., the effect of inflation has been removed, the discount rate they use is correctly an after-tax real discount rate which they call r. Given a real after-tax discount r, there must exist a nominal pre-tax discount rate which I have called R. The relationship between r and R is as follows:

$$r = \frac{R\,(1 - T) - \theta}{1 + \theta},$$

where r is real after-tax discount rate, T is tax rate, θ is inflation rate, and R is nominal pre-tax discount rate. Table 1 lists R for different values of θ and r, assuming a tax rate of 25%.

Using a real after-tax discount rate of 5% implies nominal pre-tax discount rates of 6.7%, 13.7%, and 20.7% for rates of inflation of 0%, 5%, and 10%, respectively. If these nominal discount rates do not apply, then assuming a constant real discount rate after tax of 5% in our example is not valid.

Inflation and the Discount Rate

The discount rate has been viewed in different ways, e.g., the "cost of capital," a growth of reinvestment rate or in the limiting case where the farmer/investor did not have any better alternative use for his equity than to lend it to himself or pay off existing debts, as the cost of borrowed money to finance the particular asset acquisition. Whichever view is adopted, it is clear that the rate of inflation will affect the value of the nominal discount rate and thereby the real discount rate. If we look at bank lending rates it is apparent that while the lending rate is higher under inflation, the real rate of interest has not kept pace with inflation. Table 2 shows the interest rate on trading bank overdrafts for Australia for the period 1969–76.

In the limiting case where the real discount rate after tax is simply the cost of borrowed money (after tax) adjusted for inflation, then this rate is certainly not invariant to the rate of inflation, as shown in table 2. In only half the years is the real discount rate before tax positive, while in only two years out of eight is the real discount rate after tax positive. While the bank lending rate may be viewed as the minimum nominal discount rate, the general conclusion surely holds that the relevant nominal discount rate need not increase sufficiently during periods of inflation to maintain a constant real discount rate after tax.

Table 3 is taken from Bates (p. 333) and shows that for a particular tax rate and inflation rate, the lower the real after-tax discount rate, the earlier the optimum replacement age. If one accepts the view that under periods of continuing inflation the real after-tax discount rate is not constant and is lower than in the absence of inflation, then there exists an incentive to earlier not later replacement.

Whether this incentive can be realized will depend on such factors as the earnings of the re-

The author is an agricultural economist, Department of Primary Industries, Mineral House, Brisbane, Australia.

Table 3. Optimal Replacement Age, Discount Rate and Inflation

Tax Rate (%)	Discount Rate (%)	Inflation = 0	Inflation 5% per Annum	Inflation 10% per Annum
25	1	8.9	9.5	10.2
25	3	10.5	11.4	12.5
25	5	13.4	13.9	14.0
25	10	14.0	14.0	14.0
50	1	7.8	9.2	11.5
50	3	9.4	11.6	14.0
50	5	11.5	14.0	14.0
50	10	14.0	14.0	14.0

Conclusion

Bates, Rayner, and Custance's conclusion that under inflation the optimal age of replacement tends to increase depends, among other things (p. 332), on the assumption that r, the relevant real discount rate, does not alter with the inflation rate. This I have shown is unlikely to hold and that under inflation the discount rate is likely to be lower thus tending to encourage earlier, not later, replacement.

[Received August 1979; revision accepted October 1979.]

Inflation and Farm Tractor Replacement in the U.S.: A Simulation Model: Reply

J. M. Bates and A. J. Rayner

In his comment on our recent article in this *Journal*, Bartholomew has argued that under increasing inflation, the real rate of interest tends to decline, thus encouraging earlier replacement of capital equipment than otherwise would occur. In support of this claim, evidence of interest rate movements in Australia has been presented. We shall argue that this evidence indicates that an unanticipated increase in the rate of inflation is not immediately matched by an increase in nominal interest rates, but that it says little about the effects of a sustained and constant rate of inflation. We also shall suggest small modifications to his equation (1) and to his table 1.

Inflation and Real Interest Rates

First, we must admit that an unanticipated increase in the rate of inflation almost certainly will lead to a temporary (and not necessarily short) period in which real post-tax interest rates are lowered. Similar tables can be presented for interest rates in the United Kingdom (see, for example, the article by Barr), and no doubt also for the United States and other countries. Thus, because expectations concerning the rate of inflation adjust only slowly to changes in the current rate of inflation, nominal interest rates are likely to change only slowly: this implies that real rates of interest initially will decline when inflation increases. It is, however, by no means certain that an increase in the inflation rate will, if sustained, lead to real rates of interest declining. With a given tax rate on business profits, another (possibly different) rate on unearned personal incomes, the gross return on projects, will be higher than the net return to the business, which itself is higher than the net return to the tax-paying saver. In an inflationary situation, the gap between gross business returns and net returns on savings widens, and the amount of investment/savings is reduced. The important factors here are the interaction between net returns on savings and the amount of funds made available by lenders, and the marginal efficiency of capital. Not knowing the elasticities of the two relevant functions (the savings function and the marginal efficiency of capital) we cannot say whether real post-tax returns are more likely to increase or to decrease, but we assume that, to the first degree of approximation, it will revert to an unchanged level once expectations have been fully revised to take account of the new rate of inflation. Support for our argument is given in Feldstein's article.

Relationships between Real and Nominal Interest Rates

The relationship given in Bartholomew's comment in equation (1) assumes that tax payments are made immediately after any interest is received. If, alternatively, it is assumed that tax payments and rebates occur with an average lag of one year, the relationship between real post-tax and nominal discount rates is given by the equation

$$(1) \quad 1 = \frac{(1 + R)/(1 + \Theta)}{1 + r} - \frac{TR/(1 + \Theta)^2}{(1 + r)^2},$$

where r is real after-tax discount rate, T is tax rate, Θ is inflation rate, and R is nominal discount rate. Table 1 records values for R for different values of r and Θ, given a tax rate of 25% and a one-year lag in tax payment. Nominal rates are still higher than real after-tax rates of discount, but by a slightly smaller magnitude. A mathematical expression of the difference made by having lagged tax payments and receipts is available from the authors.

Conclusion

Bartholomew quite rightly draws attention to the relationship between the rate of inflation and the

Table 1. Nominal Discount Rate, Real Discount Rate, and the Rate of Inflation, with Tax Payments Lagged One Year

Real Discount Rate (%)	Nominal Discount Rate (%) — Inflation Rate (%) 0	5	10
1	1.3	7.9	14.3
3	4.0	10.6	17.1
5	6.6	13.3	19.8
10	13.0	19.8	26.5

J. M. Bates is senior lecturer in econometrics, and A. J. Rayner is reader in agricultural economics, Department of Economics, University of Nottingham, England.

real discount rate. We wish to take this opportunity to state that when the rate of inflation initially increases (assuming it does) replacement will normally be quicker while farmers take advantage of lower real post-tax rates of interest; even the modification introduced in equation (1) does not shake this conclusion, though the magnitude of the difference between real and nominal rates is lower where the settlement of taxes is lagged. But if the higher rate of inflation is sustained we would expect real post-tax interest rates to rise to their former levels, and for replacement of equipment then to be delayed.

Supply Shifts and Research Benefits: Comment

Roger N. Rose

In their recent article, Lindner and Jarrett (LJ) developed a general procedure for measuring gross research benefits (*GARB*). In deriving their measure of *GARB*, LJ made a fundamental error which invalidated the bulk of their findings. The source of that error is described in the first part of this paper, and a simple alternative measure is outlined. The meaning of commodity supply curves is then discussed, and it is pointed out that the interpretation of supply price as rent-free marginal cost is incorrect. Under these circumstances, predicting whether a particular innovation will produce divergent, parallel, or convergent supply shifts is virtually impossible.

The existence of some error in the LJ procedure can be demonstrated from their comparison of parallel and pivotal supply shifts. Consider the alternative supply shifts illustrated in figure 1 below. The movement from a pre-innovation equilibrium at M_0 to a post-innovation point at M_1 is taken as being the result of either a parallel shift from supply curve A_0S_{10} to A_1S_1 or as a pivotal shift from A_1S_{20} to A_1S_1. For a parallel shift, *GARB* is given by the area $A_0M_0M_1A_1$. For a pivotal shift, *GARB* is given by the area $A_1M_0M_1$. Clearly, the value of *GARB* for a pivotal shift cannot be less than 50% of the value for a parallel shift, with an equal cost decrease at M_0. LJ presented estimates of pivotal shift values as low as 12% of equivalent parallel shift values.

The problem with LJ's analysis can be illustrated by reference to figure 2, where industry demand is given by DD_1 and pre-innovation supply is given by S_{e0}. The slopes of DD_1 and S_{e0} are based on elasticities estimated to apply at the pre-innovation equilibrium point M_0. It is assumed that the post-innovation supply curve, S_{e1}, is parallel to, and a vertical distance M_0B_1 below, S_{e0}. Following Pinstrup-Andersen, Ruiz de Londoño, Hoover, and LJ, the post-innovation equilibrium point, M_1, can be found by equations (1) and (2):

$$(1) \qquad P_1 = P_0[1 - (ke)/(e + n)],$$

$$(2) \qquad Q_1 = Q_0[1 + (ken)/(e + n)].$$

Demand and supply elasticities are n and e, respectively, (n is an absolute value) and k is the cost decrease as a proportion of P_0. Throughout this paper, k is positive for a cost decrease. LJ's analysis was made confusing by changes in signs for the parameter. In their text and in the equation defining intercept values (p. 52), k was defined as the cost decrease but in their equations (5) and (6) it was negative for a cost decrease. In the footnote to table 1 it was again positive.

The basic error in LJ's analysis arose from improperly incorporating additional information into the supply model. While the elasticities used may be valid in the region of M_0, LJ argued that the extrapolation of S_{e0} and S_{e1} to the origin could produce the incongruous result that positive quantities would be supplied at negative prices. They therefore argued that A_0 and A_1, the pre-innovation and post-innovation intercept terms, should be estimated independently of S_{e0} and S_{e1}. Their analysis then included two conflicting sets of information, one based on elasticity estimates and the other based on intercept estimates.

The end result of that conflict was a divergence between the shift which LJ intended to measure and that which they actually measured. In figure 2, for a parallel shift, the cost reduction at the origin (A_0A_1) must equal that at M_0 (M_0B_1). Having reached this point, LJ estimated *GARB* as the rectilinear area $A_0M_0M_1A_1$ for a parallel shift. But the vertical distance between M_0 and the curve A_1M_1 is equal to M_0B_2, and $M_0B_2 = M_0B_1$ only when the slopes of A_1B_1 and S_{e1} are equal. That is the trivial case where the problem which LJ set out to solve, that of elasticity estimates leading to unrealistic intercept values, does not exist. In fact, for all cases treated by LJ, M_0B_2 was substantially less than A_0A_1. Exclusion of the area $A_1M_1B_1$ from the measure of *GARB* is common to all types of supply shift estimated by LJ. For the parallel example, with M_0B_2 less than A_0A_1, LJ's estimates were for convergent, not parallel, shifts. Since the coordinates of M_1 vary with elasticity changes, the shift measured at M_0, and thus the degree of error, is different for each possible combination of e and n.

The simplest alternative measure is to use k and S_{e0} to establish the coordinates of M_1 and to estimate separately the area $M_0M_1B_1$ (X) and that between M_0B_1 and the price axis (Y), clearly specifying the value of M_0B_1. Then total benefits are given by equation (3):

$$(3) \qquad GARB = X + Y.$$

From LJ's equation (2), but substituting the coordinates of B_1 for M_1, the area $A_0M_0B_1A_1$ (Y) is given by equation (4):

$$(4) \qquad Y = \tfrac{1}{2}Q_0(kP_0 + A_0 - A_1),$$

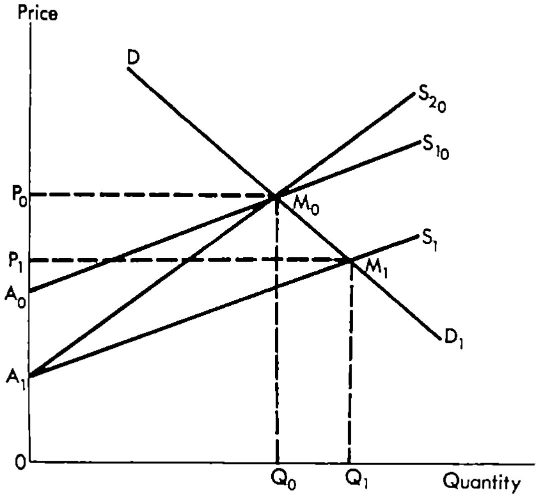

Figure 1. Parallel and pivotal supply shifts

which reduces to equation (5):

$$Y = kP_0Q_0, \tag{5}$$

for a parallel shift. Only the shift at the origin (A_0A_1) influences the area of $A_0M_0B_1A_1$, with the position of the intercept (A_0) being of no consequence except in the case of proportional shifts. In the latter case, A_0A_1 is explicitly set as a function of A_0. The relationship between values of Y for divergent, parallel, and convergent shifts is fixed by that between A_0A_1 values.

The area $M_0M_1B_1$ (X) is approximated by equation (6):

$$X = \tfrac{1}{2}kP_0(Q_1 - Q_0). \tag{6}$$

When the coordinates of M_1 are set from equations (1) and (2), that equation is strictly correct only if

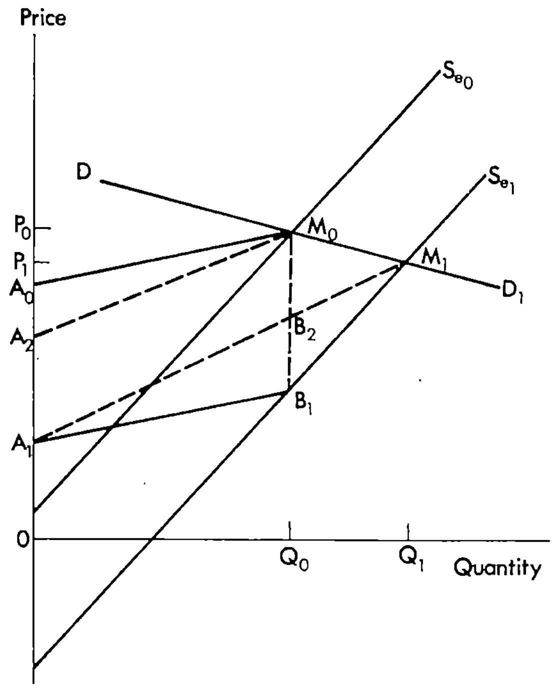

Figure 2. Intended and actual measures of benefit from a parallel shift

the shift is parallel. But X is generally small relative to Y and differences between alternative derivations are likely to be insignificant.

Given that X is relatively small and that Y is independent of n and e, changes in elasticity are of little significance for *GARB* and the relative values for different types of shifts are virtually fixed. This relative fixity of *GARB* for different elasticities can be seen to some extent in table 1. The error in

Table 1. Sensitivity of *GARB* to Assumptions About the Nature of Supply Shift: Comparison of Equation (3) Results with LJ Results (LJ Results in Parentheses)

Demand Elasticity n	Supply Elasticity e	Intercept A_1/P_1	Type of Supply Shift: Pivotal[a]	Proportional[b]	Parallel[c]	Convergent[d]
0.50	0.20	0.20	0.50 (0.29)	0.61 (0.43)	1.00 (1.00)	1.50 (2.72)
		0.80	0.50 (0.24)	0.93 (0.85)	1.00 (1.00)	1.50 (1.76)
2.00	5.00	0.20	0.53 (0.70)	0.63 (0.76)	1.00 (1.00)	1.47 (1.31)
		0.80	0.53 (0.55)	0.92 (0.91)	1.00 (1.00)	1.47 (1.45)

Note: For each elasticity and intercept combination *GARB* is expressed as a proportion of that for a parallel shift.

[a] $A_0 = A_1$
[b] $A_0 = A_1/(1 - k)$
[c] $A_0 = A_1 + kP_0$
[d] $A_0 = A_1 + 2kP_0$

measuring the variable value M_0B_2 as the supply shift, and not any actual variation in benefits, accounts for most of the sensitivity of LJ's results to elasticity changes.

Results reported in LJ's tables 1 and 2 contain a further error. Since k is defined as M_0B_1/P_0, A_0A_1 is equal to kP_0 for a parallel shift. Therefore, $A_0 = A_1 + kP_0$, not $A_0 = A_1 + kP_1$ as defined by LJ. Similarly, for a proportional shift, $A_0 = A_1/(1-k)$ not $A_0 = A_1(1+k)$. This occurred despite the fact that the relationships were properly specified in the text (p. 52). The effect of these misspecifications can be demonstrated in figure 2, where A_0 is the true estimate and A_2 is that produced from the LJ definition. Benefits equal to the area $A_0M_0A_2$ are excluded from the LJ estimate.

Using equation (3), two comparisons made by LJ were repeated. The new values, along with LJ's original estimates, are presented in tables 1 and 2. In table 1, the values of *GARB* derived from four types of supply shift are compared for various elasticities and intercept terms. P_1 and Q_1 were set at unity, and k was set at 0.1, which appears to be the value used by LJ in their table 1.

In table 2, values are given for the percentage overestimate of *GARB* produced by using Griliches' formula $GARB = kP_1Q_1(1 - \frac{1}{2}kn)$. Following Griliches and LJ, it was assumed that the supply shift was proportional and k was equal to 0.13 [since Griliches' k was defined at M_1, it is not equivalent to k in equations (1)–(6)]. Because of the assumption made in arriving at equations (1) and (2), that S_{e0} and S_{e1} are parallel, the results presented can only be approximations to a proportional shift. A parallel shift of $0.13/P_1$ was assumed to apply between M_1 and M_0, allowing equations (1) and (2) to be used to find M_0. The shift was then assumed to be proportional between M_0 and the price axis.

It is clear from tables 1 and 2 that the magnitude of error involved in using the LJ procedure is substantial. Only one of the propositions made in the first part of their paper is valid; that other writers have, at times, grossly overestimated benefits. Much of the estimated variation in *GARB* with elasticity changes was due to error. The same was true of the degree of difference found between different types of supply shift.

Table 2. Percentage Overestimate of *GARB* Produced by Applying Griliche's Formula (LJ Results in Parentheses)

Supply Elasticity[a] Intercept A_1/P_1	0.2	1.0	5.0
0.2	59	61	62
	(225)	(72)	(32)
0.5	26	29	31
	(128)	(47)	(20)
0.8	4	7	9
	(76)	(29)	(10)

[a] Demand elasticity was assumed to be 0.5 for all cases.

Although the measured difference between *GARB* for different types of supply shift is still substantial, it is doubtful if these shifts can actually be identified. The approach used explicitly by LJ and implicitly by previous authors is based on the assumption that the area above the supply curve and below the equilibrium price line (producers' surplus) is an accurate measure of surplus accruing to fixed factors of production. Only then does the change in economic surplus have any validity.

Mishan pointed out that the producers' surplus is a valid measure only when the industry supply curve is both a marginal cost curve excluding factor rents and an average cost curve including factor rents. This can be strictly true only when a single productive factor is in fixed supply and all others are in infinitely elastic supply to the industry in question. One case in which Mishan stated that these conditions would apply was the "Ricardian case of a fixed supply of land." On the "Ricardian case" rests the validity of interpreting supply curves for agricultural commodities as marginal cost curves.

That case is purely hypothetical. It is true that the aggregate supply of land is virtually fixed and therefore it would be expected that pure rents accrue to landowners in the long run. What is not true is the suggestion that this argument has a simple extension to individual commodity supply curves. Whenever there are at least two competing uses for land, the amount supplied for production of one commodity is not fixed but is a function of other commodity prices. The supply curve for an agricultural commodity therefore includes marginal rents to land (from alternative enterprises) as well as marginal nonland costs. It is not a marginal curve exclusive of rents.

Some measure of the care needed in interpreting cost and supply curves can be gained from the synthetic example presented in table 3. The hypothetical cost and returns are for two areas of land, both of which can be used to produce either wheat or barley. The first is contrived to be at the origin of the wheat supply curve, A_0, the second at the point of initial equilibrium production, Q_0. In the three cases illustrated, identical supply curves were derived from different combinations of rent and nonland costs.

Comparisons can be made from table 3 between actual cost savings, due to an innovation which reduced nonland costs of wheat production by 10%, and estimates which would be produced if supply price was assumed to exclude rent. Estimates reproduced in table 3 were made on the basis that the $6/tonne cost decrease for wheat at the origin was predicted correctly but that a 10% change was therefore assumed to apply to the initial price of $140 at Q_0, the initial market equilibrium. Such estimates could be produced, for example, if minimum average cost estimates from an economies-of-size study were taken to equal the intercept A_0. Actual benefits from such an innovation would clearly differ between the cases illustrated in table

Table 3. Points on Hypothetical Supply Curves: Rents and Other Costs Actual and Estimated Benefits from a 10% Cost Decrease for Wheat Production

Crop and Cost/Benefit Category	Costs and Benefits at the Origin		Costs and Benefits at Equilibrium Point Q_0: Case 1 Constant Rents		Case 2 Increasing Rents		Case 3 Decreasing Rents	
	A[a]	B	A	B	A	B	A	B
Barley:								
Yield (T./ha.)	1.0	1.0	1.0	1.0	1.4	1.4	0.6	0.6
Revenue ($/ha.)	100	100	100	100	140	140	60	60
Nonland cost ($/ha.)	60	60	60	60	60	60	60	60
Wheat:								
Yield (T./ha.)	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0
Nonland cost ($/ha.)	60	54	100	90	60	54	140	126
Barley rent ($/ha.)	40	40	40	40	80	70	0	0
Supply price ($/T.)	100	94	140	130	140	134	140	126
Cost Decrease:								
Actual ($/T.)	6		10		6		14	
Estimate ($/T.)	6		14		14		14	

[a] A is pre-innovation; B, post-innovation.

3. However, if supply price and marginal cost were considered to be equivalent, no difference would be noted between the cases. Such an approach would lead to accurate estimates only by coincidence.

When it is admitted that supply prices are inclusive of rents, the difficulty of determining the nature of a supply shift becomes apparent. Even the implication above, that low-cost (exclusive of rent) producers are likely to be close to the origin, is not necessarily true. A producer who is efficient in producing one commodity is quite likely to be efficient in producing others. In such a case, when nonland costs may be low, rents may be correspondingly high and the producer may only supply the good in question at a relatively high price.

The suggestion made by LJ, that scale-dependent innovations are likely to benefit low-cost producers close to the origin of the supply curve and therefore give rise to convergent supply shifts is unsustainable. Such producers are just as likely to have substantial potential earnings from alternative enterprises and therefore be associated with other points on the supply curve. Unless evidence exists to link particular levels of nonland cost with points on the supply curve, there is little basis on which to make assumptions about the nature of supply shifts.

One case in which the nature of the supply shift may be predictable is that of a yield-increasing innovation which does not require input changes per unit of land. For such a change, both the demand for land and the demand for other inputs would be proportionally reduced for each unit of output. Therefore, whatever the structure of rents relative to other costs, the innovation would be likely to reduce all costs proportionally. However, it is unlikely that any sensible measure of A_0, for a rent free cost curve, could be made and the critical shift A_0A_1 could therefore not be estimated.

For most innovations, the best information available may be a cost-reduction estimate for a single point on the supply curve. For the reasons outlined above, it is unlikely that any knowledge of the shape of the supply curve, or the position at which the single estimate applies, will be available. The only realistic strategy is to assume that the supply shift is parallel. This amounts simply to taking the product of the original equilibrium quantity and the estimated cost change, equation (5), and making a minor adjustment for price response as in equation (6) above.

The procedure outlined above is crude but that it also appears to be so may be useful. Previous treatments have been concentrated on increasing the geometric sophistication of explanatory models and even that has been subject to fundamental errors. What is more important is to have an understanding of supply curves and the derivation of cost changes. Geometric manipulations are of little help at that level.

Supply Shifts and the Size of Research Benefits: Comment

William S. Wise and Elisabeth Fell

In presenting their own procedure, Lindner and Jarrett have claimed that "all previous techniques used to measure gross annual research benefits may produce biased results" (p. 48). The purpose of this comment is to draw attention to a mathematical flaw in their treatment.

As one of us (Wise) has indicated elsewhere, the shifts from one supply curve to another as technology changes are not, in general, vertical, although Lindner and Jarrett supposed that they were. However, for present purposes a vertical shift is considered. The symbols used by Lindner and Jarrett (LJ) are retained including the unitary system $P_1 = Q_1 = 1$; their numbered equations are distinguished by LJ.

The essential construction is given in figure 2 LJ (p. 50). It is convenient to label as N_1 the intersection of supply curve S_1 with the vertical through output Q_0. Also, let A_0 be expressed as $(A_1 + \alpha k)$ where for the pivotal, proportional, parallel, and convergent shifts, as defined by Lindner and Jarrett, α is, respectively, 0, A_1, 1, and 2.

The national benefit is $A_1N_1M_1M_0A_0$, and discussion centers on how this area is to be estimated. Consider first the cost curve A_1M_1. We find entirely convincing the argument of Lindner and Jarrett that an econometric supply elasticity cannot apply over the whole course of such a cost curve and, indeed, would ourselves reject the use of supply elasticities in this context altogether. However, to follow through the compromise adopted by Lindner and Jarrett, it may be supposed that A_1M_1 is constituted of two segments, viz., (*a*) from A_1 to N_1, an empirical, linear-cost curve determined by the parameters A_1 and k; and (*b*) a supply curve of elasticity ϵ having only local significance over N_1M_1. On the assumption that over the short path N_1M_1, the supply curve is approximately linear, then the national benefit can be found as the sum of the areas of trapezium $A_1N_1M_0A_0$ and triangle $N_1M_1M_0$. With $P_1 = Q_1 = 1$, with A_0 given by $(A_1 + \alpha k)$, and with M_0N_1 defined as kP_0, this reduces to

(1) $$\textit{national benefit} = \tfrac{1}{2}k(\alpha Q_0 + P_0).$$

This is not, however, the expression reached by Lindner and Jarrett. They proceeded from the assumption that N_1 lay on the straight line joining points A_1 and M_1. The assumption is only valid when the supply elasticity has the particular value which makes the slopes of A_1M_1 and N_1M_1 equal. If, as Lindner and Jarrett do, ϵ is arbitrarily varied, then the slopes of A_1M_1 and N_1M_1 generally will differ; this means that there will be a kink in the cost curve A_1M_1 at the point N_1, or, in other words, N_1 does not lie on the straight line joining A_1 and M_1.

Given the kinked cost curve which this LJ model implies, then the national benefit is as in equation (1). On the false basis that N_1 lies on the straight line joining A_1 and M_1, the national benefit would be calculated as the trapezia $A_0M_0Q_00 + M_0M_1Q_1Q_0 - A_1M_1Q_10$. The result would then be

(2) $$\textit{national benefit} = \tfrac{1}{2}(A_0 + P_0)Q_0 + \tfrac{1}{2}(P_0 + P_1)(Q_1 - Q_0) - \tfrac{1}{2}(A_1 + P_1)Q_1.$$

This reduces to equation (2) LJ. Because equation (2) incorrectly estimates the national benefit, it follows that equation (2) LJ must likewise do so.

Estimation of P_0 and Q_0

From the conditions that points M_0 and M_1 lie on the demand curve, N_1 lies on a supply curve of elasticity ϵ passing through the point M_1, and M_0N_1 is equal to kP_0, it is possible to find the values for P_0 and Q_0 as

(3) $$P_0 = (1 - k) - \epsilon/(n + \epsilon),$$

(4) $$Q_0 = (1 - k)n\epsilon/(n + \epsilon).$$

Binomial approximations can then be made, for $k << 1$, to give

(5) $$P_0 = 1 + k\epsilon/(n + \epsilon),$$

(6) $$Q_0 = 1 = kn\epsilon/(n + \epsilon).$$

Comparison of these last two equations with equations (5) LJ and (6) LJ show the latter to be in error. It is clear that they must be since $P_0 > 1$ and $Q_0 < 1$, but equations (5) LJ and (6) LJ predict the reverse. It appears that the error only lies in a misprint because we were able to reproduce the LJ tables with the correct equations (5) and (6).

W. S. Wise is head of Programmes Section with the Agricultural Research Council, London; Elisabeth Fell is a principal scientific officer in Programmes Section, ARC.

Comparison of Benefit Estimates

Various estimates of the national benefit can be made. An exact value can be found as follows. $A_0M_0N_1A_1$ is a trapezium whose area B is given by

$$B = \tfrac{1}{2}Q_0k\,(\alpha + P_0). \tag{7}$$

$N_1M_1M_0$ is a curvilinear triangle whose area can be found by integration as

$$\delta B = \frac{n}{n-1}\left(1 - Q_0^{\frac{n-1}{n}}\right) - \frac{\epsilon}{\epsilon+1}\left(1 - Q_0^{\frac{\epsilon+1}{\epsilon}}\right). \tag{8}$$

The exact national benefit is then $B + \delta B$ where δB will generally be small relative to B.

Next, a simple "trapezoidal estimate" can be made by using equation (7) but taking P_0 and Q_0 as approximately unity. This corresponds to the constructions of figures 1 LJ and the approximate national benefit is then given by

$$\textit{trapezoidal estimate} = \tfrac{1}{2}k(1 + \alpha). \tag{9}$$

A "binomial estimate" can be made by using equations (5) and (6) to find P_0 and Q_0 and then inserting these values into equation (1). Lindner and Jarrett's procedure was to insert the values of P_0 and Q_0 found from equations (5) and (6) into the incorrect equation (2) LJ.

Numerical comparisons of the various methods of estimation are given in table 1. This relates to a k of 0.13 which, we believe, was the value used by Lindner and Jarrett. For convenience, the unitary system was altered to $P_1 = Q_1 = 100$ for table 1.

Under all conditions, the binomial approximation gives an estimate close to the exact one. The even simpler trapezoidal estimate often would be acceptable given the roughness of the agricultural data which sometimes have to be used for research benefit analyses.

In contrast, the LJ procedure yields substantially different results. In particular, attention may be drawn to the sensitivity of the LJ estimate to the value of the parameter A_1. This parameter does not enter in the estimates of the pivotal. parallel, and convergent cases given by the other procedures, as can be appriciated from figures (1) LJ. All the shaded areas lie on the same base, kP_0, on the vertical line D_0Q_0; they all have the same height, Q_0. The areas of the triangle, parallelogram, and trapezium of figures 1 (*a*) LJ, 1 (*c*) LJ, and 1 (*d*) LJ, respectively, are, therefore, in the proportions 50 : 100 : 150, irrespective of the position of point A_1. The additional component of the national benefit, δB in equation (8), is independent of the parameter A_1 and is, in any case, relatively small. Hence, the national benefits in the pivotal, parallel, and convergent cases should be roughly in the proportions 50 : 100 : 150, irrespective of the position of point A_1; the results in table 1, apart from those obtained by the erroneous LJ procedures, follow this pattern.

It might be objected that the exact method still shows benefit estimates varying by a factor of 3, depending on the shift postulated. In reply to this, it

Table 1. Comparison of Estimating Procedures

			Type of Supply Shift				
				Proportional			
Procedure	n	ϵ	Pivotal	$A_1 = 0.2$	$A_1 = 0.8$	Parallel	Convergent

LJ: $A_1 = 0.8$	0.5	0.2	204	—	715	842	1,480
$A_1 = 0.2$	0.5	0.2	260	388	—	898	1,536
Exact	2	5.0	712	819	1,139	1,245	1,778
Binomial	2	5.0	710	816	1,134	1,240	1,769
Trapezoidal	2	5.0	650	780	1,170	1,300	1,950
LJ: $A_1 = 0.8$	2	5.0	650	—	1,073	1,179	1,709
$A_1 = 0.2$	2	5.0	1,207	1,313	—	1,736	2,266
Exact	0.5	5.0	736	858	1,224	1,347	1,957
Binomial	0.5	5.0	727	849	1,216	1,338	1,950
Trapezoidal	0.5	5.0	650	780	1,170	1,300	1,950
LJ: $A_1 = 0.8$	0.5	5.0	650	—	1,139	1,262	1,873
$A_1 = 0.2$	0.5	5.0	827	950	—	1,439	2,050

can first be pointed out that the convergent construction of figure 1 (*d*) LJ is an unfair comparison with the other diagrams in that the most efficient producer obtains a cost saving of $2k$, whereas in the others it is only k. Bringing the comparisons to a uniform basis reduces the factor of 3 to 2.

Second, if β is the vertical distance between curves S_0 and S_1, an approximation to the national benefit is

$$\text{(10)} \qquad \textit{national benefit} = \int_0^1 \beta. \quad dq.$$

Comparison of equations (9) and (10) shows that the assumption of a parallel shift ($\alpha = 1$) will produce the correct national benefit if

$$\text{(11)} \qquad k = \int_0^1 \beta. \quad dq.$$

Equation (11) implies that an unbiased result will be obtained if analysts assume a parallel shift but use for k a value for β averaged over all producers rather than the largest β obtainable by the most efficient producer.

Lindner and Jarrett have performed a valuable service in showing that supply curve elasticities should not be used uncritically in benefit calculations; their emphasis on the need for analysts to consider what does happen under production conditions rather than to assume that the best experimental yields will be achieved is also salutary. Nevertheless, even supposing that their model of vertical supply-curve shifts and their "kinked" cost curve were acceptable, we still must point out that their working contains a mathematical flaw, and that their numerical results are consequently invalid.

Supply Shifts and the Size of Research Benefits: Reply

R. K. Lindner and F. G. Jarrett

The central proposition in our paper on supply shifts and research benefits was that the size of *GARB* is sensitive to the nature of the shift in the supply curve induced by adoption of a process innovation. We also argued that because the available formulas for calculating *GARB* typically presumed a particular type of shift, estimation error would result from the application of such formulas if the actual shift did not correspond to that presumed. Despite the claim by Rose that "LJ made a fundamental error which invalidated the bulk of their findings," none of the arguments made in either comment have persuaded us to reject either of the above propositions. All of the comment by Wise and Fell (WF) and the first part of that by Rose relate to the calculations we carried out to numerically illustrate these propositions, and to provide some idea of their quantitative importance. The second part of the comment by Rose is a restatement of arguments contained in a paper by Mishan (1968), and in our view is a general attack on the notion of producer surplus rather than a specific criticism of our paper.

While we cannot accept all of the detailed criticisms made in the comments, we do accept the main thrust of the argument by both authors that the computational procedures underlying the results in our illustrative tables were in error; and that as a result we overstated both the sensitivity of *GARB* to the nature of the supply shift and the magnitude of the possible error which would result from using a formula based on a particular type of shift. We also have some reservations to be outlined below about the computational procedures advocated by WF and by Rose, and hence about the tables of results they derive using these procedures, but would agree that either approach is to be preferred to our earlier proposals.

Nevertheless, we note that the illustrative tables calculated by WF and by Rose still support our two main contentions, namely, that the size of *GARB* is sensitive to the type of supply shift, and that formulas which presume a particular type of shift can lead to substantial errors. According to Fell and Wise, "the exact method still shows benefit estimates varying by a factor of three, depending on the shift postulated." Similarly, it can be seen from table 1 of Rose that a formula which presumed a pivotal shift when the actual shift was convergent would underestimate *GARB* by a factor of two or more. Furthermore, there is no reason why the particular cases of a pivotal and convergent shift which we chose originally for illustrative convenience should be treated as limiting cases. It is by no means inconceivable that particular innovations might only affect marginal output, and have no effect at all on the cost of producing the bulk of intramarginal output. In such a case, the S_0 and S_1 supply curves would be coincident over much of the relevant range, so that use of a formula based on the assumption of a parallel shift would easily overestimate *GARB* by several hundred percent.

Partly because of the almost unlimited diversity in possible types of supply shift, and partly for other reasons to be discussed below, we now believe that our earlier attempt to provide a more generally applicable formula for the measurement of *GARB* also suffered from being too mechanistic. Nor do we regard the alternative formulas advanced by WF or by Rose as entirely satisfactory, since they both more or less follow the same general approach used in our original article. Accordingly, we do not propose to detail all of the ways in which we disagree with specific aspects of the above comments. Instead we prefer to take a more positive approach by discussing what we now perceive to be the state of the art.

We commence by considering the issue raised by Rose in the second part of his comment. In common with the rest of the literature on research benefits with which we are familiar, we accepted the validity of using the area below the demand curve and between the S_0 and S_1 curves as a measure of *GARB*. Rose has now challenged the underlying legitimacy of this branch of the literature, and it is with certain misgivings that we broaden the scope of our response to encompass this more fundamental issue. Rose bases his attack on an article by Mishan which was not directly concerned with the measurement of *GARB*.

If we understand Mishan correctly, he argues that producer surplus, as measured by the area above the long-run industry supply curve and below market-clearing price, does not capture all of the rent earned by the fixed factor (which we take to be land in the case of agriculture), as it has alternative productive uses in other rural industries. Thus the

R. K. Lindner is a visiting research fellow, University of Sussex, and F. G. Jarrett is a professor of economics, University of Adelaide.

Peter Wagstaff helped clarify the authors' thoughts on a number of points, but any errors are the authors.

use of land by any particular rural industry will involve an opportunity cost which accounts for part of the area below, rather than above, the industry supply curve. We are persuaded by this argument, but do not believe that it invalidates the established procedure for measuring *GARB* which is based on the change in economic surplus, and not on its absolute value. Because that part of the rent to land which is not captured by industry-specific producer surplus is left unchanged by adoption of a process innovation, the conventionally defined area for measuring *GARB* does provide a valid measure of the change in consumer surplus plus the change in economic rent to the fixed high factor land.

Rose goes on to imply by way of the hypothetical example in table 3 that we advocated an erroneous procedure for estimating the reduction in costs consequent upon adoption of a process innovation. As described by him, the procedure would involve estimating the cost reduction at a particular point on the supply curve, and then predicting the cost reduction at some other point on the basis of an apparently arbitrarily assumed supply shift of a particular type. In the specific example presented by Rose, no explanation for choosing a proportional supply shift is provided, and the estimated reduction in cost at the supply curve intercept is used to predict that at the initial market equilibrium. This is the exact opposite of the procedure which we had in mind, but apparently we did not describe it sufficiently lucidly. In brief, our intent was that the nature of the supply shift should be determined by separate (gu)estimates of the reduction in costs at the supply curve intercept and at the market equilibrium level of output, Q_0 and not vice versa. Given our approach, as well as the ability to guess cost reductions accurately, case 2 in Rose's table 3 would have been perceived as a parallel shift, case 3 as a proportional shift, and case 1 as a divergent shift intermediate between the other two. The possibility of errors of the type which the table purports to illustrate simply would not arise because the question of how the innovation reduced costs would have been determined first.

We found the response by Rose to our challenge to debate the determinants of different types of supply shifts much more constructive. In particular, we agree with him that the rent component in supply price makes it particularly difficult to link given units of production with particular points on the supply curve. This difficulty of identifying points on the supply curve, together with the deficiencies inherent in the linearity assumption noted above, have persuaded us that we did not go far enough in our first attempt to develop a more general procedure for measuring *GARB*. Accordingly, the remainder of the discussion concerns what we now perceive to be the significant problems which should be considered in future attempts to estimate empirically *GARB*, and on the compromises involved in the feasible set of alternative procedures. In doing so, we take the view that di minishing returns have set in to *ex post* studies, and that henceforth the emphasis in the debate over the most appropriate measurement procedure should be conducted in the context of *ex ante* estimation o research benefits. In our opinion, this necessarily restricts the feasible set of techniques to those which are computationally simple and relatively undemanding in terms of required data.

The problem of measuring *GARB* can be decom posed into the following three principal subcompo nents: (*a*) estimating the size of the shift, which ha usually been measured by the size of the vertica downward shift of the supply curve at the 'without innovation' equilibrium level of output, Q_0; (*b*) es timating the type of shift, which necessarily implie estimating the reduction in costs at one or mor additional points on the supply curve (e.g., $A_0 - A$ in our previous article); (*c*) estimating the expan sion in output induced by adoption of the innova tion, (i.e., $Q_1 - Q_0$).

Empirical studies typically have made th simplifying assumption that supply curves can b satisfactorily represented by a relatively simpl mathematical function, and most of the early stud ies avoided (2) by using a formula which presume a particular type of supply shift (typically eithe parallel or proportional, but sometimes pivotal). B estimating the size of the shift at Q_0, problems o the type raised by the second part of Rose's com ment were avoided, so the essence of the problem was reduced to determination of the parameters o the "with innovation" market equilibrium, and es pecially Q_1. This was a familiar problem to econo mists, and only required estimates of local suppl and demand elasticities, plus an estimate of the siz of the shift at Q_0. Part of the motivation for writin our original paper was the belief that the use of suc formulas for calculating *GARB* was too mechanisti and, in particular, diverted attention towards th relatively unimportant question of supply and/o demand elasticities, and away from the more impor tant issue of the effect of adoption of the innovatio on production costs.

In an attempt to develop a more generally appli cable formula that allowed for different types c shift, we explicitly introduced a consideration c how the innovation affected production costs at th intercept of the supply curve with the vertical axi as well as at Q_0. Notwithstanding the contrary clai by Wise and Fell, we still maintain that given th coordinates of the four corner points A_0, A_1, M_0, an M_1, our equation (2) does compute *GARB* correctl provided that supply and demand curves are linea However, in our illustrative calculations, we faile to recognize that this simplifying assumption c linearity was violated by the procedure of estima ing P_1 and Q_1 from P_0 and Q_0 using a value of th local elasticity of supply which was not necessaril consistent with the arc elasticity of supply implie by the chosen values of A_1 relative to P_1, Q_1. As

result, the computed values of *GARB* on which our tables were based did not measure the benefits of the types of shifts which we intended.

To get around this problem, both WF and Rose partially abandon the linearity assumption by introducing a kink in the S_1 curve at the "without innovation" equilibrium level of output Q_0. As a result, *GARB* is represented by a pentagonal area which can be measured quite easily by partitioning into a trapezium and a triangle. While this device satisfactorily overcomes the principal cause of the errors in our illustrative examples, it leaves untouched three problems which are likely to cause serious difficulties in empirical studies.

The first of these relates to the use of an estimate of local elasticity of supply derived from an econometric study to calculate Q_1 from Q_0, as this implicitly assumes that adoption of the innovation does not alter the local elasticity of supply. We know of no evidence to support such an assumption, nor can we think of reasons why this should generally be the case. Indeed, innovations specific to marginal locations are likely to alter the local elasticity of supply, as are more widely applicable innovations such as the development of plant varieties which are more responsive to fertilizer and other purchased inputs. Hence we believe that considerable caution should be exercised in using local elasticity of supply estimates to calculate Q_1 from Q_0 (or vice versa).

One alternative approach which does not utilize such econometric estimates of local elasticity of supply, but retains linear supply curves as well as the same procedure for estimating the nature of the supply shift from cost reductions at zero output and Q_0, would be to determine Q_1 by linear extrapolation of the S_1 curve to its point of intersection with the demand curve.[1] Once the four corner points of the tetrahedra have been located in this manner, equation (2) from our previous paper could then be used to calculate its area. It could be argued that this procedure has a slight advantage over those discussed above in terms of computational simplicity, but this is achieved only by making a possibly even more unrealistic assumption about the local elasticity of the S_1 supply curve, and hence incorrectly estimating Q_1.

The only other alternative we can think of is to rely on expert opinion to estimate $(Q_1 - Q_0)$. One suspects that those sufficiently expert on both industry production conditions and the characteristics of the innovation in question, and especially its location specificity, are unlikely to fully comprehend the significance of an inelastic demand curve. However, errors in estimating $(Q_1 - Q_0)$ normally will be relatively unimportant since they only affect the area of the triangle, which is typically small in relation to the area of the trapezium. In those less common cases where the output-inducing effect of the innovation is large in relation to inframarginal output, we think that this rather subjective approach will almost always provide superior predictions to those based on a more mechanistic procedure.

The second problem is really a set of problems that relates to determination of the size and type of the supply shift. It is further complicated by the fact that its nature differs somewhat depending on whether the process innovation increases yield per unit of land, reduces "nonland" costs per unit area, or is some combination of the two. For the sake of expositional simplicity, only the two pure types of strictly yield-increasing, and strictly cost-reducing innovations are considered below. For an innovation which reduces only the "nonland" costs of production, but by varying degrees for different sets of output (e.g., from different parcels of land), it is necessary to identify the particular units of output corresponding to the points A_0 and M_0 on the S_0 supply curve to correctly determine the size and nature of the supply shift. Marginal output probably can be readily identified either from recent experience, or by expert opinion, but the former will be of no assistance in identifying the unit of output at A_0, and the latter most likely would need to understand the principle of comparative advantage to do so with tolerable accuracy.

For strictly yield-increasing innovations, it is supply price (i.e., marginal cost) rather than just the "nonland" cost component which is of concern. As this equals market-clearing price at the margin, estimation of the size of the shift at Q_0 should not be unduly difficult. However, estimation of $(A_0 - A_1)$ is doubly difficult for this type of innovation, since not only does the ultimate intramarginal unit of output need to be identified, but the opportunity cost component of the land rent for this unit of production needs to be measured. This component of rent cannot be observed directly since land prices reflect both the industry specific and opportunity cost components of rent. Nor does imputation of this component by calculating the rent to land in the next best use represent a practicable alternative for *ex ante* studies. Possibly the best that can be done is to establish upper and lower bounds (using market clearing product prices and solely nonland costs, respectively), and maybe undertake limited sensitivity analysis.

The third problem concerns the inflexibility, in terms of ability to accommodate different types of supply shift, inherent in the linearity assumption, or for that matter any other mathematically tractable function used to represent the supply curve. The idea of WF and of Rose of introducing a kink into the S_1 curve offers the potential of some gain in flexibility without unduly sacrificing computational

[1] Estimates of *GARB* derived from this procedure would be slightly larger than those calculated using the WF or Rose procedures and the same values for cost reduction, etc. Note also that in contrast to the Rose procedure, both *GARB* itself as well as its sensitivity to the type of supply shift will be influenced by the chosen value of A_0.

simplicity. Such an approach is implicit in the discussion above where the problem of estimating induced output ($Q_1 - Q_0$) was divorced from determination of the type of supply shift for inframarginal output (i.e., up to Q_0). The alternative is to approximate the use of integral calculus to measure the area representing *GARB*. Specifically, this would involve subdividing the production area into homogenous regions in terms of the impact of the innovation in question on yield and production costs. Within each region, a parallel shift could be presumed without risk of serious error. For innovations which only reduce costs without affecting yield per unit area, the sum of all the cost savings on intramarginal land would be approximately equal to the area of the trapezium, and the principal problem would be to identify the additional areas of land which would be induced to enter the industry as a result of the reduction in costs from adopting the innovation. The cost savings from this additional land would need to be (approximately) halved before adding to the inframarginal cost savings, since its net contribution to *GARB* is the triangle $M_0M_1B_1$ in Rose's figure 2. Yield increasing innovations pose additional problems, since output from intramarginal land (in terms of S_0) will produce output greater than Q_0 once the innovation is adopted. In fact, if demand is sufficiently inelastic, the rent which some previously intramarginal land could earn in the industry will fall below its opportunity cost, and consequently will be switched into production of other commodities. Apart from estimating the extent of this switch, there is the additional problem discussed above of estimating the opportunity cost component of land rent to include in supply price for the purpose of calculating the change in social surplus.

To sum up, there are a number of possible procedures which could be used to measure *GARB*, but no one procedure is clearly superior to the others under all possible circumstances. All of the alternatives involve compromises of one form or another and all are deficient in one or more respects. Purely cost-saving innovations present fewer problems but many innovations also alter yield per area, so that in general the extremely difficult problems arising from the fact that land has alternative uses in different industries cannot be avoided.

mpact of Farm Size on the Bidding Potential for gricultural Land: Comment

wang-Siung C. Ling

'he theoretical model of farm size and farmland rice bidding potential developed by Harris and Iehring (HN) and published in the May 1976 *Jour-al* has been referred to as significant in explaining ıctors affecting farmland price competition (Lee nd Rask, Stanton, Carter and Johnston). As de-ate will likely continue over family farm problems nd future farm policies (Bergland), further re-earch using the HN model is to be expected. esearchers already have extended the HN model. ıdams regarded the HN model as providing a roader framework than previous models for in-estment decisions. He considered the bid prices onceptually more general and complete than deci-ion rules based solely on present value. Harris and Iehring (1977) extended the model to include a andom element.

he Bid-Price Model

IN states the maximum bid price of an acre of armland as

$$B = E(z) - \frac{1}{r(x)} \pm \left\{\frac{1}{[r(x)]^2} - \sigma_z^2\right\}^{\frac{1}{2}},$$

or $r(x) \neq 0$, and $B = E(z)$ for $r(x) = 0$, where B is he maximum price for an acre of land; z, the dis-counted value of future income; E, expectation perator; x, net worth of the decision maker; $r(x)$, Pratt's measure of local risk aversion; and σ_z^2, the variance of z.

The discounted value of future income from an ıcre of land, z, is derived from a standard per-etuity model incorporating a constant rate of growth: $z = y \dfrac{(1-t)}{(i-g)}$, where y represents a ran-lom before-tax income stream, t is the marginal ncome tax rate of the decision maker, i is the lecision maker's pure time preference, and g is the expected rate of growth of after-tax income. Thus, $E(z)$ and σ_z^2, respectively, become

$$(1) \qquad E(z) = \frac{(1-t)}{(i-g)} E(y), \text{ and}$$

$$(2) \qquad \sigma_z^2 = \left[\frac{(1-t)}{(i-g)}\right]^2 \sigma_y^2.$$

A real solution for maximum bid price B is feasi-ble if and only if $\dfrac{1}{[r(x)]^2} - \sigma_z^2 \geq 0$, or

$$(3) \qquad r(x) \leq \frac{1}{\sigma_z}.$$

That is, the rate of risk aversion has to be less than or equal to the inverse of the standard deviation of the value of an acre of land.

HN, in discussing the effects on the bid price of the marginal tax rate of the decision maker's time preference, and expected growth rate of after-tax income (p. 163), evaluate the signs of the effects with a rather ambiguous qualification: "under rea-sonable assumptions about the sizes of the param-eters in the model." The ambiguity is a result of the uncertainty regarding the sign of

$$(4) \qquad \left[\frac{E(y)}{(i-g)} - \frac{(1-t)\sigma_y^2}{D(i-g)^2}\right] \gtrless 0,$$

which affects the signs of

$$(5) \qquad \frac{\partial B}{\partial t} = -\left[\frac{E(y)}{(i-g)} - \frac{(1-t)\sigma_y^2}{D(i-g)^2}\right] \gtrless 0,$$

$$(6) \qquad \frac{\partial B}{\partial i} = -\frac{(1-t)}{(i-g)}\left[\frac{E(y)}{(i-g)} - \frac{(1-t)\sigma_y^2}{D(i-g)^2}\right] \gtrless 0, \text{ and}$$

$$(7) \qquad \frac{\partial B}{\partial g} = \frac{(1-t)}{(i-g)}\left[\frac{E(y)}{(i-g)} - \frac{(1-t)\sigma_y^2}{D(i-g)^2}\right] \gtrless 0,$$

where

$$(8) \qquad D = \left\{\frac{1}{[r(x)]^2} - \sigma_z^2\right\}^{\frac{1}{2}}.$$

Further consideration of equation (4) will clarify the ambiguity. From equations (1), (2), and (8), (4) becomes

$$(4') \qquad \frac{E(z)\left\{\dfrac{1}{[r(x)]^2} - \sigma_z^2\right\}^{\frac{1}{2}} - \sigma_z^2}{(1-t)\left\{\dfrac{1}{[r(x)]^2} - \sigma_z^2\right\}^{\frac{1}{2}}} \gtrless 0,$$

---

wang-Siung C. Ling is an agricultural economist, Cooperative Marketing and Purchasing Division; Economics, Statistics, and Cooperatives Service; U.S. Department of Agriculture.

The author gratefully acknowledges the helpful comments of wo referees. John R. Dunn and Charles A. Kraenzle reviewed an earlier draft.

Table 1. The Properties of the Rate of Risk Aversion Based on the 1969 Iowa Cash-Grain Farn and Farmers

Farm Class	Rate of Risk Aversion or Measure of Concavity	$R = \frac{E(z)}{\sigma_z\sqrt{[E(z)]^2 + \sigma_z^2}}$	Concavity Constraint $1/\sigma_z$	Margin Incom Tax Ra
0	0.00000298	0.01190	0.01211	.43
I	0.00000594	0.00922	0.00938	.32
II	0.00000699	0.00967	0.00985	.28
III	0.00000709	0.01218	0.01240	.25
IV	0.00001467	0.00926	0.00976	.24

the sign of which is determined by

$$(4'') \qquad E(z)\left\{\frac{1}{[r(x)]^2} - \sigma_z^2\right\}^{\frac{1}{2}} - \sigma_z^2 \gtreqless 0.$$

Solving (4″) for $r(x)$ and letting

$$R = \frac{E(z)}{\sigma_z} \cdot \frac{1}{\sqrt{[E(z)]^2 + \sigma_z^2}},$$

then, when $r(x) < R$, (4) is greater than zero, and it follows that equations (5) and (6) are less than zero and equation (7) is greater than zero. When $r(x) > R$, (4) is less than zero, and it follows that equations (5) and (6) are greater than zero and equation (7) is less than zero. Finally, when $r(x) = R$, equations (4), (5), (6), and (7) all equal zero.

The R-value is quantified in table 1 using the HN data for the 1969 Iowa cash-grain farms and farmers. Assuming normal distribution for the value of an acre of land, R is the standard normal mean value of an acre of land deflated by a term in the square-root of the sum of the mean square and the variance. The correct interpretation of equations (5), (6), and (7) is contingent upon the inequality relationships between R and $r(x)$.

Policy Implications

Implications considerably modifying the interpretation of the HN model, e.g., "Harris and Nehring note that their present value formula implies that individual valuations decrease as the marginal income tax rate rises and high income persons *ceteris paribus* bid less for farmland than do persons in lower tax brackets" (Adams, p. 540), can be drawn from these results. Given the bid price formula B and relation (3), a necessary and sufficient condition for a decision maker to have a maximum bid price to compete in the land market is that the concavity of his utility function (which is synonymous with his rate of risk aversion according to Pratt) measured at his net worth has to be less than or equal to $1/\sigma_z$. Therefore, $1/\sigma_z$ will be called th concavity constraint.

Table 1 shows that all five classes of Iowa cash grain farmers of the HN example satisfy the cor cavity constraint and have their respective biddin price. However, the utility function used by HI has little concavity. Without knowing every farm er's utility function and his rate of risk aversion, th net result of marginal income tax rate manipulatio in the context of the HN model is uncertain. De termining the effects of a change in the marginal ta rate on farmland bid prices is far more complicate than Adams has asserted.

Publications

Books Reviewed

Cochrane, Willard W. ***The Development of American Agriculture: A Historical Analysis.*** **Minneapolis: University of Minnesota Press, 1979, vii + 464 pp., $25.00, $10.95 paper.**

Harry Truman had a favorite phrase: "The only thing new in the world is the history you do not know." Some of us who thought we knew just about every facet of Willard Cochrane's professional personality—by having read his books and articles, and by having labored, disputed, and progressed with him through more than four decades—find something "new" in this book, given to us by Cochrane the historian. Historical content sets this work apart; the balance is vintage stuff, resting on such books as *Farm Prices—Myth and Reality*, and the author's other works. And the "newness," exposited as historical analysis, has given us one of the most useful books in a decade on policy issues of the United States agricultural sector. The economic analysis is so well-integrated with intertemporal political and social realities that some might conclude Cochrane missed his calling and should have written history instead of economics as a career!

After a brief introduction the subject matter model—historical analysis—is divided into three parts: a straightforward description of the historical development of American agriculture 1607–1978, an identification of key forces during that development, and a politicoeconomic model explaining the development from 1950 forward. Some concluding remarks follow in a brief chapter.

Cochrane, the historian, covers the waterfront for 156 pages (pp. 13–169) and the 371-year period 1607–1978. Professional historians, especially process historians, might quibble with method, but Cochrane's coverage is quite adequate for policy background purposes, and he gives generous references. Benedict, in his book *Farm Policies of the United States, 1790–1950* approached early policy matters from a topical-functional standpoint. The two approaches are complementary and give excellent source material.

Cochrane, the economist, restricts himself to the last three decades (pp. 355–425). It is difficult to identify his role in that large part of the book between history and economics (pp. 173–352) in which he states that he is not specifying a model of economic development but is unraveling the historical scenario by identifying the key forces during its development. This modest restriction does not jibe with the historical specification outlined for the period 1607–1950. And a major problem arises in that the casual reader may not take seriously the author's statement about his overall approach, and may wonder how everything ties together when reaching the end of the book.

Be that as it may, Cochrane, the diagnostician of history, tempered by (a new?) Cochrane, the politicoeconomist, has written his material so well and has so skillfully discriminated his market—that there is something here for many readers—for farm leaders, politicians, students, professional economists and consumers. It is only on occasion that the author lapses into seemingly rigid positions with which so many of his past critics have taken issue. This reviewer dubs one such position as Cochrane, the mercantilist. For example, he advocates that the United States abandon policies for trade liberalization in exchange for international bilateralism and other price and some trade stabilizing schemes (pp. 423 ff.) This "old" Cochrane, if he had retreated further and had included in his history a bit of sixteenth and seventeenth century England, might have learned the bitter results for much of the world of such trade policies.

In summary, the principal thesis of this book is that United States agricultural development proceeded from voluntary coordination during the period 1607 to the Great Depression, when "uncoordinated government" intervention (i.e., between Congress and the executive branch) took over for a period of about four decades. Two new phenomena emerged after 1970: more coordination between Congress and the executive, which meant an era of managed government intervention; and, second, a significant integration of the United States agriculture into the world economy via massive agricultural exports. The reviewer adds: all the while, the role of farm leaders and farm organizations in the origin and promulgation of agricultural policy was giving way to an analytical elite at various levels. In this post-1970 situation, federal as well as other policy "experts" have been constantly fine-tuning agricultural demand and supply models while hovering over computer terminals to get the latest answers for urgent political decisions.

Paul Kelly spent the spring of 1980 with me analyzing and diagnosing farm policy, arguing and disputing Cochrane's theses all the way. I conclude with several questions we raised during that time which might be of interest to Cochrane if ever he revises the book. What can we anticipate for the future role of the democratic ideal of Jeffersonian "farm policy"? Have we moved irreversibly to an era where highly concentrated farm policy planning and development will overshadow the noncentralized planning and development of policy? Will the agricultural sector, as Don Paarlberg implies, continue to lose the freedom to choose its future course, i.e., freedom to follow a path of uncoordinated intervention as it has in the past?

Jimmye S. Hillman
University of Arizona

Dent, J. B., and M. J. Blackie. ***Systems Simulation in Agriculture.*** **London: Applied Science Publishers, 1979, x + 180 pp., $28.75.**

A major obstacle to teaching the use of systems analysis in the agricultural sciences has been the lack of an introductory textbook. Published materials on systems analysis have dealt mostly with advanced topics. Undergraduate students and trained disciplinary researchers in agriculture have not had available a source that was at once introductory and comprehensive. Dent and Blackie have managed to fill that void.

The authors believe that a computer-based simulation model is an integral part of systems research. It can provide the framework for guiding agricultural experiments, accumulating and assessing results of these experiments, and assisting decision makers in controlling the system being modelled.

The bulk of the text is concerned with construction and operation of computer-based simulation models. Throughout, the authors intertwine examples from two simulation models with which they have had earlier association. One is a barley-leaf-rust model; the other is a pig-herd management model. A chapter devoted to model construction includes a discussion of a difficult problem in any area of scientific endeavor—where to begin. Their example models are used to good advantage in discussing the process of model construction.

Chapters are included on computer considerations in modelling (choice of language and design criteria), stochastic versus deterministic considerations in modelling, and validation of simulation models. The generous use of examples makes the presentation clear and the concepts easy to comprehend. A chapter on design of simulation experiments, though far from complete, explores the differences between these and real-world experiments: the total control over the experimental environment, time compression, and sequential rather than simultaneous nature of experimental events. For each chapter, a carefully selected bibliography has been prepared for the more serious reader.

The final chapter discusses applications of computer-based simulation models. The authors present several flowcharts that demonstrate the important role of simulation models in the orientation of agricultural research programs as well as in the development of recommendations for farmers.

Although the book is somewhat longer on the "how to" than on the "why," it successfully steers away from a simple cookbook approach to modelling. The authors recognize that many options are available during the various stages of model development and use; they present cases for and against each of the major approaches. Their overriding concern is that the model must fit the problem under consideration—not the reverse. Their tips on flowcharting, design, programming, and validation of simulation models demonstrates the breadth of their experience. Even experienced modellers can learn much from reading this text, and many modelling resources could be saved by considering the advice.

Kurt K. Klein
Agriculture Canada

Gardner, Bruce L. ***Optimal Stockpiling of Grain.*** **Lexington, Mass.: D.C. Heath & Co., 1979, xii + 175 pp., $19.95.**

The eight chapters of this book focus essentially on two interrelated issues: (*a*) the logical development of generalized stockpiling principles and (*b*) the application of those principles to the U.S. and world wheat situations. This combined focus, possibly as a result of Gardner's experience as a senior staff economist with the Council of Economic Advisers, provides the reader with valuable insights into the theoretical and strategical complexities of grain storage.

The first five chapters use hypothetical quantitative examples to develop storage rules for determining the optimum level of carryover stocks. Optimum is defined as that level which maximizes the present value of grain held over an indefinite time period minus the costs of production and storage and adjusted for external benefits and costs incurred. Beginning with a relatively simple two-period welfare function, the author uses stochastic dynamic programming techniques to build increasingly complex storage rules. Gardner proceeds to analyze the effect on optimum stockpile size of variations in planning horizon, elasticities of supply and demand, storage costs, random components in the production and demand of the stockpiled commodity, and the supply of close substitutes. Having set forth the economic rationale for stockpiling grain from both social welfare and private speculative viewpoints, the later chapters apply and adapt that rationale to the world wheat market and, finally, to the U.S. wheat market.

As a result of the analysis, Gardner concludes that appropriate grain-stockpiling strategies can be formulated based on principles and procedures employed in analysis of other types of economic activities, viz., maximization of a specified objective function by means of an appropriate technique subject to detailed constraints. Optimum stock levels therefore are unique to specific supply and demand conditions and must be recalculated over time. Although either price or quantity indicators may signify the need to adjust optimum stock levels, the reader becomes acutely aware of the risk of misspecified price bands and the need for absolute quantitative limits on stocks.

Gardner's analysis indicated the need for an average international wheat reserve of about 40 million metric tons with considerable annual variation. This average optimum was reduced to 10 million metric tons when price expectations were not al-

owed to impact intended production and when external costs due to shortfalls were not considered in he model. No attempt was made by Gardner to leal with the independent and often conflicting polcies of individual wheat-importing and -exporting nations. Instead, he assumes a single worldwide lecision rule commonly adhered to by all nations in estimating optimal reserve levels.

The impact of related commodities on optimum stockpiles, a factor appearing in the author's discussion of storage principles, is not included in either of his applied studies of wheat. An accounting for the impact of supply and demand of substitute grains would greatly enhance the usefulness of the applied analysis for policy makers.

In spite of these shortcomings, all of which the author is fully aware, the book makes a valuable contribution to the understanding of grain-stockpiling strategy. Gardner displays a thorough knowledge of storage literature and a keen insight into the relative value and weakness of previous studies. His own study represents a major positive addition to the literature.

The step-by-step development of optimum storage rules and their application makes this book an excellent text for graduate courses in the economics of grain storage. In total, Gardner has done an admirable job of addressing the "need to put the relevant theoretical work of economists in a form more directly usable by policy makers" (preface) and more easily understood by students.

University of Nebraska

Gold, Steven David. *Property Tax Relief*. Lexington, Mass.: Lexington Books, 1979, xi + 331 pp., $29.95.

One of the significant events in local finance over the last ten to twenty years has been the decline of the local property tax from its premier status as the source of local revenue. Gold sets out to analyze the various property tax relief measures, in order to overcome three drawbacks that he finds in the current literature: a "paucity of timely material, . . . huge gaps concerning analysis of specific relief alternatives, . . . [and] that many writers were politically naive" (p. xv). Perhaps his most important contribution is to provide "one-stop shopping" for those interested in knowing more about this subject. As at many one-stop shopping centers, convenience comes at the cost of some sacrifices in both selection and quality.

A writer of a book like this one has to make fundamental judgments when he starts. Should the book include only the programs of which people normally think when they begin to talk about property tax relief programs, such as differential assessment of farmland? Or should it also include the wide variety of programs, such as the grant programs of the Law Enforcement Assistance Administration, that may effectively be property tax relief programs but are not commonly thought of in that context? Gold takes the latter course. Along with the narrowly defined relief programs, such as residential circuit breakers, differential assessment of farmland, classification, and property tax limits, he also includes chapters on local sales and income taxes, user charges, and miscellaneous forms of relief. The book closes with a chapter on "Rural-Urban Conflict," case studies of three states and capsule summaries of the property tax situation in each state.

In opting for the broader category, Gold, to his credit, avoids leading unwary readers to consider only part of the problem. Too many erstwhile property tax relief discussions have failed to recognize the need to find other ways of raising the funds lost from tax relief or else to cut government spending. As a result of Gold's decision, however, the sheer scope of his subject matter becomes a problem. Discussions of particular programs often must be so brief they barely scratch the surface. In many ways the book becomes a text on local revenues, though it would need heavy supplementing to be used for that purpose.

Specialists will be bothered by some instances of mistaken facts or failure to specify exactly what is meant. For example, Gold talks of property taxes rising from 1945 to 1971 "from 2.5 to 6.9 percent of farm income" (p. 118). The comparisons cited are actually to the total personal income of the farm population, a related but considerably different measure. Again, Gold suggests that no states apply roll-back penalties when land changes ownership without changing use (p. 115). He appears to have overlooked Minnesota (Waldo and Yoho, p. 4).

In a somewhat different vein, this reviewer would not necessarily agree with all of Gold's conclusions. For example (p. 120), studies of differential farmland assessment "are somewhat out of touch with the reality of farm property tax relief programs in that they tend to overemphasize the goal of preserving farmland relative to the goal of enhancing the income of farmers." I would certainly agree that these programs have had more impact on farm income than on farmland preservation. However, my observation has been that they are more often sold to the public and the legislatures as farmland preservation programs. Hence, it makes sense for those who are interested in providing information for policy determination to analyze them in that vein.

Despite these fairly minor shortcomings, the book is likely to be useful for some members of our profession. In particular, it is a good place for an extension public policy analyst to get "a quick study" of the wide variety of property tax relief measures available. Others who need a broad overview will find it here. Lexington Books would do

these readers a real service if they found ways to publish at more reasonable prices.

Waldo, Arley D., And Carole B. Yoho. *Provisions for Use-Value Assessment of Agricultural and Open Space Land in Minnesota*, pp. 17–21. Dep. Agr. and Applied Econ. Staff Pap., University of Minnesota, 1977.

Roumasset, James A., Jean-Marc Boussard, and Inderjit Singh, eds. *Risk, Uncertainty and Agricultural Development*. College Laguna, Philippines: Southeast Asian Regional Center for Graduate Study and Research in Agriculture; New York: Agricultural Development Council, 1979, 437 pp., $40.00.

A number of pioneering economists working on technological, institutional, economic, and social issues of agricultural production in lesser income countries have long been concerned with the role of risk and uncertainty relative to technology adoption, distribution, and policy issues. With financial and logistic support from the Agricultural Development Council (ADC) and the International Center for Improvement of Wheat and Corn (CIMMYT), a conference was held near Mexico City in March 1976, which brought together more than two dozen economists. A synopsis of the seminar papers was published in 1977 by ADC, followed in 1979 by publication of this book.

The book contains twenty-one chapters which represent, for the most part, revised and synthesized versions of the seminar papers by topic categories assigned in the seminar. The first five sections focus upon alternative quantitative methods for modeling decision making under risk, measuring risk and risk attitudes, and the effect of risk on resource allocation. The last two sections focus upon risk and agricultural policy.

The title of the book suggests that it deals with concepts which link risk and agricultural development. Yet, one of its editors states in the very first paragraph of chapter one, "The book provides a survey of alternative methods in . . . agricultural decision analysis," an apparent inconsistency with the book title. Consequently, this review will concentrate upon the usefulness of the book both in covering risk methods and in covering issues of risk and agricultural development.

The topic of risk cannot be divorced from the realities of risk, even for economists, as evidenced by a vast growth in literature on this topic in the last decade. An unfortunate, yet predictable, event was the approximate four-year lag from the 1976 conference until publication of this book. Many of the chapters have been published elsewhere, supplemented by a vast quantity of work, extended and published elsewhere, or dominated by more recent publications on the same topic. The reviewers feel that, at the time of the conference, the material provided an excellent assessment of the art to the participants and those outsiders receiving working drafts. Alas, the participating economists were equally as vulnerable as everyone else in *ex ante* prediction, including that for growth in the supply of risk research literature.

Several points are troublesome within the context of the book as a text in risk methods. First, there is the issue of duplication. Chapters 2, 3, and 4 involved considerable overlap, for example. Second, it is a herculean editorial task to integrate a book containing a collection of papers, a task rarely accomplished. The result is a number of contradictory statements. Consider, for example, the statement on page 95, "expected utility applied to static decision problems . . . does not rest on reasonable behavioral postulates," versus the statement on page 46, "expected utility . . . is controversial only to the extent that some critics do not believe in subjective probabilities and others (behavioralists) challenge the . . . foundations." Obviously, a critic and a defender were participants. It is unfortunate that a resolution, or at least a consistent evaluation was not provided. On a positive note, it is refreshing that a sensible discussion of strengths and weaknesses of several quantitative techniques, especially on Bernoullian decision theory and other models of uncertain decisions, were provided. In general however, as stated in chapter 1, only a very limited attempt was made at resolution of technique choice selection. That issue is still largely unresolved today.

The third difficulty with the book, as a text in risk methods, relates to the empirical side. Because emphasis was on risk techniques, little focus was upon the equally important topic of the role of risk in an agricultural development environment. Such questions as: (*a*) are risk considerations important? (*b*) do risk attitudes differ within and among farmer groups? and (*c*) how might risk considerations improve the ability of economic models to function in analysis of positive and normative settings? were hardly addressed at all. To the extent that they were, two points are noted. First, Binswanger provides guidelines for addressing those substantive questions, but unfortunately, not until chapter 20. He further states, and correctly so, why it is important to address such issues, and why the authors of the book did not do so. The reader, because of this, may wish to read chapter one first, followed by chapter 20, before advancing further. Second, some empirical evidence was provided to suggest that, in lesser income countries, considerable diversity of farmer attitudes to uncertainty may prevail, ranging from risk averse to risk preferred. Further, this may be influenced by the economic environment (degree

subsistence living, tenure status, etc.) within hich the farmer operates. Also suggested by hnson and Lipton were nonmonetary values and havioral issues. More rigorous investigation of ch factors will most certainly be necessary before uch confidence can be placed in using arbitrary havioral decision rules for modeling uncertainty agriculture.

Considering whether the book is an integration of sk and development leads these reviewers to ach a negative conclusion. Of the twenty-one apters, only nine deal with lesser income counies, and three of those use such countries only in example mode rather than address development sues per se. The focus was largely upon farmer sk attitudes and their effect upon technology loption. This is not surprising, given that most sk methods to date are individual decision maker iented. Group decision making by credit institutons, research organizations, governments, and licy makers received scant attention because lit formal analysis has yet been done on this topic. hus, the practitioner of development will not find is book to be of great current significance in relatg risk to development problems. Binswanger's nclusion in appraising the literature's inadequacy worth repeating, as it represents major issues for solution: (*a*) scarcity of empirical evidence on obability distributions of decisions which focus on particular development problems, (*b*) scarcity empirical evidence on attitudes toward risk by velopment actors, and (*c*) limited knowledge out risk-specific policy alternatives and their efct upon development actors.

Major opportunities remain in assessing the role risk and uncertainty as it pertains to agricultural velopment problems. This book provides a useful int of departure, circa 1976, for further inquiry.

rong, Ann L. *Land Banking*. Baltimore, Md.: Johns Hopkins University Press, 1979, xii + 312 pp., $22.50.

ased on original research conducted in Sweden, e Netherlands, and France by the author, with pport from the National Endowment for the umanities, this five-chapter book advances owledge about land banking, "defined rather oadly as public, or publicly authorized, acquisin of land to be held for future use to implement iblic land use policies" (p. 2). This descriptive ork by the chairman of the Department of City d Regional Planning at the University of nnsylvania reviews the concepts influencing land vnership and land-use policies in the United States, presents case studies of land banking as practiced in the three countries previously mentioned, and examines the potential for land banking in the United States. Practitioners of disciplines concerned with land-use problems on the fringe of both metropolitan centers and small towns and with retention of land in agricultural uses will find this book useful.

The concepts review is especially informative, starting with Plato and ending with the Grand Central Terminal case, *Penn Central Transportation Co.* v. *City of New York*. Strong concludes that we in the United States "may be moving from a [land-use] system that rewards speculation and protects landowners from losses based on public actions toward a system that defines public purpose more broadly and judges it equitable for society to retain the values resulting from its investment" (p. 39).

To assist in accommodating this changing public view, Strong carefully chose the three countries in which she studied land-bank programs. Sweden began a land-banking program in the city of Stockholm in 1904 because of a "[c]oncern about emigration [to the United States] and a desire to make homeowning possible" by reducing the cost of land (p. 48). Given its long tradition of public landownership, this was not viewed in Sweden as a revolutionary undertaking. This case is limited to the Stockholm region and how the program there has been affected by national policy, by intranation migration, by changes in lifestyle preferences, by competition from suburban towns, and by political decisions concerning lease rates and types of development.

The Netherlands was selected because the Dutch also view land as involving an element of public trust that supercedes private rights. The Dutch started land banking in 1896, in response to rapid growth in cities and the high costs associated with developing land reclaimed from the sea. Strong found "[t]he Dutch approach to land banking . . . calm, low key, and rational. For them it has worked extremely well" (p. 107). Again she describes the development of the land bank, its relation to national, regional, and municipal planning, and how various municipalities have managed their land-bank activities.

France was selected because the concepts the French hold about landownership closely parallel those existing in the United States. The French adopted their first land-bank program in 1958. A major goal was to control land prices in rapidly developing areas "by a combination of public preemption power and purchase" (p. 140). Six programs had been adopted by the time of the study, 1973/74. Four are known collectively as the Zs, the priority urbanization zone, the planned development zone, the picturesque zone, and the deferred development zone. These are joined by a farmland preservation program conducted through "[p]rivate, nonprofit organizations called SAFERs (Société d'Aménagement Foncier et d'Etablisse-

ment Rural)" (p. 172). The sixth program is conducted by regional councils, appointed bodies with legislative authority, power to collect certain taxes, and authority to make grants for purchase of land for "continued open space or for medium-term land reserves" (p. 184). Substantive detail is presented about each program and the institution designed to fund it.

Each case gives careful attention to the land acquisition process and to the way the acquired land is valued. Ten pages are devoted to the SAFER, a unique institution managed by farmers and persons engaged in agriculture and reflecting a long-term commitment by the French "to the improvement of farm productivity and to the encouragement of the family farm" (pp. 171–72). "Overall, its role is significant" (p. 244).

The author finds that in both Sweden and the Netherlands "land banking continues to be desirable on the grounds of efficiency and equity. Public ownership enables municipalities to time development . . . and to exercise control over the mix of land uses. It also assures that owners of development sites will not benefit from land sales and thus work an injustice on those landowners restricted to farming or other low-density uses" (p. 242). The programs in France are "well conceived in legal and administrative terms. . . . are in extensive u and, for the most part, worthwhile and importan (p. 244). However, the French have been unable decide "how much of a landowner's value it equitable to remove through planning decisions . [with the result that] political pressure often lea to the granting of permission to develop sites not development zones for private housing" (p. 244

When examining the potential for land banking the United States, Strong turns to the Puerto Ric Land Administration Act of 1962 and to the *Mod Land Development Code* endorsed by the Ame ican Law Institute in 1975. Both instruments a examined, and the text of each is presented as appendix to the final chapter. Strong proposes th land banking in the United States might appropi ately begin with those intensive developments th are recognized as development of greater than loc significance.

The author completed an enormous task qui well. Only the section discussing the Zs is tedio reading. This excellent descriptive work lacks ar economic analysis, a criticism regularly made t economists of studies conducted by planners.

Necrology

Paul H. Bebermeyer, retired professor of agricultural economics, University of Missouri, died 2 May 1980 at the age of 84.

L. C. Davis, retired farm management professor at Oklahoma State University, died 19 September 1979. He was 69.

Theodor Heidhues, University of Göttingen, died 11 November 1978 after a prolonged illness. He was 45.

Sidney Samuels Hoos, professor emeritus of agricultural and resource economics, business administration, and economics, University of California, Berkeley, and an AAEA Fellow, died 0 September 1979 in Berkeley. He was 69 years old.

Joseph M. Johnson, professor emeritus, Virginia Polytechnic Institute and State University, died 22 April 1979 at the age of 61.

William H. Nicholls, Vanderbilt University, died 4 August 1978, following a heart attack. He was 64.

Truman R. Nodland, professor emeritus, University of Minnesota, died 25 August 1979, at the age of 71 after a long illness.

W. J. "Aggie" Nucholls, associate professor emeritus, Virginia Polytechnic Institute and State University, died in March 1979, at the age of 74.

Loris A. Parcher, retired professor, Oklahoma State University, died 23 October 1979.

Percy Leo Strickland, Jr., USDA employee stationed at Oklahoma State University, died 0 June 1979.

Maurice C. Taylor, long-time member of the Department of Agricultural Economics and Economics, Montana State University, died of a heart attack 7 June 1979.

Robert M. Walsh, agricultural economist and administrative official in the Department of Agriculture, died 21 August 1979.

Statement of Ownership, Management, and Circulation (Act of 23 October 1962; Section 4869 Title 39, United States Code)

1. Title of Publication: *American Journal of Agricultural Economics*
2. Date of filing: 1 August 1980.
3. Frequency of issue: Quarterly and December Proceedings issue (February, May, August, November, and December). (*a*) No. of issues published annually: 5. (*b*) Annual subscription rate: $12.50; $25.00 and $35.00.
4. Location of known office of publication: Agricultural Experiment Station, University of Kentucky, Lexington, Kentucky 40546.
5. Location of headquarters or general business office: Agricultural Experiment Station, University of Kentucky, Lexington, Kentucky 40546.
6. Name and addresses of publisher, editor: American Agricultural Economics Association, University of Kentucky, Lexington, Kentucky 40546; Editor: V. James Rhodes, Department of Agricultural Economics, 200 Mumford Hall, University of Missouri, Columbia, Missouri 65211.
7. Owner: American Agricultural Economics Association, Agricultural Experiment Station, University of Kentucky, Lexington, Kentucky 40546.
8. Bondholders, mortgagees, and other security holders: None.
9. Nonprofit organization: Status unchanged during preceding twelve (12) months.
10. The following circulation figures are provided for (*a*) the average number of copies of each issue during the preceding twelve (12) months and (*b*) the single issue nearest to filing date:

	Average Copies	Actual Copies
Total number of copies printed	(*a*) 7,250	(*b*) 7,250

Information on Submitting Manuscripts

1. **Cover letter.** In a cover letter, the author(s) must state (*a*) that the material in this manuscript has not been published and is not being published or being considered for publication elsewhere, and will not be submitted for publication elsewhere unless rejected by the *Journal* editor or withdrawn by the author(s); (*b*) that the material in this manuscript, so far as the author(s) knows, does not infringe upon other published material protected by copyright; (*c*) that the employer of the author(s), if any, either does not assert an ownership interest in the manuscript or is willing to convey such interest to the American Agricultural Economics Association (AAEA); and (*d*) that submission of this manuscript gives the AAEA the exclusive right to publish, to copyright, and to allow or to deny reproduction of the manuscript, in whole or in part. If the applicability of point (*a*) is unclear, the author(s) should explain.
2. **Author's identification.** In order to protect their anonymity in the review process, authors should avoid identifying themselves in the manuscript. Attach a separate page including the names of the author(s) and appropriate biographical information, as well as the title of the manuscript. Include only the title on the first page of the text.
3. **Typing.** Double-space all material, including footnotes, tables, quotations, and references, on 8½-by-11-inch standard weight white paper with margins on all sides of at least 1¼ inches.
4. **Style.** Follow *A Manual of Style* by the University of Chicago Press as well as previous issues of this *Journal*.
5. **Mathematical notation.** Use only essential mathematical notation; such notation is costly to typeset and may limit the readership. Avoid using the same character for both superscripts and subscripts, using capital letters as superscripts or subscripts, and using overbars, tildes, carets, and other modifications of standard type. Asterisks, primes, and small English letter superscripts are suitable substitutes.
6. **Footnotes.** Number footnotes consecutively throughout the paper, not page by page. Type the footnotes, double-spaced, on a page following the article. The institutional paper number and acknowledgments, if any, should be placed at the beginning of the list of footnotes. Footnotes should be only explanatory and should not be used for citations or for directing the reader to a particular work. This information can be incorporated into the text itself.
7. **References and citations.** Place all references, alphabetized by author, in a list at the end of the paper entitled "References." Only cited works should be included in the reference list. All citations should appear in the text and contain the author's name and page numbers, when necessary. Citations can be inserted parenthetically, e.g., (Doe) or (Doe, p. 5). Specify the date of publication if the same author appears more than once in the reference list, e.g., (Doe 1971, p. 5). If the author's name appears as part of the sentence, a parenthetical reference is unnecessary unless you need to cite page numbers or a date. A style sheet on references and citations is available upon request.
8. **Tables.** Place each table on a separate page; double-space all material; omit vertical rules.
9. **Figures.** Prepare figures on heavy white paper or acetate sheeting using black India ink or paste-up types suitable for black and white reproduction by a photographic process. Typescript is not suitable.
10. **Three copies.** Send the typed original and two carbon copies or photocopies. All copies should be inspected for completeness and quality of reproduction.
11. **Abstract.** Instructions for the preparation of an abstract will be sent when the manuscript is accepted for publication.
12. **Page charge.** Major support for this *Journal* is provided by page charges of $40 per printed page, or fraction thereof, payable by the supportive institution or granting agency. Payment does not affect acceptance, scheduling, or form of publication. Instructions for making payment are provided with galley proofs.

American Agricultural Economics Association

Objective

The AAEA seeks to further the systematic development of knowledge of agricultural economics in order to improve agriculture and agriculture's contribution to the general economy. The activities of the AAEA include:

—publishing the *American Journal of Agricultural Economics;*
—planning and conducting two annual meetings of the membership;
—sponsoring annual awards for outstanding extension programs, distinguished teaching, and outstanding research;
—recognizing outstanding agricultural economists through a fellows program;
—supporting a literature retrieval system in cooperation with the U.S. Department of Agriculture;
—publishing periodically a biographical directory of the AAEA's members;
—supporting an employment registry for agricultural economists in cooperation with the U.S. Department of Labor.

Membership and Subscriptions

Membership in the AAEA is open to individuals having a professional interest in agricultural economics. Dues, payable at the beginning of each calendar year, are as follows: regular members, $25, senior members, $12.50, and junior members, $12.50. Senior membership is open to persons, upon written request, who are sixty-five years of age or older and have retired from active professional work. Junior membership is for students and is limited to three years; students should use application forms available from and signed by the head of the department in which they are studying. Members receive this *Journal*.

Any firm, corporation, association, or partnership may become an institutional member upon payment of $100 per year; institutional members receive three copies of each issue of the *Journal*. Library subscriptions are $35 per year. Individual issues of this *Journal* are $10.00.

Payment of membership dues, correspondence regarding subscriptions, orders for individual copies of the *Journal*, changes in address, or inquiries about the general affairs of the AAEA should be sent to John C. Redman, Secretary-Treasurer, American Agricultural Economics Association, Department of Agricultural Economics, University of Kentucky, Lexington, Kentucky, 40546.

American Journal of Agricultural Economics

Volume 62 Number 5

December 1980 Proceedings Issue

In this Issue: Proceedings from the annual meeting of the American Agricultural Economics Association held 27–30 July 1980 in Urbana-Champaign, Illinois

The *American Journal of Agricultural Economics* is published five times a year (February, May, August, November, December) by the American Agricultural Economics Association. Prior to 1968, this *Journal* was the *Journal of Farm Economics*.

Printed for the AAEA by Heffernan Press, Inc., Worcester, Massachusetts, USA.

Second class postage paid at Lexington, Kentucky, and additional mailing offices, Pub. No. 019500.

ISSN 0002-9092

Editorial Policy

The purpose of the *Journal* i to provide a forum for creative and scholarly work in agricultural economics. Thus, acceptable manuscript should have a relationship to the economics of agriculture natural resources, or rural and community development Contributions, methodological or applied, in the business, extension, research, and teaching phase of agricultural economics ar equally encouraged.

Editorial Communications

All manuscripts and editorial correspondence, except as noted below, should now be addressed to the new editor, James P. Houck, Departmen of Agricultural and Applied Economics, University of Minnesota, St. Paul, MN 55108

Communications concerning book reviews and books submitted for announcement in the *Journal* should be sent to the new book review edito Ronald A. Schrimper, Department of Economics and Business, North Carolin State University, Raleigh, NC 27607

Harold O. Carter

1980 Fellow

Chairman, Department of Agricultural Economics, University of California, Davis, 1970–76; Chairman of the Faculty, College of Agricultural and Environmental Science, U.C.-Davis, present.

Visiting professor, Agricultural College of Sweden, Upsalla, 1967; Center of Agricultural Economics, University of Naples, Italy, 1971; Senior Research Scholar, International Institute of Applied Systems Analysis, Laxenburg, Austria, 1976–77.

AAEA Editorial Council; associate editor, *AJAE* 1968–71. AAEA Award for Outstanding Research, 1963, 1967, 1971, 1975. President, WAEA, 1975–76.

Senior Staff Economist, President's Council of Economic Advisors, 1969–70; member, Economic Advisory Board to the Secretary of Commerce, 1973–74.

Harold O. Carter has achieved wide recognition for his research within the broad area of production economics and for his ability to focus on important public policy issues. Especially notable have been his pioneering efforts and imaginative empirical analyses pertaining to risk and variability in agricultural production, input-output applications in agriculture, production function methodology and applications, measurement of economies of scale in agricultural production, and interregional analysis and projections. While most of these studies have involved collaborative efforts, the importance of Carter's contributions is revealed by the fact that the work in each of the above areas and with various individuals has been recognized for its uniqueness and quality by AAEA or WAEA awards.

Born in Michigan, Carter received B.S. and M.S. degrees at Michigan State University and his Ph.D. at Iowa State University. He joined the faculty at the University of California, Davis, in 1958, served as chairman of his department from 1970–76, and has served on a wide range of University governing committees, including current service as chair of the faculty for the College of Agricultural and Environmental Sciences.

In his career at Davis, Carter also has made excellent contributions to teaching and has been particularly effective in his work with graduate students and in his contributions to the development of the graduate program. He was a visiting professor at the Agricultural College of Sweden, Upsalla, in 1967, and at the Center of Agricultural Economics, University of Naples in 1971.

Carter has served his profession in a variety of ways. He was a member of the Editorial Council and served as associate editor of the

Journal from 1968–71. In 1969–70 he was a Senior Staff Economist, President's Council of Economic Advisors. He served as a member of the Economic Advisory Board to the Secretary of Commerce, 1973–74 and was elected president of the Western Agricultural Economics Association, 1975–76. In 1976–77 he was a Senior Research Scholar, International Institute of Applied Systems Analysis, Laxenbürg, Austria.

Kenneth R. Farrell

1980 Fellow

Administrator, Economics, Statistics, and Cooperatives Service, U.S. Department of Agriculture, Washington, D.C., 1977–present.

Deputy Administrator, 1971–77; Chairman, Outlook and Situation Board, Assistant Administrator, Director Marketing Economics Division 1967–68; Economic Research Service, U.S. Department of Agriculture, Washington, D.C.

Associate Director, Giannini Foundation of Agricultural Economics 1969–71; Economist, Giannini Foundation and Cooperative Extension Service, Lecturer, Department of Agricultural Economics 1957–67; University of California, Berkeley.

Director 1972–74; President 1976–77, American Agricultural Economics Association.

Kenneth R. Farrell is a tireless public servant devoted to using the discipline of agricultural economics in widening service to society. Growing into increasingly demanding administrative positions, first in a university setting and then in government, he has brought a deep sense of social relevance, an instinct for workmanship, and a continuing search for improved scholarly standards to increasingly complex social problems. Operating under a set of democratic principles, his transactions with peers and subordinates are always conducted with grace and equanimity.

Born and raised in rural Ottawa, Farrell received a bachelors degree with honors from Ontario Agricultural College, University of Toronto, in 1950, taught agriculture in North Dakota in a veterans' rehabilitation program for two years, then attended Iowa State University, receiving the M.S. and Ph.D. degrees in agricultural economics. In 1957, he joined the staff of the University of California at Berkeley.

At California, he served for a decade in various administrative, research, teaching, and extension posts, including Fulbright Lecturer in Agricultural Economics at the University of Naples and an assignment with the National Commission on Food Marketing. During this period, he made major contributions to the application of economic theory and statistical methods in the analysis of marketing problems of agricultural commodities. The results of these analyses were used extensively in the design and management of federal and state marketing orders for California commodities. Throughout this ten-year period, Farrell was heavily involved in public education programs of the University. He was regarded as an excellent teacher and com-

municator, and was recognized for his integrity, objectivity, intellectual leadership, and professional vigor in research and extension.

Beginning in 1967, Farrell has held a succession of increasingly responsible and complex administrative posts, all related to agricultural economic research, statistics, and information programs. As Associate Director, Giannini Foundation, he was responsible for the development of program planning and coordination mechanisms involving research on two campuses and extension on three campuses of the University of California.

From the University of California, he moved to the USDA where he has held a succession of administrative positions—Director, Marketing Economics Division; Chairman, Outlook and Situation Board; Assistant and Deputy Administrator in the former Economic Research Service; and Administrator, Economics, Statistics and Cooperatives Service. In those positions, Farrell has made major contributions to the development and strengthening of economic research and outlook programs in the department. He has recruited competent staff and research leaders, set consistently high standards of professional excellence, dedicated the agency to serving the public interest. He has insisted upon integrity and objectivity in research and statistical programs and provided intellectual leadership and vision in the long range planning and development programs.

Farrell has contributed significantly to the development of our professional societies. He was a member of the Board of Directors of AAEA for six years, serving as its president in 1976–77. During that period he provided effective, forward-looking leadership, as evidenced in the creation of an Outstanding Public Policy Award, the development of organized symposia as an integral part of the AAEA annual meeting, strong encouragement and support of a public policy institute, and the encouragement and support of AAEA sponsorship of special workshops and symposia to address major public policy and professional issues. His presidential address, "Public Policy, the Public Interest, and Agricultural Economics," provided useful insights into the status of policy research in the profession and contributed to a resurgence of interest and activity in public policy research and extension in the profession.

In addition, he has chaired the contributed papers competition at the three most recent meetings of the International Association of Agricultural Economists. That activity illustrates a way in which Ken Farrell leaves his mark. Spanning a decade, the role of the contributed paper in improving the scientific vigor and social relevance of international discussion of food and agricultural problems has grown ever larger and more effective.

There is perhaps no better indication of Farrell's approach to his chosen fields of interest than the following excerpt from his presidential address to this Association in 1976: "We should broaden our professional perspectives, cultivate new clientele and professional alliances, recast and reorder our agenda, and experiment with modified and new institutional arrangements. In so doing, we could better address emerging public policy issues and better serve the public interest concerning food and agriculture."

John W. Mellor

1980 Fellow

Director, International Food Policy Research Institute, Washington, D.C.
Professor, Department of Agricultural Economics, Cornell University, 1954–77.
Chief Economist and Associate Assistant Administrator for Policy and Development Analysis, USAID, Department of State, 1975–77.
Editorial Council, *Journal of Farm Economics*, 1961–64; *Human Organization*, 1965–70.
American Agricultural Economics Association Awards: Outstanding Published Research Report, 1968; Publication of Enduring Quality, 1978.
Visiting Professor, Balwant Rajpat College, India, 1959–60; Indian Agricultural Research Institute, 1964–65; American University Beirut, 1968.
Member, American Academy of Arts and Sciences.

John W. Mellor is one of the leading scholars in the economics of agricultural development. He and his students have made important contributions in research, teaching, and the implementation of development programs both in the United States and overseas. His publications are widely read. He has given high priority to the growth of agricultural economics as a discipline in developing countries. His energy, optimism, and enthusiasm are infectious and redound throughout his work.

Born in Paris, France, Mellor grew up in Vermont and operated a sizeable poultry enterprise while in high school. He completed a bachelors degree in agriculture at Cornell University in 1950, held a Fulbright fellowship at Oxford University in 1951–52, and completed his doctorate at Cornell in 1954.

Mellor began his career as a faculty member at Cornell by teaching the introductory undergraduate course in agricultural economics to more than 300 students each year. Development economics was introduced in this course, even though the primary emphasis was given to the reasons various types of agricultural production occur where they do throughout the world.

He organized Cornell's first formal course on the economics of agricultural development after spending eighteen months as a visiting professor at a small agricultural college near Agra, India. His energy and enthusiasm for work in this field was a major factor in a successful effort to obtain funding for a teaching and research program in international agriculture at Cornell. Mellor was appointed to one of the first professorships in international agriculture in 1962. He served as associate director of the university-wide Center for International Studies 1961–66. He also held courtesy

appointments in the Departments of Economics and Asian Studies and was director of the Program on Comparative Economic Development.

Mellor's first book, *The Economics of Agricultural Development,* grew out of his experience as a teacher and research scholar and his work with graduate students. Widely used, it has been translated into French, Spanish, Portuguese, Arabic, and Vietnamese. It received the AAEA Award as a publication of enduring quality in 1978. He is the author of two other books, *Developing Rural India: Plan and Practice* (with Weaver, Lele, and Simon) in 1968, and *The New Economics of Growth—A Strategy for India and the Developing World,* 1976. He is editor of the volume, *India: A Rising Middle Power,* 1979, and he has made contributions to eleven other books and collections of readings. He has published articles and notes in nine major journals including the path-breaking paper, "The Role of Agriculture in Economic Development," in collaboration with Bruce Johnston. This article, first published in the *American Economic Review,* has been reprinted, notably in the AEA *Readings in the Economics of Agriculture.*

The commitment to publication and to share the results of research has been transferred to those with whom he has worked. Many of Mellor's students have been the sole author of a monograph, bulletin, or book based on thesis research. No study goes unreported. Perhaps most important, he encourages continued professional growth and involvement in the discipline wherever former students are located.

Mellor has had wide experience overseas, though most of his own research has been associated with work in south and southeast Asia. He has been a member of the Board of Directors of International Voluntary Services since 1962. He also has been a member of the National Screening Committee, Foreign Area Fellowship Program in Asia, and chairman of the Mekong Development Panel of the Asia Society; and a consultant to the World Bank, FAO, and the Rockefeller Foundation.

After serving as director of a number of research contracts funded by USAID at Cornell University, Mellor took leave in 1975 to be chief economist and associate assistant administrator for policy development and analysis at USAID. In 1977, he accepted the challenge of the directorship of the International Food Policy Research Institute in Washington. He was elected to membership in the American Academy of Arts and Sciences that year as well.

John Mellor has had an important impact on teaching, research, and scholarship in international agriculture. He has a strong allegiance and concern for rural people and their key role in the development process. His interest in policy and his analyses reflect a respect for original data and the need for firsthand knowledge from the field.

Luther G. Tweeten

1980–81 President

Regents Professor of Agricultural Economics, Oklahoma State University.
Visiting Professor, Stanford University, University of Wisconsin-Madison.
Board of Directors: AAEA, 1969–72; Bread for the World 1980–83.
Chairman: AAEA Contributed Papers 1972; Economic Statistics Committee 1976–78; Oklahoma State University Faculty Committee 1970–72.
Consultant: Harvard Development Advisory Service; U.S. Senate and House committees on agriculture; U.S. Department of Agriculture; Oklahoma Department of Education; Joint Economic Committee of Congress; National Commission on Employment and Unemployment Statistics.
Awards: Distinguished Alumnus, Waldorf College; Outstanding Research, Western Agricultural Economics Association.

Luther Tweeten was born in 1931 at Las Vegas, New Mexico. He grew up on a farm in northern Iowa and graduated from Lake Mills High School in 1950. After attending Waldorf College for two years, he entered Iowa State University in 1952 and received a B.S. degree in agricultural education in 1954. Following two years as a Special Agent in the Army Counter Intelligence Corps, he entered Oklahoma State University in 1956, where he received his M.S. degree in agricultural economics under Burl Back in 1958.

He returned to Iowa State University to work under Earl Heady and received the Ph.D. degree in agricultural economics in 1962. Tweeten advanced from assistant professor in 1962, to associate professor in 1963, to professor in 1965, and to Regents Professor in 1972, in the Department of Agricultural Economics at Oklahoma State University. He was visiting professor at Stanford Universit in academic year 1966–67, and at the Institut for Research on Poverty at the University c Wisconsin-Madison, 1972–73.

His research emphasis has been on prob lems of regional and national economic deve opment, the economics of human resource: and public policy for agriculture. Of his fou books and over 200 national journal article and published papers, perhaps the best know are *Foundations of Farm Policy* and *Micro politan Development*, the latter coauthore with George Br. kman.

He has taught c rses in research metho ology, mathematical economics, rural deve opment, and farm policy. He is a member six professional societies and three honora fraternities.

In 1964, he was granted an award by tl American Farm Economics Association to a

tend the international meeting of agricultural economists at Lyon, France. In 1970, he received the Distinguished Alumni Award from Waldorf College in Forest City, Iowa. He received the award for "outstanding published research" from the Western Agricultural Economics Association in 1972. He was major advisor to graduate students who won the award for "best thesis" given by the AAEA in 1970 and in 1975. Tweeten has been called to serve as an expert witness before congressional committees numerous times.

He is married to the former Eloyce Hugelen, and they have four children.

Macroeconomics in Crisis: Agriculture in an Underachieving Economy

,uther G. Tweeten

'he American economy performs like an auto ngine whose radiator is choked with lime de-osits. Some time ago, it was discovered that dding generous amounts of tap water to the adiator permitted high power output without ›verheating. As the years went by, however, ime deposited in the radiator by the tap water educed cooling capacity—tap water had to be dded continuously for adequate engine per-ormance even under normal loads on level ighways. Deposits finally built to the point /here nearly all agree that something has to be one to restore power to this basically sound, ut occluded, engine. One recommendation is ɔ use a high pressure radiator cap for increas-ıg engine performance without continually dding water. But the concern is that some-hing will burst under the pressure. Another ecommendation is to remove the radiator and ook out the lime deposits. The drawback is ›rotracted engine downtime.

These are basically the dilemmas and op-ions facing macroeconomic policy today. Per-ormance of the economy as apparent in high ıflation and unemployment rates, in slow real rowth, and in a weak dollar in international xchange has reached crisis proportions. :conomists and the public are convinced the conomy is capable of better performance, but ıere is no concensus about how to restore igor to the underachieving economy.

My thesis is that misguided macroeconomic ıeory and practice have created a chronically nderachieving national economy. Just as the conomic debilitation wrought by misguided ›olicies has been slow to emerge, it will be low to dissipate. The underachieving econ-›my is a degenerative malaise transcending he current recession. The economy will be slow to respond to remedial policies because underachievement is rooted in attitudes and institutions which change slowly.

The underachieving macroeconomy is the single most important characteristic of the economic environment facing agriculture in the 1980s. I briefly review evidence of the crisis and the contribution of macroeconomic theory and practice to the crisis. I then exam-ine two directions macroeconomic policy could take to begin to restore health to the economy. A principal objective of the paper, dealt with in the final sections, is to trace im-plications to the farming industry of (*a*) an underachieving national economy in the 1980s, and (*b*) alternative policies likely to be pursued to restore economic vitality.

The Gathering Crisis

The crisis in macroeconomics is evident in fact and logic. Society seeks equity and efficiency from an economic system. The dis-tribution of income in the United States has remained remarkably stable since World War II, and we look to measures of efficiency such as productivity and per capita income for signs of economic progress. The following indi-cators reveal deteriorating national perfor-mance since the 1960s:

	1960s	1970s	1979
	(annual average, %)		
Unemployment rate	4.8	6.2	5.8
Inflation rate in CPI	2.2	6.5	13.3
Labor productivity rate (increase in output per hour in the private business sector)	2.8	1.3	−1.0
Real income growth rate (increase in real disposable personal income per capita)	2.7	2.2	−1.0

(Source: Council of Economic Advisors, pp. 229, 237, 246, 259.)

Average rates of unemployment in the 6%

'resident's address.

Luther G. Tweeten is Regents Professor, Department of Ag-ricultural Economics, Oklahoma State University.

Journal article of the Oklahoma Agricultural Experiment Sta-tion.

Comments of Leo Blakley, Bruce Bullock, and Daryll Ray were helpful; the author bears sole responsibility for deficiencies herein.

range are hardly cause for approbation, but of principal concern is the high and accelerating rate of inflation coupled with slow and declining rates of growth in labor productivity and real income per capita.

Proximate causes of the economic slowdown are multiple: (*a*) rising energy costs because of OPEC price increases; (*b*) increased spending on pollution control, health, and safety; (*c*) entrance into labor force of inexperienced workers, especially youth, females, and minorities; (*d*) realignment in terms of international trade to correct for previously over-valued dollar; (*e*) shift from agriculture and manufacturing to service industries with low productivity growth; (*f*) depletion of natural resources including oil, iron ore, and soil; (*g*) increased tax burden of social security and other social programs; (*h*) rising minimum wage; (*i*) declining high payoff investment opportunities; and (*j*) low savings and investment rates.

Rising energy prices (*a*) are a convenient scapegoat for deteriorating performance but only two to three percentage points of the 13% increase in consumer prices in 1979 were attributed to OPEC price increases (Council of Economic Advisors, p. 162). The economies of Japan and West Germany, for example, are strong despite greater dependence than the United States on high-priced imported energy. Environmental programs have absorbed resources and are of value. If their value were included in conventional national accounting for output of goods and services, the performance of the economy might be raised from a grade of "fail" to "low pass." Entrance of inexperienced workers into the labor force and realignment in terms of trade also caused economic performance to falter. The important point, however, is that the retarding influence of items (*a*)–(*d*) has crested—these factors will arrest the growth rate less in the future than in the past.

Economic progress contains the seeds of its own slowdown, as shares of income-elastic but low-productivity-growth service industries become prominent relative to high-productivity-growth industries such as agriculture, and as natural resources become depleted. Elements (*e*) and (*f*) retard growth in the long run, are expected, and are not the basis for classifying the secular decline in growth as economic underachievement. They do not account for the poor performance of the United States relative to other advanced capitalistic economies that possess few natural resources.

Therefore, we turn to factors (*g*)–(*j*) fo sources of chronic economic underachieve ment. Sluggish investment and savings mea slow capital formation at a time when capita formation is desperately needed to buil energy-producing capacity, more jobs, an more output per worker. The savings rat dropped cyclically from 7.4% of disposabl personal income in the 1970–75 period to 3.3% in late 1979 (Council of Economic Advisors p. 228), but for decades propensities to sav and invest have not declined secularly in thi country. I regard no increase in such propen sities as underachievement in a society ex periencing a growing surplus of production i excess of basic needs, increasing depreciatio of capital stock, and keen competition fron abroad. Propensities to save and invest ar low in relation to those of other advanced in dustrialized countries.

Average annual plant and equipment in vestment increased only 2.6% annually in rea terms 1968–78, compared to 6.2% annually i the previous decade. Capital investment i manufacturing as a percentage of gros domestic product 1960–76 averaged only 9.1% in the United States, compared to 28.8% i Japan, 15.9% in West Germany, 14.7% i Canada, and 13.5% in the United Kingdon (Committee for Economic Development, p 3).

The United States invests a smaller share o national income in research and developmen than other leading industrial nations, and pat ent application rates are falling. Excess-profit taxes, government regulations, and othe forces frequently direct investment into ven tures with low social rates of return or dis courage investment in ventures with high so cial rates of return. Investment level and profitability cannot be separated; i.e., the lack of profitable and productive capital investmen opportunities reduces the magnitude of sav ings and investment. Ruttan (p. 896) stresse the interaction among growth-inhibiting ele ments, noting that inflation reduces growth i labor productivity. Finally, it is well to not that growth dividends from unleashing factor (*a*)–(*d*) will be absorbed by demands for capi tal to meet needs for energy, social welfare fo an aging population, and national defense.

Disenchantment with Neo-Keynesian Macroeconomic Theory

Disappointing levels of saving, investment, efficiency, and hence of economic progress,

ive roots in the neo-Keynesian (NK) macro-conomic paradigm that has guided this nation r over three decades. Neo-Keynesian eco-omics holds to Keynesian precepts of a hort-run equilibrium at less than full em-oyment, capacity for short-run tradeoffs be-veen unemployment and inflation, and for a overnment role in monetary-fiscal policy to imulate aggregate demand in depressions id severe recessions when planned savings ceed planned investment. But NK econom-s adds to these Keynesian precepts the opositions that advanced capitalistic nations e chronically prone to (*a*) high unemploy-ent, (*b*) economic instability, and (*c*) increas-g concentration of resources and wealth. he underlying causes of these three phenom-a include unpredictable "animal spirits" at shift nationwide spending moods from otimism to pessimism, and big business that ploits labor and the consumer—tendencies hich must be countervailed by perennial onetary-fiscal stimulation of aggregate de-and, by social legislation to redistribute ealth and protect the worker and consumer, id by formation of politicoeconomic collec-ves to promote economic democracy through paternalistic government.

The neo-Keynesian economic paradigm de-rves much blame for an underachieving na-onal economy. Shortcomings of the NK par-ligm discussed in the next section call for w directions in macroeconomic theory and actice. But neither economists nor the pub- agree whether the call is to the right or to e left.

ost-Keynesian Macroeconomics

ost-Keynesian economists are united in eir disenchantment with neo-Keynesian acroeconomics. Their critique and prescrip-on for a new paradigm vary widely as appar-nt below.

ight-Wing Macroeconomics

ight-wing post-Keynesian macroeconomics, nlike left-wing post-Keynesian macroeco-omics to be discussed later, acknowledges tle debt to Keynes, although many right-ving adherents concede that Keynesian eco-omics is applicable to a depression. Right-ving macroeconomics contains several ranches including natural rate and rational xpectations schools—largely monetarist in orientation, and a supply-side school—largely neoclassical in orientation.

Natural rate and rational expectation economics. In Keynes' statement that "It is probable that the general level of prices will not rise very much as output increases, so long as there are available efficient unemployed resources of every type" (p. 300), he recognized the trade-off between unemployment and inflation. Following quantification of the relationship by Phillips, the notion that it was possible to sustain low levels of unemployment by tolerating inflation became widely accepted.

Protests to the position emerged, however. The case began to build that workers, given time, react to real rather than money wages (cf. Dernburg and McDougall, pp. 283–5, 393; Morley). The long-term Phillips curve was perceived as vertical at the natural rate of unemployment. The long-term aggregate supply of national output was viewed as vertical, or even sloping upward to the left as a function of the inflated general price level. To be sure, monetary-fiscal stimulus raises nominal demand for national output, and the resulting rise in the general price level induces workers and other suppliers to increase output. But suppliers discover that the increase in the demand price is mostly nominal, not real, and increase their supply price for a given output. The resulting higher nominal aggregate supply curve intersects the nominal demand curve at a higher general price level but approximately at the former equilibrium quantity Q. The economy tends to overreact and temporarily moves to a lower output than Q. Termination of the monetary-fiscal stimulus may return both the price level and output to the initial level but not without substantial trauma in the form of high unemployment and underutilized capacity until equilibrium at Q, the natural or equilibrum output, is restored. This inflation cycle of expansion and stabilization behaves much like the traditional business cycle. (See Morley for an extended discussion.)

The rational expectations hypothesis, originally associated with Muth and applied broadly to macroeconomics by Lucas and Sargent, as well as by others, holds that decision makers adjust expectations for the impact of public policy so as to remove systematic error in their predictions. In the case of stimulation of aggregate demand by fiscal-monetary policy, decision makers learn to anticipate that the initial increase in the marginal value product of labor and in aggregate demand is

pecuniary and will be attended by an upward shift in nominal wage demand by workers and in aggregate nominal supply. After the learning experience of first increasing and then decreasing output in response to monetary-fiscal stimulus before reaching a new equilibrium at a higher general price level but at the natural rate of output Q, suppliers learn to shift nominal supply upward at the same rate as nominal demand. This short-circuits real impacts of monetary-fiscal stimulus and real output holds at Q. Monetary policy loses its intended impact; real demand and supply, output, and employment are unchanged by public policy, whatever the inflation rate. Although unanticipated policies have real impacts, they are not useful government policy because their impact, if repeated, is anticipated and hence solely pecuniary.

Those who have witnessed farm commodity cycles repeated for decades are skeptical about the rational expectations hypothesis. Nevertheless, a learning process occurs with successive stimulation of aggregate demand, which in turn generates the inflation cycle. This cycle of expansion and contraction in output under the natural rate hypothesis becomes less pronounced as learning proceeds—behavior consistent with the rational expectations hypothesis.

Supply-side economics. The nation blundered into the Great Depression blindly following Say's Law that supply creates its own demand; the nation blundered into stagflation by blindly following Keynes' Law that demand creates its own supply. Many students first encountered economics defined as the science of allocating scarce means among unlimited wants to satisfy those wants as fully as possible. NK macroeconomics would allocate limited wants among unlimiting means to utilize those means as fully as possible. Except in the short run, the concept of limited wants and unlimited means fails to square with even casual observation of reality.

In the traditional Keynesian model, another dollar of investment or government spending adds $1/s$ dollars to income, where s is the marginal propensity to save. As s approaches zero, the multiplier approaches infinity. Small doses of autonomous investment are required to boost national income in an economy where s is small. To make the economy responsive to stimulative policies by making s small, spending became a virtue and thrift a vice. The allure of the "free lunch" and the sanctioning of massive government spending to stimula demand through consumption, as opposed stimulating supply through investment (whic requires deferred gratification), made ne Keynesian remedies irresistible. The prope sity to save s could be made small, for exam ple, by making social security universal an financed by taxes rather than by actuarial sound investments. The problem is that as becomes small, all is consumed that is pr duced and growth comes only as inflated, n real, dollars.

Sobering vignettes from economic theo emphasize the importance of supply-side ec nomics. The Harrod-Domar tautolog showed that the rate of growth of real income was a product of the output-capital rat (efficiency) g and the propensity to save s, i.e $r = gs$. This conclusion that a high rate savings is associated with a high real rate economic growth is contrary to the NK mod and received little attention from ma roeconomic textbooks, politicians, and th public because it called for a return to deferre gratification and the dismal science of ec nomic scarcity.

Supply-side economics recognizes that u used capacity and unemployment will b present in a "full employment" economy. A issue is whether the unutilized capacity profitable to operate at the margin. In keepin with neoclassical theory, supply-side econon ics emphasizes the importance of examinin whether it pays employers to hire unemploye workers and whether workers hired und public employment or other NK-type pr grams contribute more to real output tha would alternative uses of the resources.

Neo-Keynesian prescriptions have stru tural impacts on supply. Persistence Keynesian prescriptions slowly alters institu tions and attitudes in a manner that robs th market economy of savings, investmen flexibility, and other features critical for ec nomic progress. Firms in an atomistic, com petitive industry find it difficult to pass inflate costs to other industries and consumer Firms possessing much bargaining power in highly concentrated industry and laborers i powerful trade unions can more readily pa on costs to the next link in the market chai Minimum wage laws, unemployment insu ance, collective bargaining legislation, an other measures established by government t provide built-in economic stabilizers fc aggregate demand also provide a framework c

nabling-legislation for growth of monopoly in ie form of big labor and big business which se market power to pass rising costs to conumers.

But even General Motors cannot pass all osts to consumers because of competition om foreign firms. In world perspective, ajor U.S. industries are in many cases omistically competitive, and scope for onopolistic exploitation is limited without ollusion of government in the form of trade arriers. Major American industries have lost heir world dominance partly because of eo-Keynesian macroeconomics. In part beause of the growth of organized labor and its emonstration effect on other workers, and in art because major U.S. industries operate in highly competitive world market where risg labor costs cannot be passed to consumrs, labor has increased its share of firm reeipts. The result is less investment in capital increase worker productivity and expand bs. Federal double-taxation of corporate rofits and allowance for depreciation at less an replacement costs further erodes capital rmation in an inflationary economy.

Special interest politics has played a role in tting "full employment" targets that cannot sustained because of intolerable inflation. mphasis on raising aggregate demand by imulating consumption has attracted a host political special interest groups to share vernment largess. Government has become e politics of distribution. The distribution s been to those possessing political power d not necessarily to the poor or disadvanged. Critics argue that economic democracy ks government to perform far more than it s capacity to deliver. Before goods can be stributed, they must be produced.

Right-wing charges of neo-Keynesian conbutions to an underachieving economy go , but more positive dimensions of right-wing onomics exist. The right-wing argues it is in ne with wants of people for personal freem while at the same time funneling the selfterest of impersonal man to serve the public terest through the invisible hand of the comtitive market. Right-wing economists point the economic success of the essentially free nterprise economies of Singapore, Hong ong, Taiwan, and, prior to recent times, the nited States.

American agriculture of today provides one the best sector examples of the right-wing odel. The competitive farming industry plows back 30% of its income into capital investment, whereas the nation as a whole invests about 10% of national income. Farm labor productivity perennially increases at approximately 6% annually, while nonfarm labor productivity has stagnated. Farmers account for only 3% of national income but supply over one-fifth of all exports. Farming industry performance is unparalleled for contributing to low domestic food costs, export earnings, and redistribution of income from high income to low income consumers and taxpayers.

Left-Wing Macroeconomics

Left-wing post-Keynesian economists subscribe to no common paradigm (see Croity and other articles in the series). However, leftwing macroeconomists more or less accept the Keynesian and neo-Keynesian precepts and prescriptions listed in the previous section. In mildest form, left-wing macroeconomics merely adds to these the need for a "high pressure cap on the overheated radiator" in the form of wage and price controls. More extreme forms of left-wing macroeconomics call for government ownership of industry and a centrally planned economy.

History provides compelling evidence that large, complex economies cannot be centrally planned and administered with acceptable levels of efficiency, that price and wage controls are unworkable in all but the short run, and that socialized industry rarely operates as efficiently as private industry.

More workable are alternative forms of left-wing macroeconomics that reject both the neo-Keynesian ideology of monetary-fiscal pump priming for all seasons and the conspiratoral views of industry exploiting labor. In the successful economies of West Germany, Japan, Sweden, and Norway, government plays a major, paternalistic role in managing (but not centrally planning) the economy, reconciling labor-management conflicts, and redistributing wealth. Labor and industry cartels are allowed, even encouraged. Industry and labor are concentrated into so few entities and each has such a large impact on the nation that each holds itself (or is held) accountable to the public at large for its price and wage actions. National priorities for wages, output, and prices are worked out in negotiations among industry, labor, and government. Cooperation among these public and

private power centers is also commonplace in research and development of new products and markets as well as other endeavors not well suited to private investment alone because of risk, externalities, and economies of size. Such managed economies seem to perform well only in countries characterized by a highly industrious labor force in an atmosphere of mutual trust between labor and management. Applying the above left-wing strategy to the United States is fraught with peril because powerful collectives would be formed which could go dangerously out of control in a heterogenous nation with the tradition of an adversary relationship between labor and management.

The Untenable Middle Ground

The most notable distinction between successful economies of the right and left is whether they use competition or other forces to channel self-interest to serve the public interest—each type of successful economy exercises monetary-fiscal restraint and control over special interest groups. The latter probably makes possible the former; this is, control of economic collectives restrains cost-price inflation, and control of political collectives restrains demand-pull inflation.

The U.S. economy is in an unstable position between the left and right models. Its political and economic collectives are large enough to aggrandize themselves at the expense of the general public but small enough to escape accountability. Because the United States gets the worst of both worlds, economic performance can improve by moving toward the best of either the right-wing or left-wing post-Keynesian economic models.

Neo-Keynesian economics has become something of a drug habit which, despite failure to produce highs anymore, is difficult to foresake because of traumatic withdrawal symptoms. Large numbers of people and the politicians who represent them have a stake in continuing the "habit" despite the counsel of post-Keynesian economists. Even in the unlikely event of a sharp turnaway from neo-Keynesian prescriptions, the legacy of high inflation and unemployment, slow real income growth, and/or a weak dollar likely will persist through the 1980s. At issue is how an underachieving economy and a left or right turn in macroeconomics will affect the farming indu try.

Implications for the Farming Industry

Once farmers prospered under national boor because of a relatively high income elastici of domestic food demand and easy credit a sociated with business expansion. No domestic demand is of lesser importance- nearly three-fourths of the growth in demar for farm output comes from foreign market Once a strong labor market in the metropol was required to absorb excess farm labor; no there is little excess farm labor. (Gardner [14] found that local off-farm earnings so cri cal to farmers are not highly sensitive to n tional business conditions.) Once farming i dustry economic fortunes were tied to produ markets as influenced by business cycles; no such fortunes are more closely tied to inp prices as influenced by government-induce inflation cycles.

Some effects on the farm sector of an u derachieving economy are clearly unfavorabl others are favorable. Direct effects of a turn the right or left in macroeconomic theory ar policy may be massive, but whether they w be favorable or unfavorable in the short run not easily predicted.

Favorable Impacts of an Underachieving Economy

Favorable impacts for the farming indust include a faster rate of growth in export d mand, more elastic total demand, and less d mand for structural changes.

While growth in demand for some far products, such as beef with a relatively hig income elasticity of demand, will be slowe on the whole the response of farm output d mand to real income is now too low to be major concern. Of greater importance is th weak dollar, making our farm products a ba gain in world markets, and causing exports be the major source of the growth in demand As the major efficient sector of the econom where productivity has been kept high ar comparative advantage intact, the farming i dustry by virtue of its export position stands gain from mismanagement of the economy.

The fast-growing foreign demand for farm ıtput coupled with a slow-growing domestic conomy may turn the dynamic farming indusy into a growth industry—it may grow faster an industry as a whole in the 1980s. The rming industry may contribute a larger share national income in 1990 than in 1980.

Up to three-fourths of the growth in demand r farm output is expected to be from foreign urces in the 1980s compared with half in the 60s. The growing weight of exports in deand for farm output from 15% in 1965, to % in 1979, implies a 50% increase (from −.4 −.6) in total elasticity of output demand suming a domestic price elasticity of −.2 d a foreign elasticity of −1.5 in each year. Growing farm exports coupled with highly astic domestic alcohol fuel outlets for farm mmodities tend to make total demand for m output at "floor" prices less inelastic in e short run and elastic in the long run. The plication of stronger and more elastic deand for farm output is reduced need for govment loan, deficiency payment, and proction control programs to support the level farm product prices and incomes. Such poles would be in keeping with the market entation of right-wing post-Keynesian economics. Commodity reserve programs to bilize markets may become more important cause of growing but highly volatile export rkets.

Farms needed to grow in size at the real rate 5% annually in the past three decades in ponse to technology and the opportunity st of labor. Real nonfarm income per capita wing at (say) 1% per year rather than 3% ves two percentage points off the required wth in the scale of farm firms to "keep up h the Joneses." If labor-saving technology also forthcoming at a slower rate in an unachieving economy, farmers will get a welne breather from the adjustment treadmill the 1980s.

favorable Impacts of an Underachieving onomy

e principal unfavorable impact on the farm nomy of an underachieving nonfarm economy comes from inflation as (*a*) factor markets pond more quickly and fully to national ation than product markets, causing a t-price squeeze, and (*b*) immediate costs of land purchases rise whereas returns are deferred, causing a cash-flow squeeze.

Cost-price impact. In the 1980s, national inflation clouds optimism for rising real prices received by farmers from my projection that farm output demand growth will exceed supply growth rate due to productivity. Farmers have no immediate means to pass inflated input prices to the next link in the production-marketing chain as can imperfectly competitive input supply and product-marketing firms.

In a recent study (1980a) I found that for the 1963–77 period, inflation pass-through is complete in one year from retail food demand down to the farm level—each 1% increase in the general price level is associated with a 1% increase in nominal demand at the farm level. The situation is more complex on the supply side. Each 1% increase in the general price level is associated with an approximate 1.4% increase in prices paid by farmers, shifting the long-run nominal supply curve for farm output upward by 1.4%. Short-run inflation pass-through averaged 70% in the 1963–77 period; that is, each 1% increase in prices paid by farmers caused by inflation was associated with only a 1 ÷ 1.4 = .7% increase in prices received by farmers. Farmers restrain input use and output until eventually their buying power is restored in a pattern depicted by Tweeten and Griffin.

Cash-flow impact. Judging by net income per farm from all sources, by net worth per farm, by rates of return on farm equity capital versus returns elsewhere, and by firm failure rates, commercial farmers have on the average enjoyed robust financial health since 1960 (Tweeten 1979, pp. 53–61). However, the favorable average indices of the farming industry poorly reflect the situation faced by beginning or expanding family farms experiencing inflation-caused cash-flow problems.

Durable assets, principally real estate, interacting with inflation are the source of the cash-flow problem. The conceptual framework developed elsewhere (Tweeten 1980b) begins with the formula for the present value of an acre of farmland P_o:

$$(1) \qquad P_o = \int_{t=0}^{\infty} \frac{R_o e^{(i + i' + \epsilon)t}}{e^{(\alpha + i)t}}\, dt = \frac{R_o}{\alpha - i' - \epsilon},$$

where R_0 is after-tax net rent per acre in the initial period 0, i' is the before-tax real rate of increase in rents, i is the rate of national inflation, α is the desired real rate of return on land, ϵ is the rate of increase in net rent due to the tax advantage on farmland versus that on alternative investments, e is the base of natural logarithms, and time t goes from the initial period 0 to infinity. The discount rate (nominal total rate of return) is $\alpha + i$. In a well-functioning market, the capitalized present market value of an acre of farmland is $R_0/\alpha - i' - \epsilon$, the current rate of return on investment in farmland is $\alpha - i' - \epsilon$, and land rents and values increase at the rate $i + i' + \epsilon$.

Conceptual and empirical considerations of the model provide additional insights:

(*a*) The value of ϵ is so small at inflation rates likely for the 1980s that it will have a minor impact on land rents and returns; hence ϵ is ignored below (Tweeten 1980c).

(*b*) If rents are expected to increase exactly at the inflation rate ($i' = 0$), then land is capitalized at the desired real rate of return α and the initial and continuing current return on land is α. This principle constitutes the foundation for the cash-flow problem engendered by inflation, i.e., the current rate of return on farmland is invariant to the inflation rate! If $\alpha = .04$, or 4%, the land price is twenty-five times net rent, and the current return on land is 4% of the inflation rate. The long-term mortgage interest rate is the real rate of interest plus the inflation rate, hence inflation defers returns and inflates immediate costs. If inflation is 9% per year, nominal capital gain is 9%, which, together with the current return of 4%, brings total return to 13% per year. However, the real return is only 4% per year because the inflation in land values and rents does not add to buying power.

The mortgage interest rate is the real rate of interest, approximately 3%, plus the inflation rate i. An inflation of 9% means a mortgage interest rate of 12% which, coupled with current returns of 4%, leaves a cash flow deficit of $12 - 4 = 8\%$ of farmland value under a perpetual mortgage. In contrast, in the absence of inflation, the current return of 4% and mortgage interest of 3% leaves a cash flow surplus of 1%, excluding principal payments.

(*c*) Expected real increases in land rents ($i' > 0$) change the capitalization rate and current return on land to $\alpha - i'$, whatever the value of i and with farmland taxed at the same rate as alternative investments in response t inflation. If the desired real rate of return o land is = .04, or 4%, if land rents are expecte pected to increase at a real rate of $i' = .02$, 2% per year, and if land returns are taxed the same rate as returns from other inves ments, then land price is fifty times rent ar the initial rate of return on land is 2%. Usi Melichar's terminology (p. 109), farmland b comes a "growth stock" when $i' > 0$ and re capital gain accrues at the rate i'. If inflation 9% annually and with the above parameter the nominal capital gain is 9%, real capital ga 2%, and current return 2%, for a total annu return of 13%. Again, real return is only 4% percentage points each of current earnings ar real capital gain) because the 9% capital ga induced by inflation represents no increase buying power of land. With a 2% current r turn and 12% mortgage interest rate, the cas flow deficit is 10% of land price with a pe petual mortgage. Thus the tendency for farn land to become a growth stock in an unde achieving economy exacerbates the cash-flo problem.

For the beginning full-time owner-operato with limited potential to generate cash flov land is clearly "overpriced" with 9% inflatioı Operator-family labor-management returr are not expected to exceed 2% of land value in the 1980s, hence applying the entire amoui (if that were possible) to pay the intere would still leave a large cash-flow deficit wi 9% inflation. Principal payments only add t the cash-flow problem. Tenancy, off-far employment, and special assistance from pa ents and other concessional sources are var ous means operators use to cope with th problem. Unless new financial strategie sound monetary-fiscal policies, and oth measures are found to deal with the cash-flo squeeze, the trend is likely to accelerate t ward farmland ownership and operation b part-time farmers, corporate conglomerate and established, wealthy commercial farmer

Increased ownership of farms by these la ter groups conflicts with the traditional fami farm concept. Coupled with high overall cap tal requirements for an economic farming un the cash-flow squeeze has gone far to redu the farming industry to a landed class wherel the only family farmers who can become e tablished in farming are sons and daughters established farmers.

Fixed long-term interest rates inject u

cessary risk into the credit market, which uld cause severe financial hardship to rmer-debtors with the deflation that would llow a return to sound monetary-fiscal pol- y. Because the equity ratio is high in farming d because much of the current long-term bt was not incurred at high mortgage in- rest rates, it seems imprudent to continue o-Keynesian economics on the grounds that he only thing worse for farmers than flation is deflation." Indexed interest rates e one means to reduce risk to debtors and editors as monetary-fiscal policies change.

rving the Threatened Mid-Size imily Farm

any agricultural economists committed to rve the public interest have perceived farm- s to be a disadvantaged and oppressed class. here the interests of the farmer conflicted ith those of the public at large, it was easy to de with the farmer. The world is no longer at simple.

Cost-price difficulties will continue and ckets of low income farming will remain; t on the whole, cash-flow problems will rce ownership of farming sector assets into e hands of the financially strong. Per capita ealth will be considerably higher in the farm ctor than in the nonfarm sector.

Tweeten, Cilley, and Popoola show that the mposition of small farms, where low income oblems have been acute, will experience a arp turnaround. Once by far the largest cat- ory of small farms, those operated by full- ne, able-bodied persons will be compara- ely few in numbers by the mid-1980s. The tal number of small farms probably will gin to grow because of rising numbers of rt-time and/or aged operators. Part-time rmers are for the most part not a welfare oblem, and the aged are best helped by wel- e programs. Because these farmers produce little and are hard to reach, neither of the ter groups is a prime candidate for utilizing arger share of scarce agricultural research d extension resources.

Publicly supported agricultural research and tension needs to focus especially on the d-size family farms with sales of $20,000 to 00,000, that can be operated efficiently but e threatened by cash-flow and cost-price essures of neo-Keynesian economics (Tweeten 1979, pp. 70–75). These farms are less able to handle cash-flow problems than (*a*) small farms which receive large shares of in- come from off-farm sources and (*b*) large farms with access to diversified sources of earnings as well as equity and debt capital. Public research and extension will need to play a key role in improving efficiency (through improved technology, information, etc.) and financial management critical to for- mation and survival of moderate-size farms.

Impacts of a Shift in Economic Policy

The tide of political economy for the farming industry will drift with the tide of political economy for the nation. A turn to right-wing, post-Keynesian macroeconomics will mean an even greater market orientation for agricul- ture, with the government role restricted largely to correcting market imperfections, e.g., aligning private and social costs (ben- efits). The result could be continuation of conservation, information, and stability pro- grams such as the farmer-held reserve. But farm prices and incomes might not be sup- ported directly, farm import curbs might be eliminated and farm cooperative antitrust preferences might be withdrawn. The fate of public research and extension is enigmatic: would emphasis on supply-side economics bring greater outlays for public agricultural re- search and extension to substitute for higher- cost conventional sources of output? Or would a right-wing political economy be dominated by an overriding concern for cut- ting public spending? Outlays for public ag- ricultural research and extension could go up or down depending on the balance of these "substitution" and "income" effects.

The fate of tax policies is also enigmatic. Right-wing policies in general will result in lower income and estate taxes, which could favor growth in large, established farms. The resulting concentration of production in a few large farms may not be viewed with alarm if consistent with efficiency—such farms will be too numerous to form cartels and they will not be provided with enabling legislation in the form of market orders to facilitate collusion.

Pursuit of the left-wing model could bring all agricultural workers into a trade union. Ex- tension of marketing orders and the National Labor Relations Act to the entire farm sector

could set the stage for commodity-wide, perhaps nation-wide, collective bargaining over commodity prices and output. Farm cartels would not be allowed to set prices at will. The farming industry could become a giant public utility with wage and price changes worked out in negotiations with government and consumer. A milder scenario merely would continue current commodity programs but with more generous price and income supports. The left wing would place much more emphasis than the right wing on preserving a large number of farms through a structure policy including special tax advantages for small and entry level farms coupled with tax penalties against large agribusiness corporations.

Implications for Economic Theory

Scarcity is divisive and an underachieving economy exacerbates scarcity. An underachieving economy needs economics more and appreciates it less than does an achieving economy.

Kuhn lists two ingredients for a scientific revolution: a crisis in the old paradigm and availability of a superior replacement. Rates of unemployment and inflation near double-digit levels signal a crisis in the old paradigm. No satisfactory paradigm awaits to replace the existing economic theory. The most successful left-wing economies do not use price controls but exercise restrained monetary-fiscal policy in conjunction with a sociopolitical strategy of concentrated but accountable labor and industry power. The conceptual framework is not new but avoids excesses of neo-Keynesian macroeconomics. On the other hand, the right-wing model calls for a return to traditional neoclassical marginal economics, the classical quantity theory of money, and Jeffersonian democracy. The neoclassical competitive model has experienced a renaissance but not necessarily for its predictive value.

Rebirth of Neoclassical Theory of Pure Competition for Prescriptive Purposes

Right-wing post-Keynesian economics is especially difficult to relate to the public because it emphasizes deferred gratification and efficient sources of additional output rather than stimulation of demand with transfer pa ments for consumption. It is indeed "people" program, but benefits to people a less direct and often deferred as compared left-wing policies. Stress on efficiency oft concentrates wealth; the needs of the po remain, and the equity-efficiency quandry intensified as the pace of economic grow quickens. If the re-emerging neoclassical co petitive paradigm appears to be an anac ronism unable to deal with economic equit it is because our economics has been t small. Excessive emphasis has been placed prediction and Pareto-optimum efficienc The competitive model has much to say abo welfare maximization that economists ha been too timid to voice.

Since Friedman's *Essays on Positive Ec nomics*, it has been fashionable to regard theory as useful to the extent that it predic reality. Assumptions are of secondary impo tance. Students frequently protest neoclass cal competitive theory on that basis, sayi the model neither resembles nor predicts t real world. With modifications (to include t cost of time, risk, and information) the ne classical competitive model does predict re sonably well, but the competitive model is n critical for prediction—it is easily suppl mented and amended to include behavior and other elements of reality. (Whereas so reject the competitive model because it do not resemble the real world, others make t opposite mistake of equating a free mark with perfect competition.)

The most underutilized value of competiti theory is for prescription, as opposed to pr diction. Here the perspective is the reverse Friedman's: for prescription, usefulness of t competitive model lies in the fact that it do not resemble or predict the real but is a no for an allocation to improve well-being people. A device to detect automobile engi malfunction would be of no value if all engin functioned as predicted by their design specifications. Similarly, the competiti model is useful to diagnose inefficiency (le utility than possible from means availabl precisely because the real world does not r semble the competitive allocation. It is esse tial here to distinguish between pure (or pe fect) competition as a set of assumptions an pure competition as an allocation of resourc and commodities. In measuring social co and performance, the allocation of pure co

tition rather than the adherence to assump- ıns (e.g., many buyers and sellers) is impor- ıt. The competitive model is a tautology ıose marginal conditions and allocations ıst hold in a barter, socialist, or market onomy which prizes above all the well-being its people!

In short, Friedman's position that the test of theory is its ability to predict the real ›rld—assumptions are of secondary impor- ıce—is turned upside down. In prescriptive ; of theory, market concentration, degree of owledge, mobility of resources, and other ;umptions are hypotheses useful to judge portunities to improve allocations. Even t-wing cynics, who see nothing resembling re competition in the real world and who ll for enlarged collectives to exercise bar- ining power in all sectors, measure the in- iciency of economic systems by the rdstick of pure competition. But the com- titive model is not carried far enough. To ow that imperfect competition in the food- ırketing sector results in excess costs of $x lion is incomplete without examining costs reducing such inefficiency with alternatives ch as atomistic competition, cooperatives, government performing the food-marketing ıction.

ward Resolving the Equity-Efficiency 'andry

most serious shortcoming of the competi- e norm is that it is only a Pareto optimum, a sition from which one cannot be made bet- off without making someone else worse . A Pareto optimum can exist between two lividuals while one is starving and another is ed with goods and services. It is fashion- e for economists to recommend improve- nts in efficiency that make the sated indi- lual even better off, arguing that the issue of ııty should be left to radical social scientists l revolutionaries. That is precisely what has ppened too often, with tragic consequences. dical social scientists and revolutionaries have as if efficiency does not matter, ignore ; impact of redistribution on efficiency, and ıdvertantly invite trauma exceeding pre- /olution miseries. On the other hand, sitivistic economists often become hostages the status quo, behave as if distribution es not matter, and ignore concentrations of :alth that are setting the world aflame with social unrest. To ignore the equity dimension of economics is to ignore much of economics that is important in today's world. The neo-classical competitive economic paradigm has been labeled a tool of the "haves" to oppress the "have nots," legitimatizing inequality and encouraging increasing concentration of wealth. It need not be.

Neoclassical economics is robust enough to handle the conceptual and empirical modifications needed to specify an optimal distribution of resources that recognizes the utility-maximizing trade-off between equity and efficiency. What is required are measures of the marginal utilities of income and resources for groups of people. In a pilot study, Harper and I showed that intergroup (though not necessarily interpersonal) utility can be measured for policy purposes employing attitudinal scales and test instruments widely used and accepted by other sciences such as psychology and sociology. Positivistic economists have for the most part rejected such estimation to depict equity-efficiency trade-offs as subjective and value-loaded. Yet, the value judgments of the "positive" economists (that the marginal utility of income is constant and equal for all, and hence the distribution of income is of no concern) seem even more imprecise, subjective, and value-loaded.

Some express concern that economic prescriptions showing allocations of resources that would maximize utilities would be a threat to politicians, replacing their role of interpreting social welfare functions. That is unfair. The appropriate and positivistic procedure is to lay before politicians alternatives derived as objectively as possible: one (say) which increases income, another which decreases unemployment, and a third which increases utility. The politician is then free to choose among alternatives based on the trade-offs between serving his narrow constituency (perhaps of special interests) versus the public at large. The need to study equity-efficiency trade-offs is not restricted to left- or right-wing schools of economics; rather, such study can bridge some of the gaps between schools emerging from different perceptions of importance of equity relative to efficiency.

Summary and Conclusions

Neo-Keynesian macroeconomic theory and practice have helped to create an underachiev-

ing economy of crisis proportions. One road to the left from the current impasse calls for diminishing the labor-management conflict and for enhancing the concentration of power in labor and industry, while holding collectives accountable for acting in the public interest. One road to the right calls for reliance on competitive forces of the market to produce outcomes in the public interest. The United States is currently in an unstable situation between these extremes, with collectives too small to be held accountable for the nation's ills but large enough to aggrandize themselves at the expense of society. A move to the right or left that promises to restore economic vigor will come eventually, but an underachieving economy will continue to be manifest in the 1980s in the form of high unemployment and inflation rates, slow growth, and/or a weak dollar in international markets.

The underachieving economy and a turn to the right or left has strong implications for the farm sector. The backbone of the farming industry and the principal clientele of the land grant university, the moderate-size family farm is particularly threatened by the cash-flow and cost-price impacts of an underachieving economy. On the more optimistic side, the underachieving economy could change farming into a growth industry and increase the elasticity of demand to reduce the need for price supports and stabilization policies.

Farmers are reaping the bitter harvest of neo-Keynesian macroeconomic policy they did not consciously sow. They might well contemplate how to have a part in sowing the seed for the next harvest. Agriculturalists need to be as diligent in helping farmers choose a variety of macroeconomics as in helping them choose a variety of wheat. Farm organizations and spokesmen are powerful political forces, but for the most part they have not used their influence for constructive, consistent macroeconomic policy. The excesses of neo-Keynesian economics are not ultimately the fault of politicians but of citizens uninformed of the institutional requirements for operating a responsible economic system in a world where people and collectives pursue self-interests.

The economic structure of the farming industry in the long run will depend more on federal taxation, spending, money supply, and trade policies in the Federal Reserve System, the Internal Revenue Service, and Department of State than on commodity programs i the U.S. Department of Agriculture. Th "farm bloc," though less visible than befor still wields much influence in Washington. Be cause the future of the farming industry is s much influenced by sound monetary-fiscal po icy, it is well for farmers to turn some of the attention from traditional commodity pro grams to money supply, wage-earnings sup plements, measures to reduce labor-manage ment conflicts, and other macroeconomic is sues and policies so important to the economi well-being of the farming industry.

The Rise of Economic Power: Some Consequences and Policy Implications

A. C. Hoffman

The rise of economic power and its replacement of the Invisible Hand of Adam Smith as the regulator of economic activity is surely one of the most important developments of the century. Both within and without the profession there is growing concern about this. Despite this concern, it does not seem to me that there is as yet a general understanding of the direct relationship between economic power and the current condition of the economy. Nor has there been an in-depth investigation of the subject since the Temporary National Economic Committee (TNEC) of the 1930s.

In his presidential address to the American Economic Association in 1972, Galbraith took note of this deficiency. He suggested the need for a body of doctrine more appropriate for understanding and dealing with economic power than what has come down to us from Adam Smith. Clearly, neoclassical economics does not fill the bill.

When economists do address themselves to economic power (or monopoly—I shall use the terms interchangeably), their studies are usually limited to a particular product in a single relevant market; and they analyze its consequences in terms of prices, profits and output in the industry directly involved. There is nothing wrong with this and it is a needful thing to do, but economic power involves far more.

Inflation, unemployment, idle resources, an adverse balance of payments, an almost intolerable welfare burden—all are related in greater or less degree, and directly, to economic power. It would of course be a mistake to attribute all our woes to any single factor, even one as important as power; but the greater error is largely to ignore it and go chasing after lesser ones.

The Power Entities

Before going any further, perhaps we shoulc identify who some of the power entities are Big business and big labor are of course the two which come first to mind, but there are others, great and small.

Skeptics have long suspected that competition among small competitors in small markets may not be quite as perfect as we have imagined. Recently some enterprising fellow constructed a home-made index of the prices of goods and services charged by enterprisers in these small markets—I think he called it the "Knick-Knack" index—and, sure enough, it has been going up faster than the BLS index. I will not labor the point here, but neither should it be forgotten that economic power comes in small packages as well as large ones.

Among the big power entities is of course the government itself, which frequently uses its power to raise prices, restrict output, and restrain competition, just as big business and big labor are accused of doing. Those who do not understand the intricacies of agricultural economics sometimes point to the government's farm programs as examples of this. But there are others in these times who seek the exercise of governmental power in their behalf, and not always to the public good. The list of them is almost as long as the list of registered lobbyists in Washington.

It will be sufficient to our task here—I am afraid more than sufficient—to limit our discussion of economic power to big business and big labor. I bring no malice to the task. Quite the contrary, for many years I worked for big business. I believe it to be the cornerstone of the most productive economic system yet devised. And, as for rectitude and righteousness I think corporate bureaucrats will average about the same as government bureaucrats, or even college professors. As for organized labor, I think it represents one of the mos

---

Fellows address.

A. C. Hoffman is retired vice president, Kraft Foods Company, Chicago. His address is P.O. Box 347, Bull Shoals, Arkansas 72619.

onstructive forces we have for a more umane America, not only for labor, but for nderprivileged people generally.

The trouble comes when big business and ig labor take actions in their own behalf—ctions which are entirely legal and within the oundaries of accepted business practice but which may not be in the public interest. Adam mith solved this conflict-of-interest problem y assuming a competitive model in which no ne had any power. Despite Milton Friedman nd the Chicago School, I am afraid we can no onger thus assume it away.

'he Roots of Economic Power

Economic power has its roots in economic tructure, so we will begin here. For generaons, conventional wisdom about economic tructure has tolerated and even encouraged fundamental error, namely, that competition ; the normal state of a modern industrial conomy. It is not; big business and oligopoly re and for reasons it is no longer necessary to o into before this profession. In most sectors f American industry, small and mediumized firms are long since gone, and only a andful of big firms remain.

Nor is there any stability even in this situaion. Both by merger and internal growth, the emaining firms go right on trying to increase 1 size, in share of market, in doing everything n a bigger scale than the year before. They re spurred on in this by institutional investors who want to see growth in those companies whose stocks they hold, and by those gadflies f corporate performance, the security anaysts, who think largely in these terms.

Now there is nothing wrong in this, per se. ncreases in size and market share (other than y merger) usually come as a reward for sucessful performance in the market place, and nore frequently than not are associated with echnological progress and efficiency. The rouble is that the corporate technostructure, 1 doing its job successfully, tends to drive its veaker competitors to the wall. Chrysler is he latest example; but in greater or less deree, it is going on throughout American inustry, and no end is in sight.

I am among those who believe we may be earer than we think to plain, simple, one- or wo-firm monopoly in quite a few vital sectors f industry.

Of Price and Output under Oligopoly

I shall discuss the consequences of economic power mainly in terms of what, in older days, we used to call economic theory. Events did not always turn out the way the theory said they should, but I guess that is the way with economics.

It is something of an over-simplification, but the essence of price-making theory can be stated about as follows: In the competitive model, of which agriculture is the best example, prices tend to rise and fall with changes in demand, with supply tending at least in the short run to remain fairly constant. At the other extreme is monopoly, where the monopolist has the power to raise or lower his price and output to maximize his profit. In between is oligopoly, a sort of fuzzy area where price is indeterminate. But the general view was that even in the more concentrated areas, competition among a few firms was "workable" in the sense that it tended to produce a price/output closer to the competitive model than that of monopoly.

So what is happening in most sectors of American industry today? The *sine qua non* of monopoly power is the ability to raise prices and reduce output in the face of falling demand, and that is precisely what is happening in the industrial heartland of America today.

The theory of price making under oligopoly is crucial to understanding the performance of American industry, so let us take a walk back into history and see how it developed.

Among the first to perceive the revolutionary changes being wrought by the rise of big business were A. A. Berle and Gardiner Means, whose monumental work, *The Modern Corporation and Private Property*, appeared about fifty years ago. They clearly saw that price making in a large corporation was not only administratively determined but inherently restrictive in the sense that supply would be controlled to achieve the desired price. They gave us a name for it, "Administered Prices." Curiously enough, the book did not receive the attention it deserved from the 'mainstream' economists of the day, but it had a great impact outside the profession.

At about the same time another book appeared, Chamberlin's *Theory of Monopolistic Competition*. Like Berle and Means, Chamberlin clearly saw that the competitive model was no longer valid for many parts of the economy. However, his theory was largely

cast within the paradigms of neoclassical economics, and perhaps for this reason received greater professional attention.

In essence, Chamberlin's concept was that where small numbers of firms are involved (oligopoly), the outcome as to price and output is indeterminate as between that of competition and that of monopoly, depending on how each competitor anticipates and reacts to the moves of the others. It was a kind of game-theory thing, which led naturally to the conclusion that the greater number of competing firms, the harder it would be for each to anticipate the other's moves, and hence the nearer the outcome would approach that of the competitive model. This in turn led to the concept of "workable competition," which consoled a whole generation of economists and still comforts many.

We now know that Chamberlin was basically wrong, and that an oligopolistic industry will follow much the same policy as to price and output whether it is comprised of two firms or ten—and usually without either overt or covert collusion because none is needed. I do not want to overstate the case here. Common sense tells us that from a competitive standpoint, ten firms are better than two, but observation tells us, not by much.

Big Business and Big Labor: The Symbiotic Relationship

Of great concern and growing annoyance to the public are those power confrontations which take place between big business and big labor when it is time to renew a labor contract. Galbraith has called this a "mating dance," with, it might be added, the government standing by wringing its hands and urging the two parties to consummate so a strike can be avoided. The unions, having the power to withhold labor on an industry-wide basis, are usually in position to drive a pretty hard bargain; and the companies, having the power to pass along any wage increase, plus maybe a little something for themselves, are not inclined to offer great resistance. Anyway, since all the firms involved will end up paying the same wage rate for labor, the actual level of wages is not of overwhelming consequence to them. Now this is the basis of cost-push inflation—we call it the wage price spiral.

Nor is this the only consequence of the symbiotic relationship between big business and big labor. It is difficult to measure, but n less true, that it also contributes, and directly to unemployment and the welfare burden Ancient theory had it that productive re sources idled by the exercise of monopol power would find employment elsewhere—th old "Allocation of Resources" doctrine—bu the unemployment figures and the welfar rolls these days do not give much validity t this anymore.

I am well aware that many economists con tend that organized labor does not create un employment, and argue to the contrary tha high wages increase purchasing power an thus reduce it. As to this controversy, I can d no better than refer to the presidential addres of Robert Solow to the American Economi Association last December on the causes c unemployment. Solow quotes approvingl from that old master of neoclassical econom ics, Professor Pigou, as follows: "If there i 'thorough-going competition' among work ers, then the only possible equilibrium posi tion is at full employment." He goes on t quote Pigou regarding trade unions: "O course, these agencies [the trade unions] wil have no wish to set wage rates so high that hal the people in the country will be thrown out o work. Nevertheless, there is reason to believ they do not have regard to the demand condi tions [for labor] in such degree as would b necessary to secure, as thorough-going com petition would do, the establishment of ful employment" (p. 4). Professor Pigou's pros is appropriately solemn and obtuse, but hi meaning is clear.

Consider the following sequence of event in the steel industry. The steel industry i comprised of ten or a dozen firms (it is hard t keep track, there may have been a merger) an a union which does industry-wide bargaining Some months ago a new wage contract wa negotiated, which the union president de scribed as the most favorable the union ha ever received—this in an industry where wag rates were already among the highest in th economy.

At about the same time, the steel companie announced a price increase. As I recall, it wa their third within a year. Next came the inevi table follow-up that there would be a cutbac in steel production. The industry is operatin presently at about 50% of capacity.

Recently the companies and the union wer all down in Washington, trying to get the gov ernment to limit steel imports.

Several years ago Russia overtook the United States as the world's leading steel producer.

But some good may yet come out of this deplorable situation. Recently U.S. Steel permanently closed one of its plants in Youngstown, Ohio. Some of the former workers in the plant are trying to form a consortium to reopen the plant and operate it for their own account. They have asked the government for a loan, and have cited the Chrysler bail-out as a plausible reason why they ought to have one. The project probably will not get off the ground because this kind of thing is not yet accepted public policy in the United States, but it just might work out to everyone's benefit if it did.

Bilateral Monopoly: A Neglected Concept

A neglected but very important concept with respect to the consequences of economic power is bilateral monopoly. It relates to a situation in which power entities deal with each other vertically—at successive stages in the marketing system, as buyer and seller, as bargaining groups, or between big business and big labor in the setting of wages.

There are two diametrically opposite views among economists as to the consequences of bilateral monopoly. In his *American Capitalism*, published about thirty years ago, Galbraith treated it under his concept of countervailing power. His conclusion was that the power entities tended to offset each other, and went so far as to say that this was a sort of self-regulating substitute for competition itself, and clearly in the public interest. Apparently he did not think this was one of his more inspired insights, and in his later and more definitive work he largely abandoned it.

Joe Bain, whose *Industrial Organization* is usually regarded as the Bible for the structure-conduct and performance school, seems largely to have missed the importance of bilateral monopoly. He does not even relate it to the wage-price spiral, and considering that his book was published in the 1950s, this is amazing. He devotes only a few pages to the concept, concludes that the results appear to be largely indeterminate, but insofar as there is a central tendency, "the overall or average effect of bilateral oligopoly negotiations is in fact or should be generally to produce a competitive price of the sort which might rule if both buyers and sellers were numerous and individually small" (p. 337).

So far as I am aware, the first economist of note to take the opposite view was Cournot. He reasoned that under bilateral monopoly, each monopolist takes as the basis of his own operations the monopolistically determined price or output of the other with whom he is dealing. Obviously, in such a situation, bilateral monopoly is restrictive in its effect, and synergistically so. An interesting derivation from this is the paradox that two monopolists, dealing vertically with each other at successive stages in the marketing system, may be worse for the public than a single monopolist combining both their functions!

I first became interested in bilateral monopoly more than forty years ago when writing a monograph for the TNEC, *Large-scale Organization in the Food Industries*. I thought then, and still believe, that Cournot's restrictive concept of it was the correct one. The late William Nicholls, working independently in the same field at about the same time, came to a similar conclusion (*Imperfect Competition within the Agricultural Industries*). Neither of us then saw its importance and broad application.

If examples of bilateral monopoly are needed, they abound. We have just seen how it is one of the root causes of the wage-price spiral and cost-push inflation. Many observers, in fact most of them, point out a similar relationship between the Organization of Petroleum Exporting Countries (OPEC) and the big oil companies.

Application on a lesser scale can be made to the bargaining process by farmer cooperatives. This becomes increasingly important these days as antitrust officials are bringing the cooperative movement under closer scrutiny. Many agricultural economists are arguing that equality of bargaining power in the market place results in benefit to the farmer in dealing with buyers who may have monopoly power, as of course it does. But frequently they go on to argue that such bargaining tends to produce a price outcome near the competitive model and thereby also benefits the public (Bain's concept). In his work cited above, Nicholls demonstrated, and I thought rather convincingly, that when organized milk producers bargained successfully with milk distributors, it was the milk consumer who largely paid for the bargaining gains of both. The qualification must be added here that farmer cooperatives rarely

achieve a control of supply adequate to give them much monopoly power.

Many years ago, using Cournot's concept, I put forth the view that vertical integration was frequently in the public interest, as when a grocery chain integrates backward to cut through a monopolistic situation, or a food manufacturer integrates forward into distribution or backward into the self-manufacture of some of its supplies for the same reason. I never got very far with it. But recently, in looking through some of the economic journals to see what economists are up to these days, I found several articles by young economists who have dusted off Cournot and are having another go at it.

One of the most interesting applications of bilateral monopoly is "indexing" to compensate for inflation. This is being done increasingly these days—in wage agreements, business contracts, social security payments, and recently some of the OPEC countries have suggested hooking the price of their oil into our inflation rate, which could turn into a fine kettle of fish! The result of such "indexing" is clearly to add to inflation, and there is no end to it.

Before moving on to some of the implications of economic power for public policy, a final summation as to its consequences: In times of stagflation, the consequences of such power (whether exercised vertically or horizontally, by private entities or by government in behalf of private groups) are clearly restrictive as each such entity tries to improve (or hold) its position against other groups trying to do the same thing. In economic fair weather, the same inherent tendency is present, but so many good things are happening that we do not seem to worry much about it—at least not thus far.

Some Policy Implications

I am among those who believe that capitalism itself is in greater danger today than at any time since the early 1930s. In some respects the situation is even worse, since there seems to be no sense of direction, other than the old and discredited nostrums, as to what to do about it. In what follows, I do not ask you to share my point of view, only my concern.

Antitrust versus Control

There are basically two schools of thought with respect to dealing with economic power. The first would do it under the antitrust concept, by trying to preserve both the structure and the practice of competition. The other school has no great faith in antitrust, and would move in the direction of government control. Perhaps I should also mention the newly emerging third school—those who think we already have too much government regulation and would, in that happy phrase, "unleash competition." I cannot bring myself seriously to discuss this third school.

The major criticism of the antitrust laws is that they have not prevented what has happened. This is of course true, but I do not on that account think they should be abandoned. Antitrust is for the time being about the only weapon the government has, and it could be amended to make it a good deal more effective than it is.

One thing currently being proposed is to proscribe, unconditionally, all mergers between large firms. I am not at all sure I agree with this. For one thing, it would not restrain internal growth toward increasing concentration of control. And in some cases a merger of large firms might be in the nature of a "rescue operation" and serve to preserve or even increase competition. But certainly the government should have, in clear and unmistakable terms and without all the hassling around in the courts, the right to prevent a merger when it tends to lessen competition.

Another proposal for amending the antitrust laws was advanced a decade or so ago by the late Senator Hart. It would have provided, in certain key industries, for some restructuring, by dissolution proceedings, to increase the number of competing firms. I was in favor of this legislation and testified before several congressional committees in support of it. But for reasons discussed earlier in this paper, I did not have as much faith as some of its other supporters that it would greatly change price-output performance under oligopoly.

Toward Control

I am among those who believe we must move in the direction of government control of private economic power. There are those who hope that somehow this can be avoided, that the basic conflict-of-interest problem can be solved by adjudication and voluntary means rather than by confrontation. I cannot find much in economic history to support this.

There is growing support these days for greater public representation on the governance bodies of big business and big labor. An

example is the recent placing of a labor union representative on Chrysler's board of directors. Many nowadays are proposing that one or more public representatives be placed on corporate boards of directors and labor union organizations, and there is much to be said for this. But I do not believe that basic conflict-of-interest decisions as to wages, prices and output can be resolved by debating them in corporate board rooms or labor union councils.

As we move in the direction of control, where do we start?

With rolling inflation largely of the cost-push type and feeding on itself, I think we need a wage-price freeze, and quickly. According to the polls, a majority of the American people, if not of economists, are in favor of this.

It is a funny thing about economists and price control. For as long as I can remember, the leading pundits of the profession (not quite all of them) have proclaimed and put it in their textbooks that price control will not work. Then they defend this position by offering as proof that prices tend to go up after price controls have been removed! Now no one argues that price control, in and of itself, is a permanent cure-all for inflation. But in an emergency situation it is a useful tool, and about the only one we have which can be applied quickly and directly while more permanent measures are being put in place.

Even though we finally manage to slow down the current rate of inflation, if we do, by bleeding ourselves half to death in recession, the problem of economic power will remain. I believe it may therefore be necessary, as a long-run measure, to have some kind of wage-price guidelines in those sectors of the economy where economic power rather than competition clearly rules the market place.

Even this may not be enough. It may be necessary to give what amounts to public utility status to certain key industries where virtually no competition remains. I am aware that it is currently the fashion to condemn public utility regulation as inept, ineffective and sometimes venal, and in some cases this may be true. But what is the alternative? Unless we are prepared to live permanently with unrestrained economic power, nothing may be left in some situations but nationalization.

Capitalism and Socialism

Unlike most West European countries which have had an important socialist movement for nearly two centuries, most Americans shun anything which smacks of socialism. I wonder if this is any longer a reasonable, or even a possible, thing to do.

The central problem of capitalism is unemployment, and except in times of war, this has been true throughout the twentieth century. Along with basic unemployment is the fact that many sectors of the economy are starving for labor and capital investment because private enterprises cannot make an adequate profit there: rebuilding of inner cities, low-cost housing, public transportation, environmental control—the list of things to be done is endless.

For years we have been attacking these great problems with palliatives and half-measures: government unemployment projects (mostly of a leaf-raking type and on a temporary basis), training for jobs which do not exist, tax incentives, or, as the politicians keep telling us these days, tax cutting to "get the economy moving again."

Surely the time has come to cut through all this, and for the government itself to move directly on the unemployment problem, on a permanent basis, with useful public service employment in areas where it is most needed, and in an entrepreneurial capacity. This is socialism. The alternative is more welfare.

Some jobs these days are too financially risky and just too big even for the biggest of the big corporations. One of these is the production of synthetic fuels. The Congress has recently passed the synthetic fuels bill, which provides large sums of money for a kind of joint enterprise between the government and private industry to produce synthetic fuels. In the legislative debate which preceded passage of this bill, some legislators criticized it on the grounds it was socialism, others praised it as the most important piece of legislation in several decades. However this may be, I think we shall be seeing more legislation of this type in the years ahead, and should.

As many suspect but do not openly say, the Chrysler bailout opens up a Pandora's Box for all sorts of things, including some socialism. The American taxpayer is long-suffering, but sooner or later he may tire of paying out large sums for "loans" to bankrupt corporations, and demand of his government that it either let them go broke or take out a mortgage and foreclose if they can not repay the loan. About the only way the government could do this would be to take an equity position in the firm, which is of course socialism. But this might not be all

that bad. Several government-owned European companies manage to make automobiles, and even sell them in the American market.

If and as we move in the direction of more socialism in the economy, and I think we will have no alternative, it ought to be understood that the purpose is not to supplant the private enterprise system where it is doing a good job, as will be the case in most places most of the time, but to supplement it in those areas where it is not.

It may well be that if capitalism is to survive in anything like its present form, it may have to co-exist with a little socialism, and this may indeed be the best of all possible worlds.

I can think of no more appropriate way to close these remarks than by reference to a recent address by Felix Rohatyn to The Conference Board. Rohatyn is a senior partner in a prestigious Wall Street firm, was Chairman of the Municipal Assistance Committee which recently arranged the financial rescue of New York City, and is a highly respected member of the business community. He believes, his words, that the economy is out of control and heading toward bankruptcy, and that capitalism itself is in jeopardy unless something of consequence is done.

Among other far-reaching measures, Rohatyn proposed a modern Temporary National Economic Committee, patterned after the old TNEC of the 1930s, but with a broader charter. It would be charged with developing an integrated economic strategy for the balance of the twentieth century.

Rohatyn would give a prominent role in the new TNEC to the economics profession, just as it had in the old one. I cannot think of anything better for the profession, especially at this time. Many economists are in some disarray these days, following the failure of "The New Economics" for which so many had such high hopes. But this failure will not have been an unmitigated disaster, if it helps the profession turn away from the past and move forward into new ways of thinking about the great problems which confront us. Certainly the people have no better place to turn for help.

Good luck to all economists everywhere.

Effects of the International Donor Community on Farm People

Theodore W. Schultz

According to biblical law, being rich makes it hard to get into heaven. The corresponding law in economics is: Being rich makes it hard to comprehend the economic behavior of people in low income countries. The struggle of the Scandinavian immigrants to the United States is poignantly recorded in E. O. Rolvaag's *Giants in the Earth.* By today's standards, they were indeed poor. Among them there were notable individuals who understood better than most of us the difficulties faced by farmers who are poor. But in the complex economy of the United States today where farm people, in spite of their abundant productivity, derive over half of their income from off-farm sources, the simple truth is that it is exceedingly difficult to comprehend the preferences and scarcity constraints that determine the choices farm people in low income countries make.

Most of the people throughout the world are poor; and most of the world's poor are farm people who earn their living from agriculture. If we had a comprehensive understanding of the economics of agriculture, we would know much of the economics of being poor. I have argued elsewhere that economists find it hard to understand this part of economics (Schultz 1980b).

I have also argued that our studies of the economic dynamics of low income countries have suffered from several intellectual mistakes. The major mistake has been the presumption that standard economic theory is inadequate and that a different theory is needed. New economic models developed for this purpose were widely acclaimed until it became evident that they were at best intellectual curiosities. Most economists, however, who specialize in this branch of economics have come to realize that the received core of economic theory is fully as applicable to the scarcity problems that confront low income countries as to the corresponding problems of high income countries. Another mistake is to neglect what can be learned from the economic history of Western Europe during the centuries when most people on the continent were poor. Still another mistake is to give too little attention to the economic behavior of farm families, especially as they opt for improvements in education and health—the so-called contribution to the stock of human capital.

Although there remains much about the economics of being poor that we do not understand, we know more now about the economic dynamics of low income countries than we did a few decades ago. We have learned that poor people are no less concerned about improving their lot and that of their children than those of us who have incomparably greater advantages. In their small private domain, they are competent in obtaining the maximum benefit from their limited resources. In a number of low income countries, the record in improving population quality and in acquiring useful knowledge is positive. Where this is true the economic prospects can be seen as favorable, provided they are not dissipated by governmental policies that discriminate against agriculture.

I want now to examine how actions of the international donor community affect farm people in low income countries. Specifically I will offer a critique on the following classes of foreign aid activity: research, capital for agricultural development, dumping and tied aid, arrangements for experts, the equity-productivity tensions, role of the market, and the distortions of agricultural incentives.

Foreign Aid Puzzles

The United States has long been a donor of various forms of aid. The economics of aid is beset with puzzles. Why was the aid provided by the Marshall Plan so successful? Why has

Invited address.

Theodore W. Schultz, Nobel Laureate, 1979, is a Professor Emeritus of Economics, University of Chicago.

the large amount of aid extended to low income countries been much less successful? Why did the Point Four Latin American Aid program contribute so little to the productivity of agriculture in our hemisphere? There is also the puzzle of why our private foundations—except in the case of agricultural research—have had limited success in improving the economic environment and schooling of farm people in low income countries.

Attributes of Aid

The international donor community has become a large, complex organization. It should be noted that most of the members of this community have evolved a "live and let live" policy in support of their common interest; and that interest depends less on the support of the countries receiving aid than on that of the high income and oil-rich countries providing the funds. Quite a few of the many donor agencies with their varied programs maintain regional and country offices. They recruit and finance development and welfare experts, donate resources in kind (mainly food and agricultural commodities), provide emergency relief, finance agricultural research and extension, control large funds for agricultural development, and acquire stocks of food grains presumably to stabilize the supply available to low income countries. The international donor community supports the World Bank and various regional banks. Donor agencies also produce and distribute information tailored to support their objectives.

Yet foreign aid of these kinds is still an ambiguous concept in economics; the dialogue between economic theory and observable foreign aid is not one of the cogent parts of economics. Thus, my presentation is exploratory; there is no generally accepted economic rationale for foreign aid on which I can build in order to determine its economic effects with some precision. Studies of foreign aid based on political considerations are not as a rule useful for economic analysis.

Foreign aid nevertheless has substantial economic properties. Obviously, resources entering it are sufficiently large to have economic effects on both donors and receivers.

A personal account may be instructive. While I was with the Army of Occupation at the end of World War II, I had the good luck of anticipating the reasons for the success of the Marshall Plan. The war had destroyed a great deal of the physical capital of Western Europe, whereas the human capital had been much less impaired. Recovery depended primarily on rebuilding factories and houses and acquiring equipment and inventories. The Marshall Plan contributed a good deal of capital for these purposes. Western Europe and also Japan, given strong market demands and international trade, recovered rapidly. The economic importance of human capital and of domestic and international markets is clearly illustrated. But this lesson has been persistently overlooked in providing aid to low income countries. All too little foreign aid has been allocated to enhance the stock of human capital and to strengthen markets in these countries.

The agricultural failure of Point Four aid is also instructive. In the early 1950s the Ford Foundation made a generous grant to the National Planning Association to evaluate the technical assistance of Point Four throughout Latin America. I agreed to serve as the director of that enterprise. We discovered the reasons for the failure of the agricultural part of that program. It was that the design of Point Four was based on the assumption that research knowledge was adequate and only a delivery system was lacking. But the extension services developed cooperatively with host governments failed when little worthwhile technical information was found to be available for distribution.

Approaches to agriculture taken by the major foundations are a mixture of pluses and minuses: the early Ford Foundation agricultural program in India was a premature commitment to extension activity; by contrast, the agricultural research program by the Rockefeller Foundation in Mexico, cooperative with the government of that country, was a successful innovation. The Kellogg Foundation is committed by its charter to extension activities. The International Agricultural Research Centers are a major innovation in principle, on a par with that of the Rockefeller Foundation in Mexico. The Centers initially financed by the Ford and Rockefeller Foundations were joined later by the Canadian International Research Development Centre. The total annual budget of the twelve International Agricultural Research Centers has since come to exceed $100 million. Most of the funds now come from the World Bank, regional banks, USAID, Canadian aid, Western European donors, and Japan (Schultz 1979).

A Modest Economic Critique

Farm people in low income countries have virtually no direct contact with the international donor agencies, except for a little in agricultural research. For all practical purposes farm people have no influence on what these donor agencies do to affect their wellbeing. Foreign aid is predominantly a public activity, where governments deal with governments and where UN agencies—which are also public entities—deal only with the host governments. In the interactions between these respective public bodies, most of the reckoning of economic effects on farm people is swamped by political considerations. In view of the heterogeneity among low income countries—including their governments—and given the various classes of foreign aid, only a few useful generalizations can be offered.

Research

Achievements in agricultural research are substantial, despite the limitations of some of the donors. United Nations agencies have a poor record except in their recent financial support of the International Agricultural Research Centers. U.S. bilateral aid has a mixed record; most of it is marred by a lack of continuity in research support. Congress is largely to blame, having imposed on AID a structure that is inefficient in funding agricultural experiment stations and laboratories in low income countries. AID has neither a professional staff nor an appropriate mandate to finance long-term research. A low income country cannot depend on either UN agencies or U.S. bilateral aid for resources to develop its own agricultural research capacity.

Agricultural research in many countries is organized primarily to improve the biological possibilities of crops and livestock. Its genetic and breeding success is not in doubt. Too little attention is given, however, to the economic constraints that farmers in low income countries face. Some of the International Agricultural Research Centers are beginning to examine the economics of farmers' response in adopting new crop varieties. But as yet IARC economists have only a tenuous footing in the centers.

Distortions in incentives lead to unevenness among low income countries in farmers' opportunities to take advantage of agricultural research. No donor agency, no host government, and very few agricultural research organizations appear to be aware of the adverse effects of distortions on the modernization of agriculture.

Much more neglected is publicly funded research to improve the technology of farm household production. A growing and overdue concern is now expressed to improve the opportunities for women in low income countries. But it seems odd that virtually no attention is being given to farm household production, the domain of women. Simple things are called for. For instance, in rural Senegal women use heavy wooden clubs to free grain sorghum (a major food crop) from its husk. It is arduous work done under a tropical sun. In each of three villages I visited, the women asked me, "Why can't we have a simple hand mill to do this task?" My plea is for technical research and business enterprise that would make it possible to modernize household production.

The last item on my research list is food and nutrition research, still broadly neglected. I know of no international donor agency that has established, in cooperation with a host government, a viable and competent food and nutrition research center. Instead, donor agencies make pronouncements—largely self-serving—on the dire consequences of malnutrition in low income countries. It is not cynical to infer that the donor agencies know full well that pictures of malnourished children along with statements on the vast extent of malnutrition, which are far from creditable, serve their self-interest in appealing for more donor country support. Financial support for competent, unbiased, well-organized food and nutrition research is very much called for. An important part of it should deal with the economics of food and nutrition, the role that consumer preferences and income constraints play, and the implications for agricultural production. Then too, economists should be aware that the widely used calorie standard is a misleading concept of the relationships between malnutrition and poverty. C. H. Shah's presidential address to the Indian Society of Agricultural Economics on "Food and Nutrition: A Perspective on Poverty" is a useful contribution dealing with this issue.

Funds for Agricultural Capital

The donor agencies provide capital for various purposes: fertilizer, irrigation, rural roads,

farm equipment, others. The World Bank, regional banks, and various other UN agencies and also bilateral agencies administer the allocation of these funds, which are now sizable. Given time for these "investments" to be completed, they will undoubtedly increase to some extent the capacity of agriculture in some low income countries. But there is considerable misallocation in the use to which these forms of capital are put. It could not be otherwise in view of the prevailing distortions in agricultural product and input prices in many of the countries. The allocations are also marred by the funding of massive irrigation projects, which as a rule are a mistake. The Inter-American Development Bank this past year attained its goal of loans for rural development. But it did so by approving three large irrigation projects toward the end of the year that in all probability will have extremely low, if not negative, net yields. The uses to which these funds are put are also seriously marred by the prevailing equity doctrines of the international donor community.

Dumping and Tying

Aid in kind has the effect of dumping. It is a convenient way for a donor country to dispose of its own burdensome surplus. It has the effect of increasing the capacity of the government that receives such aid to continue discriminating against its own agriculture by procurement methods, marketing boards, or other means that maintain a cheap food policy, which in turn distorts agricultural incentives. As a case in point, Indian farmers felt the adverse effects of our delivering vast quantities of P.L. 480 agricultural commodities during the 1950s and 1960s. The rhetoric was "Food for Peace." Currently the large P.L. 480-type aid to Egypt has the effect of underwriting the bad internal agricultural policies of that government. This form of dumping also impairs the international markets for agricultural commodities.

The extent and effects of tied aid are difficult to observe. Tied aid occurs mainly in connection with funds and grants that are made available bilaterally. The donor government insists that a part of it be used to purchase materials, commodities, or services from its own country. Although an accounting of tied aid rarely surfaces in published records, there is evidence that over 70% of U.S. aid is tied. Privately, economists in low income countries reveal the consequences of particular tied aid. For example, Sweden recently offered India a generous training grant in forestry. After two years of negotiations, however, the Indian government was unable to eliminate the tied conditions that Sweden insisted upon. For that reason the grant was not accepted. Weaker countries do not do what India did.

Providing Donor Experts

Experts recruited from high income countries are expensive. Total costs per U.S. expert made available by U.S. aid agencies are about $100,000 a year. Often these experts are less qualified than the indigenous corps staff with whom they work. Much money is wasted in providing such experts. Agricultural personnel from land grant universities serving low income countries are increasingly subject to the same limitations.

Productivity-Equity Tensions

At present it is the policy of most members of the international donor community to reduce inequality in the distribution of personal income and wealth, even though it impairs the potential productivity of agriculture. The equity objectives are those that the high income donor governments find appropriate for their own country. The higher the personal income of the donor country, the less appropriate is this approach to the equity problems in low income countries. Sweden qualifies as the most serious offender in promoting its concept of equity in foreign aid. The effects of Sweden's aid in supporting undemocratic governments and in impairing agricultural productivity are lost sight of. These are the consequences I see in Tanzania. To a lesser degree, other donors are bent on similar equity objectives at the expense of the potential increases in agricultural productivity. United Nations aid agencies have the same bias, as does USAID. Congress, in effect, demands such equity objectives, despite the fact that the results of similar domestic policies have failed. (Congress has appropriated much money to improve the economic lot of small U.S. farmers, yet despite dedicated personnel administering them, the programs have failed.) Still, Congress expects low income countries to succeed in similar programs. It is noteworthy that the larger low income countries with via-

ble governments are resisting this policy. Small countries with weak governments are unable to resist and accordingly forego the enhancement of food supply that a modernized agriculture could bring forth.

Debasement of Markets

It is necessary to distinguish between activities in which governments have a comparative advantage and those where the market has a comparative advantage (Schultz 1980a). By this test most organized agricultural research is a function of government; agricultural research that is financed by government produces primarily public goods. In the United States, only 25% of all agricultural research is done by private firms for profit. In low income countries private firms do much less of such research. The U.S. Department of Agriculture has a marked advantage in producing and reporting agricultural statistics. The government also has a strong comparative advantage in the domain of specifying standards of measurement for products that are bought and sold. It is the primary authority in determining the property rights of buyers and sellers of products. Inspection of agricultural products with special emphasis on food is done primarily by government. The maintenance of a constant general level of prices is one of the functions of government. In high income countries, endeavors to reduce the inequality in the distribution of personal income are mainly a part of the role of government.

The comparative advantages of the market in agriculture and in other parts of the economy are neither acknowledged nor supported by most of the members of the international donor community. Donor agencies with few exceptions are strongly biased against markets. They thrive on the rhetoric of market failures. Most host governments also have a vested interest in this bias. Those International Agricultural Research Centers about which I have knowledge are among the exceptions. Private foundations tend to be ambivalent.

The comparative advantage of the price-making activity of markets, despite imposed handicaps rationalized by the doctrine of market failures, continues to be demonstrable. No government that has abolished markets has been successful in modernizing agriculture. The inefficiency in the allocation of agricultural resources in centrally controlled economies is not in doubt. Governments of low income countries that procure food grains from farmers at below market prices reduce the possibilities for their farmers to modernize agriculture. Nationalized pricing and distribution of fertilizer has been inefficient and wasteful. The governments of many low income countries, despite the urgent requirements for more agricultural production, underprice their agricultural products. In most of these countries, free trade and internal farm product and input prices at prevailing international prices would be a boon for the modernization of their agriculture.

But donor agencies are in general so strongly committed to the doctrine of market failures that they are incapable of perceiving the comparative advantage of markets. The economic effect of a good deal of foreign aid is to strengthen the capacity of the host governments to discriminate against agriculture.

It should also be noted that our domestic proliferation of political groups bent on promoting government regulations to keep farmers from poisoning the soil, from contaminating streams and the water supply, from depleting the cropland, from using a long list of man-made chemicals, and from destroying endangered species, provide ever more support for the doctrine of market failures. A market-oriented agriculture is viewed by these groups as an environmental and social hazard. Donor agencies, as should be expected, take full advantage of the political success of these groups that specialize in market failures. Government failures in controlling agriculture, including the failures of the donor agencies, are rarely on the agenda. It should not come as a surprise that the potential agricultural production in many low income countries is impaired by the resulting distortions in agricultural incentives.

I shall not elaborate further on distortions of agricultural incentives since I had referred to them repeatedly, as I have recently edited a major book devoted to this pervasive economic problem (Schultz 1978).

Two additional attributes of aid agencies call for brief comment. Small countries and countries regardless of size that have weak governments find it exceedingly difficult to cope with the vast number of donors. Bangladesh's weak government is confronted by over a hundred donor agencies. There is no way the government can ensure that the country's public interest is being served. Kenya, which has a viable government, faces a similar

problem. She recently requested the International Agricultural Development Service (a foundation) to advise her on how to cope with the proliferation of donor agencies.

Last is the distortion of information distributed by donor agencies. Much is false bad news intended to win more financial support for the agency. Simon has devoted a major paper to such false bad news. He cites the 1977 UN statement that "more than 100,000 West Africans perished of hunger" in the Sahel between 1968 and 1973 and he shows it is false. How valid is the bad news that "14 million acres a year are vanishing as deserts spread around the globe?" The truth is exactly the opposite as a country-by-country survey of the changes in arable land shows. A United Nations commission predicts "500 million starvation deaths in Asia between 1980 and 2025." The contrary evidence is strong. To the World Bank and USAID it is almost gospel that "higher population growth implies lower per capita economic growth." Here, too, there is much evidence to the contrary. The USAID publication, *Agenda*, is a fountain of bad news: earth, water, and air casualties; U.S. industries wanting to dump toxic wastes in the Third World; the threat of pesticides; time bomb in the city; the impairment of the environment in the Third World; and on and on. The "Global Report to the President's Council on Environmental Quality" is still another example of this class.

There are a few economists who have expressed concern about some of the adverse effects of foreign aid. Bauer (1972, 1980) has done yeoman work on the liminations of foreign aid. Lele (1979) has made a first rate contribution in the postscript to reissue of her book on Africa. Schuh (1978) clarified important aspects of the equity-productivity problem.

Concluding Remark

My exploratory endeavor suggests that neither the donor agencies nor the host governments with which they deal know or appear to want to know the preferences and the resource constraints that determine the choices that farm people in low income countries prefer. Farm people in most of these countries continue to have little or no political influence to eliminate the prevailing discrimination against agriculture. Distortions of agricultural incentives are endemic. International and domestic markets are deemed to be failures for which governmental substitutes must be developed. Most donor agencies do very little actually to improve the schooling and health of farm people. The achievements in agricultural research are an exception, mainly because of early innovations by private foundations and early research programs of a few land grant universities. Governmental programs designed strictly for emergency aid, however, deserve a high mark.

Farm people in low income countries deserve a much better deal than they are receiving from the international donor community. Would that economists were providing the analytical foundation for this to occur!

U.S. Small Farm Policy Scenarios for the Eighties

Frederick S. Humphries

I consider it an honor to have been invited to address this annual meeting of your association. As president of a land-grant institution, I have a particular concern for your work.

Your successful work has affected the agricultural policies of the nation. I certainly want to add my congratulations to your successes, but I am moved to challenge you to focus your talents on public policy and social science research for small farmers. Their cause represents a most exciting proposition.

The traditional debate over "agricultural policy" has been expanded to include equity. The nation no longer is interested in just food and fiber production. Costs to consumers and rural developments have become major issues. I believe agricultural economists have major responsibilities and a vital role to play in solving the problems of small farmers.

Background

Agriculture is one of America's most crucial sectors. It is big business and has great potential in the international arena. According to the U.S. Department of Agriculture's (USDA) "Agricultural-Food Policy Review," the agriculture sector had nearly $30 billion in exports in 1978. Agriculture's role as a "balancer of the books," vis-à-vis international trade markets, allows the United States a greater deal of leverage in minimizing balance-of-payment deficits.

The land-grant universities, with their agricultural research, extension, and teaching programs, are a part of the American agrarian tradition. The primary role of these institutions has been to change and modernize agriculture. These institutions provided the technology for the agricultural revolution. Improved technology released labor from food production and made it available for industrial and commercial expansion. In 1776, nearly 90% of the population was engaged in agriculture. After 200 years, in 1976, only 4% of the labor force was on farms and today it is even less than that. The productive efficiency of our agricultural system makes available to us an excellent diet by world standards at a very low cost. In addition to meeting our food and fiber needs, we have been the largest source of surplus food in a hungry world.

Technological developments in agriculture have increased the nation's agricultural output, but they also have created many problems for human resource development. These developments have displaced many workers from agriculture, workers who were either farmers or employed on farms. Many of these displaced workers have inadequate education and training for nonagricultural jobs. Moreover, the best-educated and most adaptable part of the rural population tends to move to urban areas, leaving behind many people who are unable to compete either with larger agribusiness or for rural industrial jobs. The President's Commission on Rural Poverty concluded in their 1967 report that "farm operator families without the skills or resources to keep pace in the farm technological race, and without offsetting nonfarm job opportunities, comprise a large part of the poverty problem" (President's Commission, p. 141).

You are aware of the several major structural changes which have taken place in the agricultural sector since World War II and which can be attributed partially to technological developments. These changes are (*a*) declining farm numbers; (*b*) increasing average farm size, and (*c*) increasing concentration of farm resources in fewer hands. The number of farms have decreased since reaching a peak of nearly seven million in the mid-thirties, dropping to 2.8 million in 1974 and again to 2.6 million in 1978. The rate of decrease in the

---

Invited address.

Frederick S. Humphries is President, Tennessee State University, Nashville.

number of farms, however, has slowed from 2.7% per year in the 1950s to 1.1% in the 1970s (USDA 1979, p. 13). The increase in farm size is as dramatic as the decrease in number of farms. In 1974, the average farm size was 440 acres, more than double the average farm size in 1950. However, total cropland used in recent years has been almost identical to the mid-1930s total, 370–380 million acres (USDA 1979, p. 13). Thus, the farms that "disappeared" were incorporated into other farms.

The concentration of land harvested by larger farmers has increased over time. For example, in 1974, land harvested by all farms with 1,000 acres or more was 100 million acres, against only 60 million acres in 1964. Thus, in 1974, slightly less than 10% of the farms accounted for one-third of the land harvested in the United States (USDA 1979, p. 13). Concentration in agriculture has brought U.S. agriculture to a point where 6% of the total number of U.S. producers supply 53% of total sales. The 6% figure is comprised of an estimated 162,000 farms with sales of $100,000 and greater (National Rural Center 1978, p. 4). At the lower end of the concentration spectrum exists that group of small farms which is the focal point of this paper.

The Small Farm Situation

Changes in agriculture have blurred the once clear distinction between farm and nonfarm populations. At present there is no one definition of small farms which conforms to the accepted notions of what constitutes small and which is easily quantifiable for purposes of enumeration and statistical analysis. Although the gross farm sales per year ($20,000) criterion is the one most commonly used, it can easily be misleading because of variation in input requirements and the extent to which inputs are produced on the farm or purchased (West 1979, p. 49). It is recognized that defining small farms remains a problem in the agriculture field.

A large number of farms would be identified as small, regardless of the measure used. By the criterion, average annual sales of $20,000 and less, there were 1.8 million small farms in 1974. They represented 69% of the nation's 2.8 million farms, 27% of the land in farms, and 32% of the market value of machinery and equipment on all farms (USDA 1977). But the contribution of these farms to national agricultural output was lower than either the number of farms or control of resources would indicate, as they accounted for only about 11% of all the sales. Although these farms represent a relatively modest proportion of U.S. agricultural sales, they may prove crucial and of increasing importance to agricultural policy and the development of rural areas.

Small farms are located throughout the nation, with major concentration in the South followed by the North Central region. In a recent study (Orden, Buccola, Edwards), it was reported that fourteen southern states contained 794,148 small farms, nearly 50% of the Nation's small farms. In 1974, it was determined that over 50% of U.S. farms with annual sales under $5,000 were located in the South. In contrast, this region accounts for only 23.6% of farms with sales exceeding $20,000. Southern small farms with sales less than $20,000 accounted for over 40% of the value of the region's agricultural products.

Black farmers are concentrated in the southern U.S. and are virtually nonexistent in other regions. There were 59,371 farms, or 2.6% of the total, operated by black and other races in the United States in 1974. Of these, more than 80% are located in the sixteen southern states having 1890 land-grant institutions (Comer). The number of black farmers has declined at an alarming rate: from 1959 to 1974, southern black farms declined by 82%, leaving only 47,000 black operators in 1974 (Orden and Smith, p. 13). Of these black farmers, 92% operated farms with gross sales of under $20,000 per year, or they were small farmers.

The impact of the rapid and continuing technological advance in agriculture has not been basically different for blacks than for other farmers. But blacks often are concentrated in those classes and types of farming that are most affected by technology, for example, cotton and tobacco crops.

A still sizable number of black farmers remain in the agricultural sector, and their future in agriculture is bleak. Black farmers face all the same disadvantages as white farmers, but they also must contend with problems of racial discrimination in such areas as credit, land acquisition, and services provided by the agricultural agencies.

Small Farm Issues

The present structural concentration of agriculture and the contingent ill-fated position o

ıe small farmer have been created partly due) the bent in U.S. agricultural policy. The istorical bias toward efficiency over equity as deemed that technology and programs be ɔnducive to large-scale farming, and hence as induced concentration. Accompanying the ɹccessful concentration on large-scale agculture has been the public and private secɪr's neglect of problems and issues important ı the small-scale farm. The popular book, *'ard Tomatoes, Hard Times* (Hightower), .ys bare the fallacy in U.S. agricultural policy ıd the accompanying role of the land-grant ɔmplex creating a subculture of disadvanɩged throughout both rural and urban Amer:a. Research done in land-grant universities as mostly helped relatively larger farmers. [owever, most of the research was conducted 'ith the belief that benefits would filter down ıd small farms also would be able to use the :sults of the research conducted. This has not appened. Instead, the research has helped ıe concentration process even more. Only :cently, research projects specifically for nall farmers were initiated. In 1978, a report lentified sixty-seven projects with an estiıated twenty-seven scientists oriented toward nall farms. But these sixty-seven research rojects represented less than half of one perɜnt of all state agricultural experiment station :search projects (West 1979). Another point ıat I want to emphasize is that nearly half of l small-farm research projects are being conɹcted at the sixteen 1890 land-grant univerties and Tuskegee Institute. Most of the re:arch work in this vital area of small farms as initiated primarily at these institutions. his I believe was because of the reward sysm at larger agricultural universities, as work small farm areas was not considered imporınt nor publishable in recognized journals. lso, scientists at these institutions focused ɩeir research and extension efforts on larger ɔmmercial units because they have substanɜl political clout. Thus, the role of U.S. agcultural policy and agricultural universities ɩve given rise to both an undesirable level of ɔncentration in agriculture and an intolerable vel of human disadvantage across the United tates.

The most important issue concerning small ırmers is whether they can make a decent ving within the rural community. It has never ɜen proven that small farmers, given adeɹate incentives, cannot make a decent living om their farms. There are still 1.8 million farmers trying to make a living from their farms; but, under the prevailing circumstances, ever-increasing numbers of them are forced to seek off-farm employment. The demise of small farms in an area leads to the inevitable decline of the surrounding rural communities.

In addition to the costs to the individual, there are social costs indirectly borne by consumers. The costs of social services to support, train, and employ this population have overwhelmed many cities. The President's Commission on Rural Poverty concluded that many people "merely exchange life in a rural slum for life in an urban slum" (President's Commission 1967). Furthermore, there is concern about conglomerate corporate farms, which may prove to be less efficient than family-operated farms. Also there are obvious environmental problems associated with chemical-energy intensive methods of industrial agriculture.

Specific Problems Faced by Small Farmers

If future policies are to be outlined to slow down or reverse past trends, it is important to determine causes of major problems that small farmers face. During the early decades of this century, there were a few large farms, but mostly family-operated farms similar in size and with similar problems. This is not the case anymore. Because of the heterogenous nature of farms today, farm problems and their solutions are likely to vary. Problems generally associated with small farms are: (*a*) lack of information, (*b*) production inefficiency, (*c*) appropriate technology, (*d*) energy and input prices, (*e*) marketing systems, (*f*) tax structure, (*g*) land and its availability, (*h*) government policies and regulations, and (*i*) off-farm employment.

Lack of Information

Established means of communications have failed to work for low income farms. The role of disseminating research results has been primarily the responsibility of the agricultural extension service. In theory, extension programs are freely available to everyone; however, small farms do not seek help or use information from the agricultural extension service as readily as more successful farmers. Extension has claimed to work with most-re-

ceptive farmers on the premise that knowledge would "trickle down" to others. But surveys in Illinois and Indiana (Beer, p. 6), and in New York (Wardle and Boisvert, p. 24) have shown that this has not happened. There may be several reasons for this failure. One such is the reward system within the agency: "There has not been much status in working with poor people" (Ragland, p. 12). A recent study, entitled "Evaluation of Economic and Social Consequences of Extension Programs," yielded striking realizations in support of the above notion (USDA, 1980a). Furthermore, advisory boards of the extension at the local level generally are dominated by middle class farmers. Therefore, in many places this middle class clientele continues to command all the benefits.

Similar examples and opinions were expressed by Marshall and Thompson (p. 66). Apart from the above illustrations, extension programs of today face yet another difficulty in reaching the small farmer. In many states, extension programs at 1890 institutions possess a unique empathy for the small farmer and a special capability for addressing their needs. But they seem to be subtly diverted from rendering services by the dominant and better-endowed 1862 Extension Program because of fear of reprisal by the traditional clientele. Separate and unequal, the 1890 and 1862 extension programs cooperate under a strained relationship, and the latter manages to control program thrusts toward the small farmer and the disadvantaged clientele. Furthermore, most extension programs at 1890 institutions receive only federal monies and do not receive matching funds from state or local governments as extension programs at 1862 institutions.

Production Inefficiencies

Larger farms generally are perceived to have lower production costs and are more efficient in producing food and fiber, i.e., they have economies of size. Some recent studies, however, have suggested that "that role of economies of size in the expansion of farms may have been exaggerated" (USDA, p. 108). The advantages for large farms may be less than past studies suggest. Marshall and Thompson (p. 48) have distinguished three sets of economies of size. Those are (*a*) technical economies of size, (*b*) external economies related to the buying of inputs and the selling of outputs, and (*c*) external factors from government ag ricultural and tax policies and the way policie are implemented. They conclude that "techni cal economies do not appear to preclude th viability of small scale agriculture, at least i some cooperative and livestock areas." Pre liminary results of a study in west Tennesse by researchers at my university show tha large farmers are not more efficient in allocat ing their resources compared to small farmers This research tends to confirm that the ma jority of small farmers did not receive muc help or information from extension service (Singh and Bagi).

Appropriate Technology and Its Adoption

In 1939, labor constituted 54% of total input into U.S. agriculture. This proportion of labo in total inputs dropped to a mere 15% in 197 (USDA 1976). This structural shift is attrib uted largely to changing technology, but un fortunately many small farmers were unable t adopt this technology for their use. For th most part, modern agricultural technology ha focused on reducing labor requirements—th one factor that is adequate, if not in surplus on many small farms. Thus, in *Hard To matoes, Hard Times,* Hightower points ou that benefits from mechanization accrue dis proportionately to the rich and powerful, in cluding the stockholders of agribusiness cor porations and large corporate farms, and tha massive social costs are paid by displace workers, small-scale family farms, and societ as a whole.

Many small farmers must over-invest i equipment, as smaller farm machines are no available. This increases their fixed cost o production. Buying used equipment is an al ternative, but that also means higher costs i terms of repairs and maintenance. Hiring cus tom work is another alternative, where farm ers can make use of modern technology with out making large investments. In hiring cus tom work, one also hires labor, which a sma farmer might prefer to provide himself. Plant ing and harvesting have to be done in a limite time period, and small farmers may not be abl to acquire custom services at the appropriat time. The following factors have contribute to the slow adoption of technology by sma farms: (*a*) lack of capital, (*b*) lower educa tional levels and skills, (*c*) risk bearing ability (*d*) available labor, and (*e*) attitude towar change.

Marketing

Marketing is perhaps the most important consideration for any farm commodity or product. It is said to be the single most crucial element in a farmer's business, especially for those who deal in perishable commodities and who must contend with biological uncertainties. Lack of a market where small farmers can sell their produce is a growing concern.

The small farmer has been in the past and is yet confronted with major adjustments in the marketing arena. These adjustments are felt to stem from and be initiated in response to technological innovations, institutional changes, economic adjustments, and changes in consumer preferences. The market structure for most farm products has changed in response to the development of highly efficient communications and pricing systems. During the recent past, these technological developments brought about a dramatization of regional comparative advantage and resulted in the concentration of production in supply areas that could amass large quantities for volume shipment to large regional warehouses for distribution to retail chains. Market power has been concentrated among a few buyers. For example, over 70% of all food is sold through 15% of the retail stores (TVA, p. 11).

Smaller and more isolated producers have limited access to mass merchandising food distribution systems. Small farmers, because of their relatively low volume of sales, are severely restricted as to marketing alternatives. If they produce traditional products within the local area, they are limited in alternatives and bargaining strength because of low volume. Small producers, if they produce nontraditional products, cannot attract a market because of low volume. Therefore, they must develop their own market. Development of mechanical harvesting equipment and other such technological devices have placed producers at a comparative disadvantage in production, marketing, and processing. The market structure developed in response to technological advance tends to restrict market access for the small, isolated producer.

Energy and Input Prices

There is little information available on the relation between farm size and energy intensiveness. Correspondingly, we know little about the relationship between size and energy-related production costs or about how the effects of energy price increase would differ between small and large farms. But in the short run, it looks as if increases in energy costs would affect small farmers more by increasing input costs. The ability of large operators to lower input costs through quantity purchases and discounts may result in lower costs of production, which reflect imperfections in the input markets.

Tax Structure

Tax rules favoring farming in general, and backed by farmers as a whole, have brought differential impacts on small and large farmers. While the small farmer may benefit from tax advantages, the larger operations are able to take much more advantage of them. Many provisions originally were established to simplify record keeping for small family farmers and to provide tax relief to farms subject to widely fluctuating incomes. Currently, tax policies favor or subsidize the wealthy, whether his income comes from the farm or the nonfarm sector. Tax subsidies induce nonfarm investment and a separation of the ownership and operation of farms. Operators with higher nonfarm incomes benefit more, whether there is loss or profit. Tax benefits to those with larger income, especially large nonfarm income, have contributed to the rising demand for agricultural land and have helped push up land prices. Thus, tax provisions which benefitted the small farmer in the short run become obstacles to their survival in the long run.

Land Availability

Recent high land prices raise serious questions of the feasibility of land ownership by those we generally consider to be family farmers. Prices of farmland have increased more than 200% since 1970, and no one wants to predict the future (USDA 1980b). Most experts agree, however, that even at current prices, land earnings in the first few years after purchase may not be sufficient to pay principal and interest under typical loan terms. Therefore, one of the most pressing difficulties faced by the young, beginning farmer is to acquire control over a suitable land base.

Small farmers can increase their operation by renting agricultural land. However, some small farmers may experience difficulty ob-

taining and keeping rental agreements with landowners who turn over much of their prime land to larger operators. Black farmers face similar problems, but they are compounded by racial discrimination (Marshall and Thompson, p. 54). Black farmers not only face difficulty acquiring new land, by purchase or rental, but they also face problems holding their land. Partition sales, tax foreclosures, and other devices have caused the loss of much black-held land (Marshall and Thompson, p. 54).

Government Policies and Regulations

Small farmers are affected adversely by policies and by the way these policies are implemented by various agencies and institutions. More often these programs benefit the larger, commercial farms. For example, price and income policies have affected farmers in proportion to their farm size and volume of production.

Various government regulations also place small farm operators at a disadvantage. For example, rigid inspection regulations regarding processing of milk and slaughtering of animals often require expensive equipment and facilities that are unrealistic for the small farm operator.

Off-Farm Employment

Farm operators, particularly small operators, and members of their households are increasingly combining farm work with full- or part-time off-farm employment. In 1974, 30% of all farm operators reported 200 or more days off-farm work. An additional 10% worked at least 50 or more days off the farm. Data for 1977 suggest that this trend in multiple job holding is continuing (USDA, p. 270).

Off-farm employment is more common in the South than in other regions of the United States. Families operating small farms depend more on off-farm income than families on larger farms. Thus, availability of off-farm jobs affects the well-being of small farm families more than large farm families.

Policy Scenarios

Economics has been defined as the science of allocating scarce resources among competing ends. Ultimate ends to be achieved may be defined as utility, well-being, or quality-of-life. Efficiency is regarded as a requirement for the individual to receive the maximum amount of goods and services; therefore, efficiency has received much attention by economists, and its study is viewed as objective, precise, and respectable (Harper and Tweeten). Agricultural economic research in the United States traditionally has focused on farm production and marketing efficiency and has produced excellent results.

Recently, however, questions have been raised about just and fair returns for everyone, along with efficiency. Breimyer points out that sufficient attention has not been paid to the broader questions of social stability, employment, and rural community development (1973). Though there has been an increasing amount of research and discussion directed toward the problem of equity, there has not been enough. More and more people are concerned with issues that go beyond "efficiency." Americans certainly will maintain their interest in producing farm products more efficiently, but they also are becoming more interested in making sure that changes are made fairly, justly, and impartially (West 1973, p. 9). Future U.S. agricultural policies therefore, should reflect these goals.

The fundamental issue of the 1980s will be whether agriculture will preserve its identity (Breimyer 1979). The kind of agriculture that prevails makes a difference not only to farmers but also to rural communities and to all of us, as consumers. I need not remind you that it will make a difference to you as professional agricultural economists.

Public policies may have different effects on the economic circumstances of farms of different sizes. However, as Emerson points out (p. 951), public policies ought to be neutral with respect to size of operation. Obviously, present policies are not neutral, because program benefits are heavily skewed in favor of large farm operations and seem to discourage small farm businesses.

These facts and the problems identified in the previous sections of this paper suggest the need to address a wide variety of public policy issues. It is important, however, that we look at present policies and change them so that they work to the advantage of the majority of rural and urban population, not just the minority of business establishments.

Small family farms have ceased to be regarded as the essence of American agriculture.

he notion of what constitutes a small farm as changed a great deal over the past century, nd the farm within the reach of modest means as become less competitive (Brewster, pp. 5–47). It is urgent that we analyze the small rm issue in the context of agriculture as a hole. We need one uniform agricultural poly for large and small farms. It should recogize that America's 1.8 million small farmers e, in fact, farmers, and that they must be of s much concern to the USDA as are larger, ommercial farms.

The underlying goal of the policy should be eliminate injustices and inequities within he nation's economy, while increasing the conomic integrity and self-reliance of rural ommunities. Profit maximization and "cold looded" economic efficiency may not be the nly criteria for developing and evaluating rogram successes. While the number of poly options are virtually unlimited, the followg policy scenarios are suggested for easing onstraints that small farmers face.

echnological Constraints

abor is the most significant part of the reource base for a large number of small farmrs. Their technical problem is how to get the est possible return for their labor and mangement at an acceptable level of risk. There re two main solutions to this problem: resources can be shared to attain technical balance; and technology suitable for small farms can be developed, having a low capital-to-labor ratio.

The first solution, which involves buying and selling custom work, is being used by some farmers in some areas but is not a common practice. The possibility of buying and selling custom work should be explained and nformation about it should be made available. The feasibility of developing small coops also should be studied further.

Appropriate technology and equipment should be developed to meet the small farm abor and capital situation, versatile equipment appropriate to small acreages. Spreading the use of such equipment among farmers could have major economic benefits. Production of simple farm machinery, easy to maintain, and free of unnecessary gadgets that increase cost should be emphasized. More incentives, in terms of investment credits, may be provided to manufacturers who develop technology suitable for small farms. Investment credits would also encourage small farmers to acquire these machines.

In view of the current energy situation, serious efforts should be made by the USDA and other agencies to finance the research and development of energy-efficient technology. Small solar collectors farmers could build are examples of such technology.

Other areas in which small farmers require help include: (*a*) assessment of alternative systems of livestock production, handling, and marketing; (*b*) alternative systems of crop production, harvesting, handling, and storage, including opportunities for group efforts; (*c*) use of pesticides, and fertilizers, and (*d*) integrated pest management. Future policies may encourage universities to direct their attention to less resource incentive technologies, which may restore the relationship between people and land. Tax incentives, similar to current investment credit, might be appropriate to stimulate small farmers to invest in better brood stock, plant varieties, and record keeping, for example.

Marketing Constraints

Small farmers have special needs of the marketing system. They need to develop strong organizations to capture such external economies as quantity discounts and marketing strength, and to enable them to apply pressure to counteract institutional bias. Policies and programs may be developed to improve the existing system of marketing, and for research and development of alternative marketing systems for small farmers, including cooperatives.

Specifically, "we need better documentation of cost-production as well as selling to determine real market costs of the alternative types of direct farm to consumer marketing. Small farmers need technical assistance to help them become retailers as well as producers" (TVA, p. 162). Special efforts should be made to provide timely information to farmers, such as a referral service listing brokers who are willing to handle small accounts.

Measures should be taken to stabilize agricultural prices. Fluctuating prices affect small farmers more. International transactions should be handled in a way that benefits not only grain companies but also farmers. Encouragement should be provided for the establishment and success of cooperatives to serve marketing needs of small farmers. Loan

guarantees and technical assistance to new coops would be especially useful.

Financial and Economic Constraints

Small farmers face severe capital and land limitations, often arising from the general lack of credit. Only a few lending agencies currently have the ability and the mandate to serve low-equity or beginning farmers. Farmers Home Administration, as a public institution set up to work directly with the small family farm, should take the lead in changing the credit picture for small farmers. There is a feeling that institutions such as Federal Land Bank and PCA have become more conservative and are not willing to help small units get started. Some problems may represent serious oversight on the part of the U.S. Congress and, therefore, Congress should act to correct them. Furthermore, Farmers Home Administration may recognize cooperatives and their members as eligible borrowers. The loan limits on farm ownership and operating loans should be raised, but not to the point that it excludes small farms altogether.

Farmers do not have easy access to information such as (*a*) credit availability and the agencies, private institutions, and programs involved in extending credit to farmers; (*b*) how to apply for and obtain credit tailored for farmers; and (*c*) how to use credit wisely and efficiently. There is a need to develop communications between lending institutions and small farmers. Credit institutions may receive tax relief by increasing loan activity to farmers with gross sales below a specific limit. Agricultural Credit Act of 1978 should be encouraged and staffed to accommodate the needs of small farmers. The establishment of rural development banks also might be considered in order to provide credit to small farmers and promote rural development.

The main tax policy affecting the price of land is the tax preference on income derived from capital gains. Legislation should be enacted to end capital gains, tax-loss farming, depletion allowance, depreciation, and other loopholes which encourage land speculation. Land trusts may be encouraged to take the profits out of land speculation.

Information and Education Constraints

Special programs should be developed for making modern agricultural techniques available to small farmers. Programs should be tailored to develop their managerial and technic knowledge. Such programs for small farme generally have been successful in the Sout (Orden, Buccola, Edwards). One such pro gram to raise managerial and financial capabi ity is being implemented by Tennessee Stat University in western Tennessee. The initi success of this program indicates that sma farmers are responsive to programs wher paraprofessionals are used from the commu nity to implement a one-on-one education approach (Singh 1979). Such programs can b used to assist limited-resource farmers t make the most of their available resources an to communicate research results to them.

Efforts should be made to end the continue existence of discriminatory bias in publi agencies, especially the Cooperative Exter sion Service. The small farmer, both white an black, has not received an appropriate shar of public services. Extension should provid comparable services to small and large farm ers alike and establish an institutional env ronment in which the small farmer can exist For this, the reward system within the agenc may have to be changed. Extension shoul publish more literature dealing with sma farmer problems at a level they can under stand. Extension also should play an activ role in identifying small farmer research prol lems.

Lack of Research for Small Farms

Special policies should be directed toward research and training for small farmers by the land-grant system and concerned agencies. Research should be for everyone, although the larger goals of activities should be for the poor and needy. In the past, our research programs have emphasized efficiency. This concern must be continued; but, in light of our present concerns with poverty, environment, and the general quality of life, it must be moderated with equity for all people.

In the area of small farms, two types of research are needed. First, formulation of public policy is highly dependent on the quantity and quality of knowledge (data) available. If there is one issue about small farmers on which most people agree, it is the lack of reliable information about small farms and small farm families. Research is needed to develop a meaningful typology of small farms, indicating distinctly different kinds of small farms in terms of their resource endowments, aspira-

ons, sources of income, and other factors Madden and Tishbein). The second type of search is to recognize problems and find eir solutions (Tweeten et al.; Thompson; nd West 1979)

In general, three major research goals can e identified: (*a*) socioeconomic information bout the farmers and rural communities, (*b*) ypes of farming, and (*c*) extension methodology. Research results on problem identification and the aspirations of small farmers must e fully recognized and integrated into the ormulation of research priorities at the national level.

General Policy Considerations

Small farmers are a heterogenous group (Carin and Crecink; Tweeten and Popoola; Lewis). Through public policies, more human resource development options should be provided for rural people. Options should be provided for those who wish to remain in farming s well as for those who wish to leave farming ompletely or to become part-time farmers. Goals for public policy are to raise income and o reduce poverty. Farm income can play an mportant role in achieving this goal. In many reas, especially in the rural South, the need is or an increased number of income-generating pportunities. In some areas at least, maintaining job opportunities in farming (full or art-time) might be a more desirable strategy han remedial programs to deal with future isplacement.

Policy makers need to know the answers to uch questions as: (*a*) What kinds of nonfarm kills are most suitable for small scale and/or art-time farming? (*b*) How can these skills be eveloped? (*c*) How can off-farm work in the rivate and public sector be coordinated with mall-scale farming? And (*d*) what type of nanpower training programs can be successul in rural areas?

Appropriate manpower training programs hould be developed for rural areas. Industries, in both private and public sectors, hould be encouraged to locate in rural areas vhere unemployment is high. Such industries hould be required to employ local people irst.

Conclusion

Small family farms have been disappearing at an alarming rate. Support for small farmers, until recently, has not been forthcoming from any direction. Communities have invested in highways and shopping centers, destroying prime farmland and burdening existing farms with higher taxes. Government policies and regulations have placed the small operator at a disadvantage. Existing agricultural agencies, including extension, have not responded to the need of small farmers. As the number of small farms declined and migration from rural areas increased, the economic bases of these rural communities eroded.

Despite the large-scale displacement of small farmers in the United States since World War II, many still remain, and their welfare is an important concern not only to rural communities but to the nation as a whole. Increasing agricultural income on small farms is a reasonable policy goal, and it is in the best interest of the nation. Rationale for assisting small farmers is partly based on equity, or humanitarian grounds, and partly on efficiency, or economic grounds. The programs and subsidies to assist small farmers may be less expensive than welfare payments. Although not all small farmers desire to expand or have like goals, most would welcome an increase in income.

Special programs and policies must be tailored to help small farmers. Traditional approaches of delivery and incentives will have to be altered to deal with the unique sociological, psychological, technological, and economic needs of small farmers. "Symbolic pacification programs" will not solve the complex problems of small farms. Policies and programs should be developed to solve the problems of small farms simultaneously with the larger problems of rural poverty and unemployment. The goal of such policy should be to promote sustainability, diversity, and equity in a system of small farms and consumers, thus increasing the economic integrity and self-reliance of our rural communities.

Small farm problems are not going to go away, as they are part of major problems of agriculture and rural development and should be dealt with as such. These problems are going to increase; and, in the absence of solid, relevant research, it will be increasingly difficult to make good policy judgments. Therefore, as agricultural economists, you should address this most important problem and help remove the blight from our otherwise successful agricultural system.

Finally, there are two important principles which must inform the work of any who would

do substantive research on the small farmer's plight. The first is that you must respect small farmers as an entity. That respect will insure that a first-rate effort will be exercised on their behalf. The second principle is that the work of small farmers must be viewed as important and that they (the farmers) are professional in their approach to their work. This principle insures that those who work on the problems of the small farmer will listen with care to what they have to say. The small farmer's problem is not just a problem of social rectification; it is a problem of strengthening a nation. It deserves first-rate attention. Let us get on with the business of solving it.

Comparing International Market Performance: Conceptual and Measurement Issues

arry Martin

has become fashionable to compare the per-rmance of alternative marketing systems, articularly the grain-marketing systems of anada and the United States (McCalla and chmitz, Peltier and Anderson, Food West esource Consultants, Dever). This is not urprising given that there have been propos-ls to give a centralized agency, e.g., the ommodity Credit Corporation or an entity ke the Canadian or Australian Wheat Boards, ome degree of responsibility for marketing J.S. grain. Conversely, there are numerous roposals in Canada to reduce the marketing esponsibility of the Canadian Wheat Board CWB) and to alter other elements of the rain-marketing system.[1]

With such pressures it is appropriate and ecessary that performance comparisons be nade. But to do so requires that two questions e answered: how does one conceptualize per-ormance and how does one measure it? The bjectives of this paper are: (*a*) to present a rocess for arriving at a conceptual framework or comparing performance, (*b*) to suggest a onceptual framework in the form of perfor-nance objectives for comparing grain market erformance, and (*c*) to suggest a series of neasurable performance indicators.

Developing a Conceptual Framework

t is tempting to define performance as the evel of prices received by producers (as in most of the empirical work cited above) or to attempt to define it in terms of industrial orga-nization theory. Both are necessary; neither is sufficient.

Grain-marketing systems are complex, but there is a tendency to simplify their structural aspects. For example, the Canadian system is often regarded as Board-controlled while the U.S. system is regarded as open-market. However, the private trade and a futures mar-ket play the majority role in marketing oilseeds and domestic feed grains in Canada, and the private trade operates in the interna-tional market as agents of the CWB. The Commodity Credit Corporation (CCC) has an increasingly important role in the U.S. sys-tem. In both countries, the public sectors are important actors in grain marketing through pricing, trade, food aid, and transportation policy as well as grading, provision of market intelligence, and research. Obviously, the na-ture of public policies in each country is sub-stantially different. But just as obviously, both systems contain private, quasi-public and pub-lic institutions. The differences are of degree and specific function.

The mixed nature of both countries' grain-marketing systems, as well as those of other countries, makes it mandatory that the struc-ture of the system be defined and thoroughly understood in undertaking comparative analy-ses of performance. Furthermore, given the increasing role of the public sector and the multiobjective nature of public policy, the definition of performance cannot be restricted to a conceptual framework that includes only variables internal to the grain sector. Public policy is developed by and has its impacts through a series of economic and social trade-offs. For the grain sector, these trade-offs occur not only among entities that pro-

arry Martin is an associate professor of agricultural economics, Jniversity of Guelph.

[1] Some of the most recent include: (*a*) moving responsibility for eed grain exports to private traders, (*b*) reducing Wheat Board ontrol of rolling stock, (*c*) removing the Wheat Board's power to stablish delivery quotas for nonboard grains and oilseed, (*d*) ubstantially altering the administration of benefits under the Crow's Nest Pass Agreement for freight rates.

duce and handle grain and among the various species of grain and oilseeds, but also among closely related sectors such as the domestic livestock complex, and upon matters of national concern such as international balance of payments or domestic employment.

Hence, it is not sufficient to ask which system returns the highest prices to producers nor to ask which system provides the least productive or pricing inefficiency. It is possible that a system is willing to sacrifice on these variables in order to gain elsewhere. Similarly, it is not sufficient to relate concentration ratios to profitability as is the wont of industrial organization practitioners. The latter question is irrelevant to quasi-public institutions such as the CWB or the CCC. It is both necessary and sufficient to form a concept of the sector's (or subsector's) objectives from the public point of view as well as from the view of private market participants.[2]

To formulate this concept, a process suggested by Shaffer and Jesse is adopted. The logic of this process is as follows. First, we must recognize that the marketing system is made up of many participants. For the grain sector these include: domestic consumers of food grains, domestic consumers of feed grains, foreign consumers of grains, grain producers, the handling and transport subsector, and the public sector which has expectations about the grain sector's effects on foreign exchange earnings and economic growth. Second, each set of participants has expectations or objectives of the grain sector, and these objectives may be conflicting. Third, many of the issues that relate to changing the structure, conduct, or regulatory environment of the grain sector are public policy issues. The positions of policy makers on various issues are likely affected by their (policy makers') perception of the current system's performance on the various objectives.

Given the foregoing, the framework for comparative analysis of performance consists first of specifying the expectations of market participants as generalized objectives. These are expressed in terms that are value laden, not prone to measurement and, in some cases, embody multiple concepts. To add specificity, the second step is then to define a set of performance indicators that represent the various objectives. The principal contributions of these indicators are to delineate the vario concepts embodied in the objectives and assist in moving closer to measurable va ables. The final step is to specify a set quantifiable measures that represents each the performance indicators and provides t basis for analysis.

[2] Bruce Marion made this point clear in commenting on a related paper (Martin 1979).

Objectives, Indicators, and Quantifiable Measures

The first four objectives (table 1) are intern to the grain sector and include concepts sim lar to those included in industrial organizatio In objective I, domestic consumers of foo grains are treated separately from consume of feed grains and foreign consumers (see b low). The indicators delineate the two comp nents of the objective and the quantifiabl measures are straightforward.

Objective II contains several concepts. Th first, emanating from the desire to stimulat production, relates to the level, stability, an adequacy of producer returns. The secon price spreads and marketing costs, is co cerned with the operational and pricin efficiency of the marketing system.

Because objective II includes the reflectio of consumer preferences, the third indicator market signals. The first three measures co cern product grades. The relevant question are: Are there a sufficient number (or to many) and sufficiently understood grades t reflect qualitative factors? Is the integrity c grades maintained throughout the marketin process so that those attempting to respond t qualitative factors are rewarded for so doing' Do grades reflect buyer preferences?

A third measure associated with market sig nals is the correlation between world an domestic prices. This variable should indicat how well the domestic market reflects worl demand so output and consumption can re spond.

A fourth concept is the response to chang in the preferences of consumers. For grain exporting countries, the major potentia changes in preference lie in wheat relative t coarse grains, grains relative to oilseeds, milling relative to feeding quality wheat, and traditional relative to new crops. Changes in preferences should be apparent in trends in international demand (i.e., trends in trade) for the relevant products. Where structural change is apparent, the measures of response are trends

production or acreage of the relevant prod- ts and production or acreage response to ɔrld prices.

Productivity (objective III) is in many ways e mirror image of the cost considerations in B. However, productivity ratios often can be ɜasured more easily than costs, and focusing an explicit productivity variable assists in parating changes in costs due to changes in oductivity from those due to other factors. ıch measure only partially represents the derlying concern. An alternative but ficult to obtain measure of productivity and ficiency that likely should be considered is a ɔntier efficiency measure as suggested by ırrell.

An area of central concern regarding the olution in grain-marketing institutions is uity; in fact, one of the stated objectives of ɜ Canadian Wheat Board is to ensure equi- ɔle market access to producers. Equity con- lerations of course also revolve around in- me distribution. Hence, the indicators and antifiable measures for objective IV are di- led into categories reflecting market access d income distribution.

A major issue in the debate over board- rsus nonboard-marketing systems is their ility to penetrate and maintain export mar- ts in various countries. In particular, there concern that, in a world wherein purchases ɜ made increasingly by state or quasi-state- ıding corporations, a decentralized, non- ard-marketing system has disadvantages chruben). The corollary is that a centralized lling system with greater control over ouput, ices, and transportation has greater ability negotiate long-term contracts—particu- ly with the centrally planned economies. ɜnce, accessing alternative foreign markets an objective (objective V), and the mea- res are intended to reflect performance ereon.

A related issue is the ability of the exporting stem to respond to short-term market op- rtunities (objective VI). Can a system an- ipate market opportunities and deliver oduct when opportunities arise? To measure is, the exporter's share of world trade when ɔrld trade or world price differs from trend is ggested.

Objectives VII–IX relate to the interface tween the grain and livestock sectors, as ɜll as the contributions of the grain sector to ɜ balance of payments, employment, and vestment. The two general concepts in these three objectives are intertwined. The grain sector provides an input for livestock production, but it also competes with the livestock sector for resources. If the grain sector is organized such that the domestic feed market is discriminated against in favor of the export market, then resources will be misallocated and the domestic economy may forego value added, employment, multiplier, and foreign exchange benefits of increasing livestock production. Devine has indicated that, for Canada, the value-added and multiplier effects of livestock production and processing are greater than for grain production and handling. Hence, it is necessary to consider foreign exchange earnings, investment, and employment in both the grain and livestock sectors. The final three objectives, their indicators, and measures attempt to do so.

Concluding Considerations

There are a number of issues related to making operational and then interpreting the results of analysis using the conceptual framework presented here. One is the measurability of the quantitative measures and the degree to which each measure represents the underlying indicators and objectives. Clearly measurability is variable. Some characteristics are relatively easy to obtain from secondary sources. Some, even if available from secondary sources, are difficult to express on a comparable basis. For example, a study underway at the University of Illinois (Lonergan) is attempting to compare export (West Coast and Great Lakes) and farm prices for wheat in Canada and the United States, with price spreads relative to handling and transfer costs. Some of the difficulties encountered in making price comparisons are the following: export prices for each country are reported at different positions in the marketing system; there are doubts about the representativeness of reported prices; variations appear in grade definitions, protein content, moisture content, and dockage specifications in the two countries; and farm prices are required to be calculated at points which are a comparable distance from the ports.

In many cases secondary data are not available, and substantial conceptual and empirical problems would be incurred in obtaining primary data. For this reason, alternative quantifiable measures have been suggested for

Table 1. Performance Objectives, Indicators, and Quantifiable Measures

Objective	Indicator	Quantifiable Measure
I	To assure an abundant supply of food grains to domestic consumers at economical prices.	
	A. Level and stability of available supplies	1. Trend in available supplies 2. Variation around trend in available suppl
	B. Level and stability of consumer prices	1. Trend in consumer prices 2. Variation around trend in consumer price 3. Consumer prices relative to CPI, WPI, o substitute prices
II	To stimulate and facilitate the efficient production and distribution of that combination of products and related services which best reflect the preferences of consumers and the real relative cost of production.	
	A. Level and stability of producer prices	1. Trend in producer prices 2. Variation around trend in producer price: 3. Producer prices relative to costs
	B. Price spreads and marketing costs	1. Price spreads—spatial and at alternative market levels 2. Transport, handling charges, and costs 3. Spreads relative to costs
	C. Market signals	1. Number and type of product forms and grades 2. Grade aggregation at final sale level 3. Buyer preferences compared to existing grades 4. Correlation between world and domestic prices
	D. Adaptability to structural change in demand	1. Production or acreage of new or differentiated crops 2. Output or acreage response to changes ii world price
III	To increase productivity.	
	A. Productivity	1. Trend in output or value added per unit labor/capital 2. Output relative to industry capacity 3. Turnover or turnaround ratios for variou: factors 4. Rate of technology adoption
IV	To distribute opportunities and rewards equitably.	
	A. Income distribution	1. Grower returns and marketing margins relative to production and marketing cost 2. Income distribution among owners of fac inputs
	B. Market access for producers	1. Price variations among producers 2. Sales restrictions 3. Carry-over as a proportion of production
V	To gain access to international markets.	
	A. Sales to alternative countries/regions	1. Trend in exports by destination 2. Trend in market share by destination 3. Trend in exports by destination relative 1 (exporter's) domestic production
VI	To respond rapidly to short-term market opportunities.	
	A. Response to change in demand	1. Share of world trade when trade exceeds trend 2. Share of world trade when world price exceeds trend
VII	To encourage stable growth in livestock production.	
	A. Feed grain prices and availability of supplies to livestock producers	1. Trend in prices 2. Variation around trend in prices 3. Variation in on-farm inventories of feed grains

able 1. Continued

jective	Indicator	Quantifiable Measure
	B. Livestock production	1. Trend in livestock production 2. Variation in trend around livestock production
II	To encourage foreign exchange earnings in the grain and livestock sectors.	
	A. Foreign exchange earnings	1. Trend in foreign exchange earnings for grains 2. Trend in foreign exchange earnings for livestock products
	To provide growing and stable investment and employment opportunities in the system.	
	A. Employment in grain handling and livestock processing	1. Trend in employment 2. Variation around trend in employment
	B. Investment in grain handling and livestock processing	1. Trend in net investment 2. Variation around trend in investment

me objectives; although in many cases what measurable is likely not as good a represen-tion of the objective as what is not. For ample, a frontier measure of efficiency and oductivity as suggested in the text is a better easure than the comparison of costs and mple productivity ratios suggested in table 1.

A second and related issue is that of assign-g causality where differences in performance cur. This is illustrated by two studies (Mar-n, Wilson and Anderson) which have at-mpted to compare performance of the Cana-an and U.S. systems on objectives V and VI. oth studies showed that the U.S. system is perior on both objectives. However, there e several hypotheses regarding the opera-onal and pricing attributes of the two systems hich could have caused the differences in rformance. Furthermore, some people in estern Canada contend that Western Cana-an climate limits production response and us the ability of the Canadian system to gain d hold international markets as well as its ility to respond to market opportunities. urther analysis is required to sort out the uses.

A third issue is that many of the measures not provide norms; they are merely de-riptive. In no case, for example, where vari-ility of a series is suggested as a perfor-ance measure, is it suggested that a given egree of variability is good or acceptable.

In response to the latter two issues and in fense of the framework suggested, the ob-ctive of the exercise is to provide a frame-ork that is diagnostic, as Bressler and King ve called for. Analysis of comparative eco-mic performance is done to provide policy akers information on the strengths and weaknesses of alternative systems and to determine areas in which performance of a given system can be improved. For many of the objectives of a grain-marketing system, norms cannot be determined analytically. However, comparison across systems using this framework can provide information on relative performance in various areas. It also can point out in which areas performance diverges the most, so that efforts can be productively focused to determine the causes, possible cures, and the impacts of alternative cures on other performance measures. In a world wherein business and public policies are made in response to conflicting objectives, perhaps this is what we should strive for.

armer Cooperatives in International Grain nd Oilseed Markets

'vin R. Bunker and Michael L. Cook

recent years, several grain and oilseed pro- :er cooperatives have expanded operations nternational marketing. Some of these ex- 1sions include the purchase of part of Alfred Toepfer Co., an international commodity ding company, by several North American l European cooperatives; the expansion of banese cooperatives into U.S. grain- ndling and storage functions; integration of lian cooperatives into processing industries developing countries; and the enlargement one interregional cooperative into the rth largest U.S. grain exporter.

Ve suggest that these innovations are pre- inary signals of a structural change in inter- ional grain trade. Our objective is to exam- the changing role of farmer cooperatives in complex international arena of grain and seed trade. Four phenomena are explored: farmer cooperative location in the world bean, coarse grain, and wheat market ıcture; (*b*) market share trends of U.S. peratives at the local, regional, and export els; (*c*) the increasing importance of foreign peratives in the international grain trade; l (*d*) factors that might constrain or en- ıce the growth of cooperatives in the world in trade.

rld Grain Market Structure

ain marketing cooperatives play a sig- cant role in most market economies. In t-handler functions of grain assembly, stor- , and elevation, Knutson, Cook, and Spor- er estimated that cooperatives handle 45% the grain produced in exporting nations. In the higher-risk functions of export marketing, activity is more limited, with cooperatives directly marketing 9% of the world grain exports and 10% of the imports. The greatest cooperative participation in grain export trade exists in Argentina, Brazil, France, and the United States. Grain-importing countries which have substantial cooperative involvement include Japan, the Netherlands, Federal Republic of Germany, and Belgium.

Notable structural differences exist in the international grain market (table 1). High levels of country concentration exist in soybean and coarse grain exports, while lower levels of concentration prevail in imports. State trading is relatively unimportant. International trade in soybeans and coarse grains is

Table 1. Comparison of Grain Importing and Exporting Country Concentration Ratios by Commodity and by Proprietary, Cooperative, and State Trading Market Shares for the Largest Eight Exporting and Importing Countries, 1977–78

	Soybeans and Meal	Coarse Grain	Wheat
	--------	(%)	--------
Exporting countries:			
Four-country share	100	79	86
Eight-country share	100	86	95
State-trading share[a]	0	6	27
Proprietary trade share	90	83	65
Cooperative share	10	11	8
Importing countries:			
Four-country share	45	47	36
Eight-country share	67	72	51
State-trading share	0	21	90
Proprietary trade share	80	67	10
Cooperative share	20	12	0

[a] State trading, proprietary, or cooperative share is the estimated percent of the total volume of direct grain exports or imports by state traders, proprietary firms, or cooperatives for the eight largest importing or exporting countries.

in R. Bunker is an agricultural economist with the Cooperative keting and Purchasing Division; Economics, Statistics, and peratives Service; U.S. Department of Agriculture; and hael L. Cook is an assistant professor, Texas A&M Univer-

his paper was prepared under regional research project NC- *Economic Analysis of the United States Grain Exporting em.*

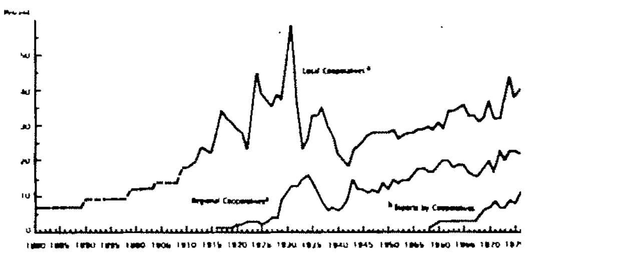
dominated by the proprietary grain-trading companies in exporting, importing, and market intermediary roles. The market shares for cooperative exports of soybeans and coarse grains are estimated at 10% and 11%, respectively, and their imports at 20% and 12%.

The international wheat market structure is considerably different from that of other grains. Exporting country concentration remains high, yet importing country concentration is relatively lower. State traders are estimated to account for 27% of the exports and 90% of the imports of wheat. Cooperative involvement is relatively small with 8% of the exports and no significant volume of imports.

U.S. Grain Cooperative Marketings

The entry of U.S. cooperatives into grain marketing initially occurred at the local, first-handler level during the mid-1800s (fig. 1). Prior to 1880, efforts at establishing grain-marketing cooperatives were scattered and usually unsuccessful.[1] During the 1880s, efforts were more organized and widespread but still largely unsuccessful. The "maintenance clause" introduced in 1890 provided financial stability, and thereafter local cooperatives commenced a period of rapid growth. The "maintenance clause" provided that members pay the cooperative a fixed fee per bushel marketed, regardless of to whom his grain was sold, for the purpose of maintenance of the cooperative. By the mid-1920s the share of grain marketings originated by local farmer cooperatives ranged from 35% to 45%. Several authors have described these early efforts at farmer organization as actions resulting from adverse economic and social conditions (Federal Trade Commission; Gardner; Knapp 1969; U.S. Congress).

To ameliorate the effects of the adverse economic conditions in agriculture during the 1920s, Congress enacted the Agricultural Marketing Act of 1929 establishing the Federal Farm Board. A chief objective of the Board was to stabilize product prices by assisting cooperatives chiefly through loans to finance storage operations. Under this program, local cooperative grain-marketing shares expanded sharply in 1930–31. But, after the failure of the



[a] Grains and oilseeds marketed by cooperatives as a percent of farm sales. Estimates prior to 1910 are based on dates organization as reported by established cooperatives in 1924
[b] Direct exports of grains, except rice, and oilseeds by coop tives as a percentage of U.S. exports of these commodities. Sc indirect exports included from 1960–1970.

Figure 1. Share of grain marketings by U local, regional, and export cooperatives, 188 1976

Federal Farm Board and its stabilization forts, the share of marketings handled cooperatives declined to an eighteen-year lo Since then, the share of grain marketings local cooperatives has increased gradually 40% by the late 1970s.

Thus, the development of local cooperativ in grain marketing began with a period of e perimentation and learning and, later, a peri of rapid growth. Both periods are chara terized by adversity felt directly by farmers marketing their grain. The adversities includ unacceptably low prices, monopolistic pra tices by existing merchants and rail lines, u fair or discriminatory treatment, and lack services offered to producers.

Since World War II, adversity does not a pear to be as important a factor in grain coo erative market-share expansion. We sugge that growth in this period is more a function action driven by opportunity, resulting fro aggressive management.

Development of U.S. regional grain c operatives follows a pattern similar to th of the local cooperatives; that is, there is period of experimentation with alternati marketing organizations lasting from abo 1915–25. From 1925–35, regional cooperativ developed rapidly, stimulated by the Feder Farm Board experiment. Growth in the ma ket share since that time has been much mo gradual. Several writers have described t adversity farmers perceived in not being ab effectively to market the grain sold to loc cooperatives without some control over ou lets in the terminal markets (American Ins tute of Cooperation; Gardner; Knapp 197 U.S. Congress; and U.S. Department of A riculture).

[1] A notable exception was the establishment of numerous "Patrons Joint Stock Companies" between 1872 and 1875. With the weakening of the Granger movement and improved marketing conditions, most of these elevators failed.

nternational Middlemen in Grain and)ilseeds Markets

oseph Halow

ears ago in a college literature course our rofessor explained that some historians disuted the fact that the *Iliad* had been written y Homer. They contended there were indicaons it had been written by someone else, hose name, oddly enough, also was Homer. am frequently reminded of this absurdity hen critics of U.S. agriculture speak disaragingly of middlemen in agricultural mareting and processing, indicating that they are ıe bad lot who intervene unnecessarily beveen the farmer and the consumer to exact a ofit. They suggest that this function be performed by representatives of the farmer, as in rmer cooperatives, or through the formation other separate groups to market and process the commodities for the farmer.

The concept of the farmer performing the ntire function is so unrealistic as to merit tle comment. It would suggest bridging the nturies and returning agriculture to a system ore compatible with Homer's time than ırs. It is ludicrous to think of marketing grain a raw or unprocessed state at farmers' marets such as those in which produce is somenes sold. Of course, wheat is marketed imarily as bread and other flour products, ıd corn is marketed principally as meat. And takes a great many people with a variety of ills to transform those grains into products ıd to bring them to the points where they are eeded. Wheat has relatively little value on e farm if someone "out there" does not ant it or if it cannot reach the consumer. nd, the consumer does not want wheat as ain, he wants it as finished product in the permarket. Soybeans are almost worthless thout expensive processing. And the farmer not in a position to perform these processing ıd transport functions because he has neither e facilities nor the time and contacts.

The puzzling part of the suggestion to form new groups or cooperatives to process and market grains is that it changes nothing, for it merely exchanges one commercial group for another. Anyone who performs these functions immediately becomes a middleman, and he is, therefore, subject to the same risks and conditions now faced by those who market and process grain. The one major difference is a negative one, for almost all who attempt to crash into the grain-exporting field know relatively little about it other than that it looks like a good business. This conclusion is reached principally because they are impressed by the volume moved.

The individual or firm that markets grain becomes more the agent of the farmer, for his function is an extension of the marketing chain which begins when the farmer sells the grain to the country elevator. Considered in this fashion, there can be no separation into "international middlemen" and, one assumes, "domestic middlemen," for they are an integral part of a system, as important as the farmer himself. From the farmer to the firm that loads the grain on a vessel for export, all are part of the marketing chain. And that marketing chain has become international because the percentage of U.S. grain in the export market is already over half of total annual sales, and growing.

The concept of a middleman who intervenes between the farmer and the ultimate consumer, profiting in the act, is an old socialist argument, one which ultimately leads to government-controlled monopolies. The other marketing alternative is to turn to government, for, given the impracticality of the other suggestions, one then must seek a group of well-meaning, honest, astute and omniscient individuals, who are without any vested interest in the function they are performing. They are, of course, always exceptionally gifted, for they assume a superior knowledge and understanding of the function they are to perform automatically when the title is conferred on them.

seph Halow is Executive Director, North American Export ain Association, Washington, D.C.

A "marketing specialist" becomes one immediately when he is promoted to that post, even though he may have been an accountant before that.

The way to a socialistic marketing system is paved with a criticism of the free enterprise system. As agriculture assumed greater importance during the past decade, there has been a constant complaint that "something had to be done" to solve the problems in agriculture, although an unbiased observer might have difficulty understanding what all the shouting is about. For, far from a poor or even a mediocre performance, U.S. agriculture has performed nothing less than brilliantly.

Ten years ago U.S. exports of wheat, feed grains, and whole soybean totaled 46.5 millions tons. This year, U.S. exports of those commodities are forecast to be about 127 million tons or, 273% of the quantity exported a decade earlier. The total world figures for the period are 108 million tons ten years ago and about 213 million tons this marketing year, or not quite double the quantity traded a decade ago. U.S. performance is clearly better than that of any, or all, of the other exporting countries.

Agricultural trade has been the best foreign exchange earner for the United States, providing us with a favorable net balance of trade of about $14 billion annually. There is no other sector of the economy [illegible]as performed so well. If they could[illegible] we [illegible] enjoy a favorable balance of tr[illegible] and payments, a thriving economy without [illegible]flation, and the international prestige and influence we took for granted when we had all those things.

The part of the farmer in the agricultural miracle is clearly understood and recognized. Less understood and appreciated, however, is the role the rest of the system plays in this outstanding performance. The exporter provides many of the facilities in which grain is collected after it leaves the farm. He also provides the facilities through which grain moves to port, and the facilities through which it is loaded. He seeks the export markets, and he assumes the risk in making and delivering the export sale. Such risks are both economic and political, and the political risks can be encountered in both the United States and other countries. It is the exporter who continues to invest whatever profit he may have made in new facilities for handling and moving the grain, for if he did not there could not have been the expansion we have witnessed durin these past ten years. Grain is worthless on th farm, and the farmer who continues to buil up a surplus because his grain cannot b shipped is inclined to plant less. Because th exporter invests in the future, he must als evaluate the market, analyzing not only i current but also its future potential.

The exporter does all of this, of cours because he does hope to make a profit in h operations—if he did not have that as an in centive, he would not be inclined to undertak the necessary investments and risks, and th industry and nation would be the loser.

The concept of profit also has been inacc rate and at times distorted, but this also is keeping with the liberal or socialist philosoph which lies behind the attack on free enterpris in agriculture. Profit is, first of all, one of th most basic incentives. It is certainly a hypo risy to criticize business' interest in profits the critic strives for promotions and incom increases in his own profession. Books hav been written criticizing the grain exporter drive for profits. Yet the prices demanded f such books indicate that the authors also ho for a share of the book sale profits. To this er the authors have attempted to make the books interesting, even if in so doing the pr sentation falls short of—or is contrary to—th facts.

Export profits are not always realized an certainly not to the extent generally believe A grain exporter remarked recently that du ing his early training, his employer had to him that it does not require much merchandi ing ability to buy a bushel of grain and sell for a little more than its cost. Real merchandi ing ability, he was told, is to buy a bushel grain and sell it at a price a little under the co to the seller and still make a profit! And this where most of the profit has been derived grain exporting.

An example is provided by the experienc of farmer cooperatives in some of their initi direct sales efforts overseas. They foun ready buyers abroad, all of whom also hope to avoid the so-called middlemen and th obtain grain at lower prices. To their di may, however, the buyers learned quickly th when they received offers against their te ders, prices offered by the cooperatives we appreciably higher than the prices other e porters offered. Their dismay was parallele by their amazement because the exporter

ho had purchased grain from the coopera-ves, were able to offer it at prices lower than ose the cooperatives were asking. Coopera-ves have learned to be more aggressive and ıve made great inroads into direct export les, so much so that one of them is now nong the top five firms in the nation. The ample illustrates clearly that profits are ade in management, not necessarily because the type of mark-up customary in other anches of business.

Because the exporter does have a vested terest in agriculture, he has the incentive to rform his function well. The argument sed frequently that government officials ay not confer with exporters because they ve vested interests is absurd on two counts: rst, because those who have a vested inter-t in an industry are those who know most out it and who are most interested in its elfare. It is offensive and inaccurate to sug-st that those who have vested interests are rsuing those interests at the expense and to e detriment of the nation. It is also absurd cause of the implication that those not in the dustry, such as government officials, do not ve vested interests. Almost everyone has a sted interest; almost everyone is interested making a profit; almost everyone is in-rested in being promoted. Those without ch ambition are not those who are making y serious contribution to the economy and e nation. Of course, there are a few nuinely altruistic people in the world, and ey do make a commendable contribution, t they are exceptional, a small percentage of e population.

A North Dakota wheat farmer eloquently pressed his concept of profit when he heard at a high level government official had indi-ted that there were farmers who agreed with e administration's action calling an embargo sales to the Soviet and then there were ners who would do anything for a buck. The mer retorted, "Of course we do it for a ck! Why does he think the farmer farms? es he think we do it because we like to oke the hogs!"

The concept of a middleman, as held in me circles, actually could be more aptly plied to government and government inter-ntion in agricultural marketing. This is not deny that government has a function to rform in agriculture. Its function should be aid and not to replace or direct. If having a constant source of food available for the people is a responsibility of the government, then government has an obligation to provide facilities to the farmers for planting a crop. Government does have a responsibility for keeping the agricultural community advised on conditions in agriculture, to aid farmers and agribusiness in making plans for food production and its movement. Government does not have a role in restricting the marketing of food except in national emergencies or in instances when there may be an inadequate supply of food for the nation. There are many persons who do not feel that these conditions have been met during the past decade, during which time there have been several embargoes, each of which was later termed not to have been necessary and none of which was ever considered to be particularly successful in achieving whatever purpose may have been given as the reason for its institution. One embargo against certain Eastern European countries was, in fact, said to have been the result of a power play between the State Department and the Department of Agriculture!

If the middleman is someone who comes between the farmer and the ultimate consumer and does so for a profit, then it fits instances when government goes beyond the function of providing assistance and begins to exercise a control over the movement of a commodity which it does not [illegible] (If someone does not believe government agencies do not make direct profits, he should check the activities of the Federal Grains Inspection Service which has produced a tidy profit of about $16 million in approximately two years of operation. And this in an area in which government does have a legitimate function but also has become overzealous.)

A more subtle form of profit is one in which government employees enhance their own positions and/or provide positions for others through intervention in the markets. An even more subtle form is through the political use to which agriculture may be put and the benefits which may be derived from such action. A blatant form of middleman intervention in the market is provided by the government's signing of a bilateral agreement with Mexico for the sale of certain amounts of grain. In doing so the government provided nothing other than an assurance to Mexico that the U.S. government would not impose an embargo on those sales. Such an assurance would not be

necessary if the government were not in the business of embargoing grain sales in the first place. Nor has the government's intervention in this business brought anything to the agricultural community or to the nation, because the sales would have taken place without the government's intervention. That is, whatever benefits there are in the sales would have taken place completely without the government. Only the government would have benefited, through whatever political advantage the government may have derived from the transaction.

The worst part of having a government middleman is that the government does not compete fairly for markets—actually it does not compete at all, so neither buyer nor seller has the benefits competition brings to a market. Government merely monopolizes business when it assumes a commercial role: there is no competition to bid up farmers' prices when grain is needed to load vessels; there is no one to bid competitively for new business. If a U.S. offer is not considered competitive, the buyer is not able to turn to another U.S. seller but must seek his grain from another source.

Conclusion

U.S. agriculture has become efficient throug the interaction of those engaged in all its a pects. The agricultural function as it exists the United States is a system which h evolved in response to the needs of agricultu itself and the nation. Despite what its criti contend, it has been extremely efficient; t problems in agriculture during the past deca have tended to be philosophical rather th economic. They have become economic b cause of the turns taken in the philosophic struggle. The continued attacks on the s called middlemen have been part of the stru gle. To suggest the introduction of an outsi entity in marketing, such as government, is propose replacing a vital part of a highly co petitive system with a real middleman who c function only in an area where he has no co petition. This can result only in destroying t competitive balance within the system, wi an accompanying loss of the incentives, whi have, in turn, been responsible for the innov tions which have been made U.S. agricultu excel and become the envy of the world.

There is an important difference in the rowth of regional cooperatives from that of ɔcal cooperatives. In 1929, just as regional rain cooperatives had established themselves s permanent institutions and had begun to xpand significantly their share of marketings, ıey were absorbed into the Farmers National irain Corporation (FNGC). The FNGC pro-ided government financial support for re-ional cooperatives in grain marketing. In 938, the FNGC discontinued its operation, nd the regional cooperatives reestablished ıemselves with only a 6% market share. The ıare of marketings since World War II has ıcreased gradually, reaching 21%–25% by the ıte 1970s.

The development pattern of exports by U.S. rain cooperatives appears to be similar to that f local and regional cooperatives. The first ɹstained attempt at export marketing came 'ith the establishment of Producers Export 'ompany (PEC) in 1958. Reynolds describes ıe primary objective of PEC as "develop-ıental" and the data indicate a relatively ıinor cooperative share of export sales. When EC terminated operations in 1969, several ooperatives had established export opera-ons, drawing heavily on the experience ained through PEC. Since 1968, integration at ıe export level by regional and interregional ooperatives has led to a significant increase in ıe share of direct export marketings. By 977, cooperatives directly exported 11% of ıe U.S. grain exports. In addition to direct xport sales, U.S. cooperatives in 1977 sold ıdirectly, but put through their own port levators, 6% of U.S. exports, making ooperatives the seller or handler of over 17% f U.S. exports of grains.

'oreign Country Grain Cooperative ʌlarketings

. review of producer cooperative activities in ıe major grain-exporting countries since Vorld War II suggests that the expansion in hare of grain marketings is not restricted to ıe United States. The major non-United tates grain-exporting countries include Au-tralia, Argentina, Brazil, Canada, France, nd South Africa. The grain export systems of ustralia, Canada, and South Africa are ominated by sole-export-authority grain-mar-eting boards and, therefore, the role of ırmer cooperatives in these countries, although important, generally is limited to first- and second-handler functions. In Argentina, Brazil, and France, grain cooperatives fulfill important roles at the first- and second-handler level and are becoming increasingly prominent at the export level.

In Argentina, a grain cooperative growth pattern similar to that of the United States can be observed. The Argentine local grain cooperatives originated assembly of grain in the late 1800s and, by the late 1970s, handled 50% of the grain at the first-handler level (Braidot). During the 1920s, the local cooperatives integrated into regional grain cooperatives. They currently market approximately 25%–30% of all Argentine grain and oilseeds. Argentine regional cooperatives began exporting prior to their U.S. counterparts, but have received several setbacks due to government monopolization of the grain-exporting activities during 1946–59 and 1973–76. However, after each period of government intervention, these producer organizations recuperated. Cooperative export shares of over 17% in 1979 surpass the 16% attained in the pre-intervention year of 1973.

The major soybean-exporting cooperatives in Brazil had their origins in the late 1950s and have been exporting only since the mid-1970s. Sixty percent of Brazilian soybeans are assembled at the first-handler level by local cooperatives. Regional exporting cooperatives receive 60% of the export licenses, but directly export only a small (8% to 10%) but increasing volume (Knutson, Cook, Sporleder). Rapid integration by cooperatives into transportation, processing, export facilities, and export institutions occurred during the late 1970s, and suggests that Brazilian cooperatives intend to at least maintain, if not increase, their share in the world oilseed market in the future.

In France, local marketing cooperatives handle approximately 70% of grain produced (Knutson, Cook, Sporleder; Sharp). Regional cooperatives, separately and with joint ventures, are the largest exporters of grain in France.

Cooperatives also play a significant role in the major grain-importing countries. In Japan, the largest feed grain importer is Zen Noh, a large, multiproduct cooperative. Zen Noh dominates the feed-compounding industry with approximately 40% of the market share. In the Netherlands, two diversified supply cooperatives process over 60% of the feed

used. Like Zen Noh, the Dutch cooperatives are experienced international importers and have participated in international cooperative marketing arrangements. Cooperatives also dominate the feed-compounding industries in the Federal Republic of Germany and Belgium and are significantly large in Italy, Spain, and South Korea.

Examination of the aforementioned trends reveals that farmer cooperatives in the major market-oriented exporting and importing countries are taking a more active role in the export/import functions in the world trade of grains. The descriptive results presented raise several issues about the future structure of the international grain trade. We briefly address three issues. What environment existed that fostered the observed trends? What factors in this environment enhance or constrain the growth of market share of cooperatives? Will the factors enhancing export growth continue to outweigh factors that might constrain growth?

Environment Creating Change

In much of the literature reviewed, both U.S. and international, a persistent yet undefined theme emerges—the general business environment that creates change in cooperatives has switched from "action because of adversity" to "action because of opportunity." Particularly, in the development of United States, Argentine, and Brazilian marketing systems, cooperative entry into grain marketing is preceded by adversity experienced by producers in gaining access to profitable markets for their products. The trends in figure 1 suggest that United States cooperatives at all three marketing levels—local, regional, and export—experienced learning periods with little market share growth during their first ten or more years of existence. But, after this initial learning period, market expansion was rapid, and is characterized by most students of these phenomena as "growth because of adversity." In the later periods, increase in market share of cooperatives is more gradual and is identified as more a function of "opportunity in the market exploited by management." Development of cooperative grain marketing at the local and regional levels in the other major market-oriented exporting countries follows a similar adversity-market opportunity pattern (Braidot; Knutson, Cook, Sporleder). Our studies suggest, however, that entrance by farmer cooperatives into export markets was more a result of market opportunity exploitation than reaction to adversity, particularly in Argentina and the United States (Braidot, Reynolds).

Factors Influencing Trends

We hypothesize that several factors have had a positive association with the observed upward trend in cooperative export marketings: (*a*) Cooperatives in all major countries have well-established cooperative bank systems. (*b*) Cooperatives originate between 40% and 50% of all grains in the market-oriented exporting nations. (*c*) In all of these same nations, a well-organized network of regional cooperatives exists. (*d*) Cooperatives in the major exporting countries control a sufficient portion of marketing facilities to achieve scale economies in handling grain. (*e*) Except in Argentina, cooperatives control a substantial percentage of the export and import facility capacity. (*f*) Grain importers perceive the quality of grain traded by cooperatives to be higher than the product of non-cooperatives. (*g*) Cooperatives in major grain importing and exporting nations have been beneficiaries of various public policies.

We also hypothesize several factors that may constrain the growth of cooperative export marketings: (*a*) the imperfectly competitive structure of the world grain trade, (*b*) rivalry between cooperatives in many local and regional markets, (*c*) management incentive systems of some cooperatives that are not conducive to expanded exports, (*d*) decentralized decision-making systems that are not always sensitive to the requirements of international trade, and (*e*) the basis of policy making (i.e., member-user board of directors) is rooted in the productivity of land and not the marketing-demand aspect of international grain sales.

Do Constraints Outweigh Advantages?

Numerous, exogenous factors, such as the world economic and the world grain situation, invariably will influence the sign and slope of the export market share trend of cooperatives. Of the factors that can be controlled by

operatives, it is often argued that two are ost important—member-user commitment d risk management.

There is much rhetoric but limited empirical idence on the importance of member comitment in increasing market share of operatives. Commitment involves setting m trading relations between producers and eir cooperatives. The "maintenance clause" mmitted U.S. farmers to support their local operative, but after cooperatives were ell-established, the clause was discontinued. nutson, Cook, and Sporleder found several ıde arrangements between importing and porting cooperatives that had played an imrtant role, especially in the initial stages of ernational trade between cooperatives. Deite some scattered examples of commitent, Knutson concluded that in the postorld War II period, institutionalized local d regional cooperative commitment was innificant in explaining increases in market ares at any level.

We suggest that the second controllable fac-, risk management, is the paramount factor at will determine the future presence of operatives in the international grain trade. e hypothesize that farmer cooperative board director awareness of the complexity of risk inagement in the international grain trade d their willingness to meet the challenge by iploying management equal to the task will termine the future sign and slope of the exrt-market share curve. Preliminary evince suggests that the quality of grain operative management worldwide has inased in recent years (Braidot; Knutson, ok, Sporleder).

Performance of International Grain Marketing Systems: Discussion

Kelly M. Harrison

I would characterize the three papers as follows: (*a*) The Martin paper is an attempt to formulate a methodology for an objective evaluation of the performance of the international grain marketing system. (*b*) The Bunker-Cook paper is an historical review of the role of U.S. cooperatives in the international grain marketing system. (*c*) The Halow paper is an emotional appeal to retain the international grain-marketing system as currently instituted.

Halow's paper is of little value to this audience of professional agricultural economists because of its polemical character. We have a proud tradition of providing objective economic analysis as an input to participants in the political process; a process which sorts out the social, political, and ideological preferences of interest groups in order to set the policy framework in which economic activities like grain marketing will be performed. As individual participants in that process, we might or might not find his comments of interest, but they are of little professional value. I, and most agricultural economists, would fully agree with Halow's point that middlemen perform an important economic function. They do so for an honorable reason—to earn a livelihood, and they are often unfairly used as whipping boys. The balance of Halow's paper, however, implies that if one accepts those premises, then he must conclude that the U.S. grain-marketing system as currently instituted should be retained without questioning whether the current mix of world conditions, international market structure, and national policy variables may be producing results which are seriously detrimental to U.S. national interests.

The Bunker-Cook paper is a useful description of the evolution of cooperative efforts to participate in international grain markets. I find little with which to quarrel except th implication that having farmers act as middl men is philosophically preferable to propri tary firms. Some might go a step further assert that having cooperatives perform th intermediary functions in the world grai marketing system would enhance its soci performance. That, of course, is not necessa ily true.

Martin has proposed an approach to th evaluation of performance of the internation grain-marketing system. The focus on obje tive criteria for evaluating performance is u gently needed, as evidenced by the Halo paper which unfortunately characterizes mo of the writing on this subject.

Martin observes that it is "mandatory th the structure of the system be defined a thoroughly understood in undertaking co parative analysis of performance." I wou add that behavioral characteristics of partic pants also should be understood. He co tinues, "given the increasing role of the publ sector and the multiobjective nature of publ policy, the definition of performance cann be restricted to a conceptual framework th includes only variables internal to the gra sector." I agree with both conclusions. B having said that, Martin proceeds to conce tualize an evaluation methodology witho doing either, perhaps because there still substantial disagreement on the structure a behavior of participants, including poli makers in the international grain-marketi system. If that is true, we as a profession mu get on with additional work to correct th deficiency.

It is my own belief that world grain pri levels have been policy determined rather th supply-demand determined for years—mai as a derivative of U.S. domestic farm polic Supply and demand forces, working primari through open U.S. grain markets, fix day-t day price levels within constraints imposed government policy. Since the United Stat

Kelly Harrison is General Sales Manager and Associate Administrator, Office of the Secretary, U.S. Department of Agriculture.

ıs been a major, if not dominant, supplier in ternational markets, U.S. domestic price ›licy has set price levels and other exporters ıve operated in their own best interest within at environment. The net effect has been an igopolistic competitive structure with U.S. ice leadership and market sharing among her exporters. The United States then acts the residual supplier through its open ex-›rt-marketing system. This, of course, is an ʼersimplification of a very complex process.

As Martin observes, it has been fashionable compare the performance of one sub-part of e international grain-marketing system (e.g., e United States) to another (Canada). I ıestion, however, whether that is the highest iority need. Perhaps a more urgent need is to ʼaluate the performance of the entire system light of U.S. economic and policy objec-ʼes. One might use the four P's of business arketing to conceptualize an evaluation pro-dure on behalf of U.S. citizens: i.e., ice—does the marketing system maximize turns to resource inputs? Product—does the stem supply overseas customers with prod-:ts which fully satisfy their needs and wants? ıysical distribution—does the logistical ›mponent of the system function smoothly to liver desired products at minimum cost? omotion—is the system dynamic in its ad-stment to changing wants and needs to main-in demand for products which can be pro-ıced economically with committed re-urces?

One must decide, as Martin observes, on hose behalf the performance evaluation is ing made. In other words, whose values and preferences count? He has not gone far enough in clarifying that issue. Nor has he specified how national security, foreign policy, and other domestic policy objectives would be factored into the evaluation.

Finally, none of the three papers has addressed what has become an increasingly important public policy issue: Has U.S. price policy in the context of existing world market structure and behavior tended to produce an export price level considerably below the real social cost for supplying commodities? Or, to state the same proposition in another way: What is the real economic value per unit of commodities exported—considering shadow prices for U.S.-produced energy, water resources, environmental costs, agricultural research, agricultural credit, and export promotion? It seems this issue should be at the forefront of any effort to evaluate the performance of the grain-marketing system from the standpoint of exporting nations. Andrew Schmitz and others have argued that several importing nations are taking advantage of exporting nations by extracting an optimum or near-optimum import tariff. Preliminary empirical analyses have estimated that the opportunity costs to the United States could be several billion dollars per year.

In conclusion, I applaud the association for focusing attention on these crucial issues. I urge association members to push ahead quickly with objective research and analysis. It appears that public pressures will bring these issues to a climax in the next few years. Your input can be most helpful.

Performance of International Grain-Marketing Systems: Discussion

Alex F. McCalla

The organizers of this session, I assume, had in mind two objectives: first, to help us get an improved handle on how we as economists can better deal with policy issues relating to market performance; and second, to add to our store of knowledge about how international grain markets really work. With respect to the first objective, Martin's paper is a thoughtful beginning upon which I will comment in more detail later. Halow's paper offers little if any insight into how international intermediaries perform their vital role in international trade. The Bunker and Cook paper presents some descriptive material about the role of the cooperative. But somehow, I expected more from this session. Major policy issues are bubbling with respect to grain marketing. Included among those are questions of whether the U.S. farmer is disadvantaged or helped by a private exporting system in a world of state traders and pervasive governmental policy intervention. Would an exporter association (a cartel) be a better road to take? Is unlimited expansion of grain exports in our long-run national interest? What are the implications of the changing structure of world grain markets for U.S. agriculture? Unfortunately, the papers presented this morning will not help policy makers much in wrestling with these and like issues. Nor do they help the profession much in improving our ability to do policy analysis.

Having made these general comments let me comment briefly on each paper.

Larry Martin's paper is a thoughtful piece. He makes the point that marketing systems exist in an environment of public policy. In particular, both the Canadian and U.S. marketing systems are to varying degrees shaped by public policy—a point Halow has yet to discover. Martin then proposes steps by which we could go about developing a set of performance indicators and measurable criteria. Most of his paper is devoted to this task an table 1 is a concise summary of thes thoughts. His scheme involves nine objectives, sixteen indicators, and forty-two quantifiable measures. He recognizes some difficu ties but does not really tell us how to solv them.

I would raise six questions about Martin' approach. (*a*) Do the objectives capture th scope of the interest of major participants? I general his objectives seem reasonable. (*b*) D the indicators accurately reflect those objectives? I have some doubts here as to wheth there is a one-to-one correspondence. (*c*) D the quantifiable measures allow us to reac conclusions about the indicators? I have som real doubts here. For example, twenty-thre of the forty-two measures are trends and var ations around trend. How are we to interpr these measures? (*d*) Can the measures b measured? Martin himself admits that there a trade-off between data available and th really needed. (*e*) What weights should be a tached to each objective? (*f*) How would on go about reaching an aggregate measure performance?

Unfortunately on the last three, Martin paper comes up short. What we have is major problem of multiattribute decision mak ing with highly interdependent variables. Ma tin has given us a good start, but there is a lon way to go.

Commenting on Halow's paper is mor difficult because there is little of intellectu substance in it. I had hoped we might lear about the role of the grain trade in intern tional markets. Instead we received a polem cal railing against some undefined enemy th is forcing us to socialism. Four pages are de voted to saying he does not like the term mid dlemen (all right, call them intermediaries be tween original producers and final consum ers). Three pages say profits are good. Tw pages say governments are bad and are in fa middlemen. He concludes by saying that w

Alex F. McCalla is a professor, Department of Agricultural Economics, University of California, Davis.

[m]ust not talk about the system because if we [d]o we will destroy its perfection. After reading [th]e paper, I assume that Halow must also have [ta]ken Logic I in college. His logic seems to run [a]s follows: middlemen are bad; governments [a]re bad; therefore, governments are middle[m]en. I think it is not worth saying any more. [H]alow did not address his subject but instead [g]ave us his philosophical position which I [s]uppose is all right, but it does not help much [in] objective analysis.

I have little to say about the Bunker and [C]ook paper. It is largely descriptive and I suppose is acceptable as far as it goes. Only toward the end of the paper do they raise analytical questions but then give us no analysis or judgment as to what the answers might be. We do not learn whether cooperative sales are FOB or c.i.f. We do not learn whether cooperatives are engaged in international risk bearing. No indication is given about how cooperatives deal with the crucial issue of information. These are only examples of what I would have expected. Hopefully they plan to go further.

Performance of International Grain-Marketing Systems: Discussion

Mark D. Newman

In discussing these three papers, it is useful to recognize that while Martin considers performance of the international grain-marketing system, Halow, and Bunker and Cook consider performance of individuals or groups of participants within the system.

I will consider the differences in the questions being addressed, some related issues which were not addressed, and implications for further research.

Martin's nine explicit criteria embody the traditional economic performance goals of efficiency, equity, and responsiveness. His framework emphasizes the multiplicity of participant interests and objectives that characterize the international grain-marketing system. The other two papers take narrower views of performance, leaving system performance questions to Adam Smith's invisible hand and concentrating on the interests of specific participants. Halow puts increasing exports as a system goal and profit as an individual participant goal. Bunker and Cook look at an increased cooperative export share as a performance criterion. Slope and trend become their performance measures.

As agricultural economists move ahead in research in this area, we need to consider performance criteria applicable to both the system and individual participants. We also need to consider the impact of the answer to the question of who will control U.S. agricultural exports and the international grain and oilseed trade. Martin's approach has potential to help answer this question. However, given the emphasis on Martin's paper by the other discussants, some comments on the points made in the other papers are in order.

Halow charges that "almost all those who attempt to crash into the grain-exporting field know relatively little about it other than that it looks like a good business." Halow's point is well taken. Some who have attempted to ent the international grain trade, and many wh purport to analyze it, fail to examine the m croeconomic foundations, the functional r quirements for export marketing, and th costs and risks involved. As Caves and m work (Newman 1980) have pointed out, thes are important considerations influencing i dustry structure, behavior, and performanc

We teach our students that certain domest marketing functions must be performed to gi time, form, and place utility to agricultur commodities, regardless of who perforn them. In export marketing, there are diffe ences in both the functional requirements a the participants involved. As agricultur economists, we need to respond to the r quirements and the participants. We (Ne man and Riley 1980) have presented o view of the microfoundations of export ma keting using nine functional components of t export process.

Moving on to the final paper, Bunker a Cook provide an interesting historical descri tion of the rise of cooperative expor although their data sources for exports U.S. grain cooperatives could be bett documented. They assert that cooperati marketing activity has shifted from "acti driven by adversity to action driven by oppo tunity." Regardless of the validity of t point, they fail to establish its relevance f the topic of this session.

The emphasis Bunker and Cook place predicting the sign and magnitude of the tre in cooperative exports provides an interesti speculative question. However, I should ha liked to have seen more emphasis on analy cal and prescriptive issues, i.e., shou cooperatives increase exports? Why? If s how?

A number of observers have asserted th cooperatives should increase exports. (what basis? The current session is supposed be considering performance. Are we talki

---

Mark D. Newman is an assistant professor of agricultural economics, Kansas State University.

bout higher producer returns, keeping the ›rivate trade "honest," or seeking a larger ıarket share per se? For farmer cooperatives, iven their particular characteristics as armer-controlled marketing organizations, here is a need to consider both price-related nd nonprice-related performance factors. 'hat requires evaluating the role and marketng objectives of cooperatives, which probably iffer from performance objectives for the verall system, and the potential contribution f exports to those cooperative objectives.

In other words, attempting to predict the ate and direction of change in cooperative xport market shares, as well as failing to tell he whole story, does not even ask enough uestions. For example, is the cooperative ble to better serve its members by increasing xports, especially on a direct or c.i.f. basis?

Cooperatives are currently in a period of ubstantial disagreement over the "proper" pproach to cooperative export marketing. eaders of some major cooperatives maintain hat emphasis should be placed on the "cooperative" in cooperative exports. They mphasize the importance of using people who ave "grown up" in cooperative organizations nd of building export marketing programs om the ground up. Other cooperative leaders mphasize the need to hire export experts, specially those who have worked in the priate trade. Some cooperatives have gone so ır as to purchase a share of concerns already ıvolved in the grain trade. The outcome of :tions of both of these groups will influence oth the role of cooperatives and who ultiıately controls U.S. agricultural exports. But unker and Cook did not consider such isıes.

In conclusion, let me add that Martin's aper gives us a tangible framework in which view performance of the overall internaonal marketing system from the perspectives f different participants. That he came up with uantifiable proxies for performance criteria hould not excuse researchers from seeking to nprove upon them, and to improve their unerstanding of the export marketing process.

The question of who will control export ıarketing of U.S. agricultural products must e continually explored. A number of recent events are worth noting: the entry of Phillip Brothers into grain marketing, the purchase of part of A. C. Toepfer by cooperatives to form InTrade, agreement by the U.S. government to serve as supplier of last resort in sales to Mexico, the rise of Farmers Export to fifth-largest U.S. exporter. All of these developments indicate that serious consideration is being given to the issue of control by those involved in the international grain-marketing system. But, where are the agricultural economists in the midst of this fray? Too often we have been content to substitute assertions for analyses, suggesting that cooperatives must increase their direct export shares, that farmers should stick to farming, or we have attempted to certify markets as perfectly competitive on the basis of application of statistical techniques to limited evidence.

The international grain-marketing process is both complex and risky. As researchers we need to look more deeply at both overall system performance and the functional foundations of the export process. While participants in the grain trade have been quite willing to proclaim that they serve the "public interest" through competition, they have not come forth with data that would permit analysts to support their case. Halow points out that good merchandisers must be able to sell grain at a lower price than they have bought it for, and still make a profit—which should demonstrate that economic analysts need to look more closely at such factors as size and scale economies, cross-subsidization, and risk management in order to understand what is going on.

Critical Choices Affecting Agriculture in an Inflationary Economy
(R. J. Hildreth, Farm Foundation, Presiding)

Inflation, Portfolio Choice, and the Prices o Land and Corporate Stock

Martin Feldstein

During the rapid inflation of the past decade, the price of land has not only kept its real value but has increased far more rapidly than the general price level. (For the 1970s as a whole, the Agriculture Department's index of the price of farm land rose at an annual rate of 13%, nearly double the 7.4% annual rise in the general consumer price index.) While elementary economic theory would predict that land and all other real assets would hold their real value when the price level rose, the increase in the relative price of land caught economists as well as others by surprise.

The reasons for the rise in the relative price of land are multiple and complex. They range from the rise in the world price of food to the political instability in the Middle East and the fears of political change in Western Europe. No single paper, let alone a short theoretical one, could hope to provide a full explanation.

There is, however, a fundamental link between general price inflation and the relative price of land that deserves particular attention. This relation is the opposite side of the same coin that causes inflation to depress the price of common stock. In essence, inflation and the tax laws interact to raise the return on land and lower the return on reproducible capital.[1] The prices of these assets must then adjust to the new inflation expectation to make investors willing to hold both types of assets in the initially existing quantities. This requires the price of land to rise (relative to the general price level) and the price of reproducible cap tal to fall.

If uncertainty could be ignored, the pri changes would be such that the real after-t rates of return were equal both before a after any change in the rate of inflation. model of asset demand that makes this simp arbitrage assumption and ignores uncertaint however, can be misleading. This paper pr sents an explicit model of portfolio demar and uses it to show how the rate of inflati and its variance affect the real prices of la and capital.

The present paper is thus an extension two earlier studies in which I presented mo els of how the interaction of inflation and t tax rules alter the real prices of land (Feldste 1979) and common stock (Feldstein 1980a,b Although these papers considered the role uncertainty in a rather ad hoc way, a form model of portfolio choice derived from utili maximization was lacking. The purpose of th paper is to remedy that deficiency.

A basic result of the earlier papers (as w as of the present analysis) is that changes the rate of inflation alter the relative price assets while at any constant inflation rate t equilibrium real asset prices remain u changed. Thus, an unanticipated jump in t expected rate of inflation causes an immedia jump in the level of the land price. After th initial jump, the price of land increases at t same rate as the general rate of inflation.

This interpretation implies that the contin ous increase in the price of land during t 1970s can best be thought of as a combinati of (*a*) many small changes in the equilibriu real price of land (as the expected rate of ge eral price inflation changed), and (*b*) a contin ing increase in the nominal price of land at t prevailing rate of inflation. Similarly, the fall

---

Martin Feldstein is President, National Bureau of Economic Research, and associate professor of economics, Harvard University.

This paper is part of the NBER study of capital formation.

[1] In this paper, I use the term reproducible capital to refer to business capital and ignore owner-occupied housing. In many ways, owner-occupied housing behaves like land in its response to inflation.

the real value of share prices combines a series of falls in the equilibrium real price of shares with continuous increases in their nominal price.

The first section of this paper presents the model of portfolio equilibrium, while the second section derives the means and variances of the asset yields. The price equations for land and reproducible capital are then developed in the third section. Next, I derive the comparative static results for changes in inflation and in the uncertainty of inflation, then conclude by discussing some of the implications of this work and possible directions for further research.

A Model of Portfolio Equilibrium

The economy that I shall describe consists of identical individuals who hold a short-term nominal asset ("bills"), land, and (reproducible) capital. The assumption of identical individuals ignores another important feature that belongs in a more complete model of portfolio choice: differences in tax rates among investors. The distinction between taxable individual investors and tax exempt institutions can be particularly important in understanding the effect of inflation on portfolio investment (Feldstein 1980a, b). The current price level and current inflation rate are known, but the rate of inflation in the future is unknown. For simplicity, it is easiest to think of the economy switching from one expected inflation rate to another—the idea of an expected time pattern of future inflation rates might be more realistic but would be more complex to analyze without adding any fundamentally new insights.

The aggregate stocks of both land and capital are assumed fixed. While this may be a realistic approximation for land—the effective stock of land can change through the loss of topsoil, forestation, etc.—it is clearly not an appropriate model for capital. If the market price of existing capital assets (Tobin's q value, the index of common stock prices per unit of real capital) falls below replacement cost, the size of the capital stock will fall while a market price of existing assets above their replacement cost will cause an increase in net investment. The anticipation of the future change in the size of the capital stock will change the expected future yields per unit of capital and labor. That in turn will influence the initial changes in the prices of these assets. While it would clearly be desirable to incorporate this effect into the analysis, the combination of dynamic price adjustments and explicit portfolio choice under uncertainty is a more complex problem than I can currently solve.[2] I have chosen to focus on the portfolio choice aspect, but I recognize the importance of extending the specification to incorporate the dynamic general equilibrium response.

Consider an individual i whose initial holdings of land, capital, and money are $\bar{L}_i$ units of land, $\bar{K}_i$ units of capital, and $\bar{B}_i$ dollars of treasury bills. These holdings reflect some previous set of expectations about asset yields and the associated covariance matrix. When the Hicksian "week" begins, there is a new set of expectations (possibly but not necessarily identical with the old ones). These expectations imply a set of equilibrium asset prices p_L and p_K relative to the numeraire; the purpose of this section is to derive equations for these equilibrium prices.

The individual's initial endowment is, thus, $\bar{B}_i + p_L\bar{L}_i + p_K\bar{K}_i$, and must be redivided among new holdings (B_i, L_i and K_i) according to the wealth constraint,

$$(1)\quad B_i + p_L L_i + p_K K_i = \bar{B}_i + \rho_L \bar{L}_i + p_K \bar{K}_i.$$

At the end of the "week," each unit of land is worth R_L, each unit of capital is worth R_K, and each unit of bills is worth R_B. Thus, $R_L - 1$ is the return per week per unit of land, $R_K - 1$ is the return on capital, and $R_B - 1$ is the rate of interest. All of these are to be regarded as real after-tax rates of return. The returns to land and capital are uncertain while the bill return is riskless. This reflects the assumption that the inflation rate for the current week is known even though the future inflation is uncertain. The individual's wealth at the end of the week is thus,

$$(2)\qquad W_i = R_L L_i + R_K K_i + R_B B_i.$$

If each individual has the same quadratic utility function, expected utility can be written as a linear combination of the mean and variance of W_i:

$$(3)\quad E[u(W_i)] = E(W_i) - 0.5\gamma \cdot \mathrm{var}(W_i),$$

where $\gamma > 0$ is a measure of risk aversion, and the 0.5 is introduced to simplify subsequent calculations.

[2] Poterba and Summers have extended the type of analysis presented in Feldstein (1979, 1980a,b) to include an explicit capital-stock-adjustment process with feedback onto the path of asset prices. They assume certainty and, therefore, that the yields of all assets are always equated, at least up to a constant.

Equation (2) implies that

$$(4)\qquad E(W_i) = \bar{R}_L L_i + \bar{R}_K K_i + R_B B_i,$$

where the bars over the $\bar{R}_L$ and $\bar{R}_K$ denote expected yields for the one-week holding period. By using equation (1), this may be rewritten as

$$(5)\quad E(W_i) = \bar{R}_L L_i + \bar{R}_K K_i + R_B[p_L(\bar{L}_i - L_i) + p_K(\bar{K}_i - K_i) + \bar{B}_i].$$

Equation (2) also implies that

$$(6)\quad \mathrm{var}(W_i) = \sigma_{LL} L_i^2 + \sigma_{KK} K_i^2 + 2\sigma_{LK} L_i K_i,$$

where σ_{LL} and σ_{KK} are the variances of the one-week holding-period returns and σ_{KL} is the covariance.

The household's optimum portfolio is found by maximizing the value of expected utility in equation (3) subject to the constraint of equation (1). Using equations (5) and (6), this implies the first-order conditions:

$$(7)\quad 0 = \bar{R}_L - R_B p_L - \gamma(\sigma_{LL} L_i + \sigma_{LK} K_i), \text{ and}$$

$$(8)\quad 0 = \bar{R}_K - R_B p_K - \gamma(\sigma_{KK} K_i + \sigma_{KL} L_i).$$

The pair of asset demand equations may therefore be written:

$$(9)\ \gamma \begin{bmatrix} \sigma_{LL} & \sigma_{LK} \\ \sigma_{KL} & \sigma_{KK} \end{bmatrix} \begin{bmatrix} L_i \\ K_i \end{bmatrix} = \begin{bmatrix} \bar{R}_L - R_B p_L \\ \bar{R}_K - R_B p_K \end{bmatrix}, \text{ or}$$

$$\begin{bmatrix} L_i \\ K_i \end{bmatrix} = \gamma^{-1} \begin{bmatrix} \sigma_{LL} & \sigma_{LK} \\ \sigma_{KL} & \sigma_{KK} \end{bmatrix}^{-1} \begin{bmatrix} \bar{R}_L - R_B p_L \\ \bar{R}_K - R_B p_K \end{bmatrix}.$$

Since all of the investors are identical, each demands the same L_i and K_i.[3] Summing L_i and K_i over all individuals gives the total demand which must equal the total asset supplies: $N\bar{L}$ and $N\bar{K}$. Because all individuals demand the same assets, $\bar{L}_i = \bar{L}_j$ for all i, j and the subscript can be ignored. Thus,

$$(10)\qquad \begin{bmatrix} \Sigma_i L_i \\ \Sigma_i K_i \end{bmatrix} = N\gamma^{-1} \begin{bmatrix} \sigma_{LL} & \sigma_{LK} \\ \sigma_{KL} & \sigma_{KK} \end{bmatrix}^{-1} \begin{bmatrix} \bar{R}_L - R_B p_L \\ \bar{R}_K - R_B p_K \end{bmatrix} = \begin{bmatrix} N\bar{L} \\ N\bar{K} \end{bmatrix}.$$

Equation (10) can thus be solved explicitly for the equilibrium asset prices as functions of the expected yields, the covariance matrix, and the initial asset quantities:

[3] I assume the conditions on the covariance matrix and yield vector are such that $0 \le L_i$ and $0 \le K_i$, and $p_L L_i + p_K K_i \le p_L \bar{L}_i + p_K \bar{K}_i + \bar{B}_i$. These conditions must surely be fulfilled in an economy of identical individuals.

$$(11)\quad \begin{bmatrix} p_L \\ p_K \end{bmatrix} = R_B^{-1} \left[\begin{matrix} \bar{R}_L \\ \bar{R}_K \end{matrix} - \gamma \begin{bmatrix} \sigma_{LL} & \sigma_{LK} \\ \sigma_{KL} & \sigma_{KK} \end{bmatrix} \begin{matrix} \bar{L} \\ \bar{K} \end{matrix} \right], \text{ or}$$

$$(12a)\quad p_L = R_B^{-1}[\bar{R}_L - \gamma(\sigma_{LL}\bar{L} + \sigma_{LK}\bar{K})], \text{ and}$$

$$(12b)\quad p_K = R_B^{-1}[\bar{R}_K - \gamma(\sigma_{KL}\bar{L} + \sigma_{KK}\bar{K})].$$

The Means and Variances of Asset Yields

I turn now to the derivation of the mean real net-of-tax returns on the three assets and the corresponding covariance matrix.

Consider first the real net rate of return on bills. If the nominal short-term rate is r, the personal tax rate is θ, and the actual current inflation rate is π, the real net-of-tax rate of return is

$$(13)\qquad R_B = (1 - \theta)r - \pi.$$

Because the tax is levied on the nominal return, the real net-of-tax returns will vary with the rate of inflation. Following Fisher, empirical studies have confirmed that the nominal interest rate changes approximately point for point with sustained changes in the rate of inflation (see, e.g., Yohe and Karnovsky and Feldstein and Summers 1978). In the current notation, $dr/d\pi = 1$ is a reasonable approximation. This implies that $dR_B/d\pi = -(1 - \theta) < 0$; an increase in the inflation rate reduces the real net return on bills. For a high enough inflation rate, the real return can be negative. This is a particularly important feature of our tax system because it suggests that the usual assumption of equal yields on all assets may be wrong and a poor approximation when there is substantial inflation.

The return on a unit of a land consists of an income return and a capital gain or loss. If the marginal physical product per unit of land (per week) is F_L, the net-of-tax marginal revenue product is $(1 - \theta)pF_L$. Increases in the price of land are taxable capital gains. The capital gains tax rate is less than the tax rate on ordinary income and the effective tax rate is further reduced because capital gains are taxed only when the property is sold. I shall use the letter c to denote the accrual-equivalent effective tax rate, i.e., the rate which levied on accruals would collect the same present value of taxes as the actual rate levied on realizations. If the increase in the price of land during the week is $\dot{p}_L$, the after-tax capital gain is $(1 - c)\dot{p}_L$.

The total nominal return per unit of land is, thus, $(1-\theta)pF_L + (1-c)\dot{p}_L$. Since a unit of land costs P_L, the nominal return per dollar invested in land is $(1-\theta)pF_L/p_L + (1-c)\dot{p}_L/p_L$. The real rate of return is the difference between this nominal rate of return and the rate of inflation, $(1-\theta)pF_L/p_L + (1-c)\dot{p}_L/p_L - \pi$. Finally, the real return per unit of land (R_L) is just the product of the real rate of return and the price per unit of land,

$$R_L = (1-\theta)pF_L + (1-c)\dot{p}_L - \pi p_L. \tag{14}$$

There are two types of uncertainty about this return, corresponding to the income and capital gain components of the price change. Because the current price level is known, the income uncertainty is caused by the uncertain marginal physical product of land. If ϕ_L is the mean marginal physical product of land and $\tilde{v}$ is the random component with zero mean and variance σ_{vv},

$$F_L = \phi_L + \tilde{v}. \tag{15}$$

In a stationary equilibrium the price of land will rise at the same rate as the general price level: $\dot{p}_L/p_L = \pi$. Change in the expected future rate of inflation or in the expected future value of any other factor that influences the value of land will cause the price of land to change by more or less than the current rate of inflation. The uncertain change in the price of land can be written without restriction, as

$$\frac{\dot{p}_L}{p_L} = \pi + \tilde{\epsilon}, \tag{16}$$

where $\tilde{\epsilon}$ is a random variable with zero mean, variance $\sigma_{\epsilon\epsilon}$, and covariance $\sigma_{v\epsilon}$ with the random disturbance to productivity.

Substituting (15) and (16) into (14) yields[4]

$$\begin{aligned} R_L &= (1-\theta)p(\phi_L + \tilde{v}) \\ &\quad + (1-c)(\pi + \tilde{\epsilon})p_L - \pi p_L \\ &= (1-\theta)p\phi_L + (1-\theta)p\tilde{v} \\ &\quad - c\pi p_L + (1-c)p_L\tilde{\epsilon}. \end{aligned} \tag{17}$$

The mean return per unit of land is thus

$$\bar{R}_L = (1-\theta)p\phi_L - c\pi p_L. \tag{18}$$

The variance of this return is

$$\begin{aligned} \sigma_{LL} &= (1-\theta)^2p^2\sigma_{vv} \\ &\quad + (1-c)^2p_L^2\sigma_{\epsilon\epsilon} + 2(1-\theta)(1-c)pp_L\sigma_{\epsilon v}. \end{aligned} \tag{19}$$

The return on reproducible capital also consists of an income return and a change in the price of the asset. Because the tax rules are based on nominal accounting definitions, a rise in the rate of inflation increases the effective tax rate on the real income from reproducible capital. (Recall that this analysis uses "reproducible capital" to refer to business capital and ignores owner-occupied real estate.) This is caused primarily by the required use of historic cost depreciation but also reflects the method of inventory accounting. (See Feldstein and Summers 1979, and Feldstein 1980b, for a discussion of how higher inflation increases the effective tax rate on the income of nonfinancial corporations and of their equity owners.) If the marginal physical product per unit of land is F_K, the net-of-tax marginal revenue product in the absence of inflation can be written $(1-\theta)pF_K$. This ignores the separate corporate income tax and the differential treatment of dividends and retained earnings. Recognizing these would complicate the analysis without changing anything fundamental. It is convenient to approximate the extra tax burden per unit of capital as proportional to the rate of inflation; the real return per unit of capital is thus depressed by $\lambda\pi p$ at current prices. The real net-of-tax income per unit of capital is thus $(1-\theta)pF_K - \lambda\pi p$. If the increase in the market price of capital[5] during the week is $\dot{p}_k$, the net-of-tax capital gain is $(1-c)\dot{p}_K$. The total nominal return per unit of capital is thus $(1-\theta)pF_K - \lambda\pi p + (1-c)\dot{p}_K$, and the corresponding real return per unit of capital is

$$\begin{aligned} R_K &= (1-\theta)pF_K - \lambda\pi p \\ &\quad + (1-c)\dot{p}_K - \pi p_K. \end{aligned} \tag{20}$$

The income uncertainty of the return on capital reflects the uncertain marginal product of capital and can be represented by

$$F_K = \phi_K + \tilde{v}, \tag{21}$$

where $\tilde{v}$ has mean zero and variance σ_{vv}. The uncertain change in the price of existing capital assets can be written,

$$\frac{\dot{p}_K}{p_K} = \pi + \tilde{\omega}, \tag{22}$$

where $\tilde{\omega}$ has variance $\sigma_{\omega\omega}$ and covariance with $\tilde{v}$ of $\sigma_{v\omega}$.

Substituting (21) and (22) into (20) yields

[4] This is the natural extension to an economy with uncertainty of the return on land derived in equation (1.5) of Feldstein (1979).

[5] This perhaps is best thought of as the market price of common stock, i.e., claims to the existing capital stock rather than new capital goods.

$$(23)\quad R_K = (1-\theta)p(\phi_K + \tilde{v}) - \lambda\pi p + (1-c)(\pi + \tilde{\omega})p_K - \pi p_K = (1-\theta)p\phi_K + (1-\theta)p\tilde{v} - \lambda\pi p - c\pi p_K + (1-c)p_K\tilde{\omega}.$$

The mean return per unit of capital is thus,

$$(24)\quad \bar{R}_K = (1-\theta)p\phi_K - \lambda\pi p - c\pi p_K.$$

The covariance between the returns on capital and land depend in general on the full covariance matrix of all four random effects:

$$(25)\quad \sigma_{KL} = E\{[(1-\theta)p\tilde{\nu} + (1-c)p_L\epsilon][(1-\theta)p\tilde{v} + (1-c)p_K\tilde{\omega}]\} = (1-\theta)^2p^2\sigma_{\nu v} + (1-\theta)(1-c)pp_K\sigma_{\nu\omega} + (1-c)(1-\theta)pp_L\sigma_{\epsilon v} + (1-c)^2p_Lp_K\sigma_{\omega\epsilon}.$$

The Price Equations

The means and covariance matrix of the returns on land and capital can be used with equation (12a, b) to obtain explicit price equations for land and capital. It is useful to begin by substituting the mean values R_B and $\bar{R}_L$ into equations (12) to obtain the price of land:

$$(26)\quad p_L = (1-\theta)p\phi_L - c\pi p_L - \gamma(\sigma_{LL}\bar{L} + \sigma_{LK}\bar{K})/(1-\theta)r - \pi$$

Collecting and rearranging terms yields

$$(27)\quad \frac{p_L}{p} = (1-\theta)\phi_L/(1-\theta)r - (1-c)\pi + \gamma p_L^{-1}(\sigma_{LL}\bar{L} + \sigma_{LK}\bar{K}).$$

There are several significant things to notice about this expression for the real price of land (p_L/p). In the absence of risk aversion ($\gamma = 0$) and inflation ($\pi = 0$), the real price of land is just the discounted value of the expected return per unit of land, i.e., $p_L/p = \phi_L/r$. If there is inflation but no risk aversion, the relationship is more complex; the perpetuity at ϕ_L is discounted by $r - [(1-c)/(1-\theta)]\pi$. Since $(1-c)/(1-\theta) > 1$, this "net discount rate" can easily become "negative." That is, as π rises $r - [(1-c)/(1-\theta)\pi]$ approaches zero and the implied relative price of land become indefinitely large. When $(1-\theta)r < (1-c)\pi$, the value of p_L/p "passes through" infinity and becomes negative. More generally, for many plausible tax parameters, the relative price of land is implausibly sensitive to changes in π.

These results show the importance of explicitly recognizing the role of uncertainty and risk aversion in determining p_L/p. Equation (27) shows that risk aversion can eliminate the anomalous results. With $\gamma(\sigma_{LL}\bar{L} + \sigma_{LK}\bar{K}) > 0$ in the denominator, relative asset prices are not nearly so sensitive to differences in the mean real net rates of return.

A more complete characterization of the real price of land is obtained if σ_{LL} and σ_{LK} are rewritten in terms of the underlying variances and covariances. The essential features of the analysis are preserved, but the analysis is simplified by assuming that the income disturbances ($\tilde{\nu}$ and $\tilde{v}$) are independent of each other and of the price disturbances ($\tilde{\epsilon}$ and $\tilde{\omega}$). Such an assumption would be reasonable if investors knew that the disturbances $\tilde{\nu}$ and $\tilde{v}$ are serially independent so that a disturbance in one period has no implications about future values of F_L and F_K. With this simplifying assumption, the relevant variances and covariances of section 2 become

$$(28)\quad \sigma_{LL} = (1-\theta)^2p^2\sigma_{\nu\nu} + (1-c)^2p_L^2\sigma_{\epsilon\epsilon},$$

$$(29)\quad \sigma_{KK} = (1-\theta)^2p^2\sigma_{vv} + (1-c)^2p_K^2\sigma_{\omega\omega},$$

and

$$(30)\quad \sigma_{LK} = (1-c)^2p_Lp_K\sigma_{\omega\epsilon}.$$

Substituting these values into equation (27) yields

$$(31)\quad \frac{p_L}{p} = (1-\theta)\phi_L\Big/\Big((1-\theta)r - (1-c)\pi + \gamma p_L^{-1}\{[(1-\theta)^2p^2\sigma_{\nu\nu} + (1-c)^2p_L^2\sigma_{\epsilon\epsilon}]\bar{L} + (1-c)^2p_Lp_K\sigma_{\omega\epsilon}\bar{K}\}\Big),\ \text{o}$$

$$(32)\quad \frac{p_L}{p} = (1-\theta)\phi_L\Big/\Big((1-\theta)r - (1-c)\pi + \gamma\{[(1-\theta)^2(p/p_L)^2\sigma_{\nu\nu} + (1-c)^2\sigma_{\epsilon\epsilon}]p_L\bar{L} + (1-c)^2\sigma_{\omega\epsilon}p_K\bar{K}\}$$

In this form, the real price of land is defined as a quadratic function of tax rates, rates of return, the expected inflation rate, and the total wealth in land and capital. If the income risk is ignored ($\sigma_{\nu\nu} = 0$), the real price of land assumes the simple form,

$$(33)\quad \frac{p_L}{p} = (1-\theta)\phi_L/[(1-\theta)r - (1-c)\pi + \gamma(1-c)^2(\sigma_{\epsilon\epsilon})p_L\bar{L} + \sigma_{\epsilon\omega}p_K\bar{K}].$$

This case is also substantively interesting because the price risk can generally be expected

to be large relative to the income risk and because uncertainty about the future inflation rate contributes to the price risk but not the income risk.

The analogous equation for the real market price of capital is

$$(34)\quad \frac{p_K}{p} = [(1-\theta)\phi_K - \lambda\pi]/[(1-\theta)r - (1-c)\pi + \gamma(1-c)^2(\sigma_{\omega\omega} p_K \bar{K} + \sigma_{\epsilon\omega} p_L \bar{L})].$$

Some Comparative Static Analyses

Equations (33) and (34) can be used to examine how the real prices of land and capital respond to changes in inflation, the uncertainty of future inflation, and other such factors. Since the stock of capital is assumed to remain constant, the results can of course only indicate the direction and not the magnitude of the change.

The derivative of p_L/p with respect to the expected inflation rate is easily shown to be

$$\frac{d(p_L/p)}{d\pi} = -\frac{(p_L/p)^2}{(1-\theta)\phi_L} \cdot \left[(1-\theta)\frac{dr}{d\pi} - (1-c) + \gamma(1-c)^2\sigma_{\epsilon\epsilon}\frac{dV_L}{d\pi} + \gamma(1-c)^2\sigma_{\epsilon\omega}\frac{dV_K}{d\pi}\right].$$

where $V_L = p_L\bar{L}$ and $V_K = p_K\bar{K}$. Note first that, in the absence of risk aversion, the effect of inflation on the real price of land is positive if $(dr/d\pi) < (1-c)/(1-\theta)$. Since $c < \theta$, this will clearly be satisfied whenever $dr/d\pi < 1$. During the increasing inflation of the 1960s and 1970s, the nominal interest rate rose by approximately the rise in the rate of inflation, causing the real net interest rate to fall by $(1-\theta)d\pi$. In contrast, the real return on land falls only because of the smaller rate of capital gains tax on the nominal appreciation in the value of the land. Because the extra tax on bills per dollar of capital would exceed the extra tax on land, the price of land rises in the absence of uncertainty in order to equalize the yields.

Introducing uncertainty leaves this conclusion unchanged but suggests that the magnitude of the effect may be reduced. If $d(p_L/p)/d\pi < 0$, $dV_L/d\pi < 0$ since $V_L = p_L\bar{L}$ and $\bar{L}$ is constant. This positive term offsets some of the magnitude of the pure tax and interest rate effect; the economic reason for this is that as p_L rises, the investor has relatively more wealth in this form, which in turn raises the risk premium that the investor requires to hold even more land or, equivalently, which reduces the demand for more land and therefore the real price of land.

If the primary reason for the covariance between the unanticipated changes in the prices of land and capital ($\sigma_{\epsilon\omega}$) are the unanticipated changes in inflation, the term $\sigma_{\epsilon\omega}dV_K/d\pi$ is also likely to be positive, further reducing $d(p_L/p)/d\pi$ but nevertheless leaving it positive. For example, $dp_L/d\pi > 0$ and $dp_K/d\pi < 0$ imply $\sigma_{\epsilon\omega} < 0$ and $dV_K/d\pi < 0$, and therefore that $\sigma_{\epsilon\omega}dV_K/d\pi > 0$. Similarly, $dp_L/d\pi > 0$ and $dp_K/d\pi > 0$ imply $\sigma_{\epsilon\omega} > 0$ and $dV_K/d\pi > 0$, and therefore again $\sigma_{\epsilon\omega}dV_{\epsilon\epsilon}/d\pi > 0$. The economic reason (in the relevant case in which $dp_K/d\pi < 0$) is that inflation reduces the value of the investors' reproducible capital and, because the return on capital is negatively correlated with the return on land, reduces the demand for land and therefore its price.

The effect of uncertainty is nevertheless to dampen the effect of inflation and not to reverse it. To see this, note that the opposite implies a contradiction. If $dp_L/d\pi < 0$, $\sigma_{\epsilon\epsilon}(dV_L/d\pi) < 0$, which implies an even larger positive value of $dp_L/d\pi$.

A similar analysis shows that a higher rate of inflation reduces the real value of capital,[6] and that the uncertainty and risk aversion again dampen the magnitude of the effect.

Consider now the effect of an increase in the uncertainty of the future inflation rate. This increases $\sigma_{\epsilon\epsilon}$, $\sigma_{\omega\omega}$, and $|\sigma_{\epsilon\omega}|$. The relative increase in each term depends on the extent to which uncertainty about inflation is the source of the uncertainty about asset prices. Two extremes will illustrate the possible results. If most of the variation in the real price of land reflects variation in anticipated inflation, while little of the variation in the price of capital reflects the inflation uncertainty, an increase in the inflation uncertainty will raise $\sigma_{\epsilon\epsilon}$ while leaving $\sigma_{\omega\omega}$ essentially unchanged. Moreover,

[6] This depends on the relative magnitudes of the historic cost depreciation effect and the real interest rate effect. For an analysis with realistic parameters, see Feldstein (1980b).

if inflation is not a major source of $\sigma_{\omega\omega}$, it is possible (although not necessary) that $\sigma_{\epsilon\omega} = 0$. Total differentiation of equation (33) with respect to p_L and $\sigma_{\epsilon\epsilon}$, with $\sigma_{\epsilon\omega} = 0$, implies that $dp_L/d\sigma_{\epsilon\epsilon} < 0$, i.e., an increase in inflation uncertainty unambiguously reduces p_L while leaving p_K unchanged.

In contrast, consider the case in which inflation uncertainty is equally important for $\sigma_{\epsilon\epsilon}$ and $\sigma_{\omega\omega}$, and $\sigma_{\epsilon\omega} < 0$. If an increase in inflation uncertainty raises $\sigma_{\epsilon\epsilon}$ and $\sigma_{\omega\omega}$ by equal amounts and leaves the correlation between ϵ and ω unchanged, equations (33) and (34) imply that an increase in inflation uncertainty reduces both p_L and p_K. Investors respond to the increased uncertainty by demanding less land and capital and more of the riskless nominal asset.

More generally, the response of relative asset prices to an increase in inflation uncertainty will depend on the relative extent to which $\sigma_{\epsilon\epsilon}$, $\sigma_{\omega\omega}$, and $\sigma_{\epsilon\omega}$ are changed. An increase in inflation uncertainty might cause the real price of land to rise if investors wish to substitute both land and bills for capital.

Conclusion

This paper has focused on the specific question of how changes in expected inflation and in its uncertainty affect the real prices of land and of reproducible capital. The analysis shows how an explicit portfolio-choice framework can be applied to derive asset price equations and how, in this framework, the interaction of taxes and increased inflation causes a rise in the real value of land and a fall in the real value of corporate equities.

Two more general points are worth noting. First, the analysis shows the inappropriateness of the common assumption that inflation is neutral, i.e., that it does not alter real magnitudes. When there are taxes on capital income, this is false and inflation can have substantial real effects.

Second, the traditional assumption that prices adjust until net-of-tax yields are equal may be misleading. In the examples shown here, the existence of a finite price for land depends on the uncertainty of the asset yields.

This paper has shown that an explicit utility maximization model of portfolio choice can be applied to analyzing the effects of changes in the rate of inflation. A natural next step is to embed this analysis in a more general dynamic framework in which changes in the price of capital change the supply of new capital goods and therefore the future path of the real marginal products of capital and land.

[I]nflation, Agricultural Output, and [P]roductivity

[D]. Gale Johnson

[W]hy should inflation have an adverse effect [u]pon agricultural output and productivity? [S]ince most economists accept the view that [i]nflation is bad and should be avoided—if [d]oing so does not cost too much—our knee-[je]rk reaction is that inflation has significant [a]dverse effects upon output and productivity.

True, inflation redistributes wealth and in[c]ome, as most of us who work for universities [a]nd, in addition, have annuities derived from [d]efined contributions realize. And when infla[ti]on rates reach some levels, the breakdown of [c]onfidence in money and financial institutions [c]an have serious economic, social, and politi[c]al consequences. But have the inflation rates [o]f 10% to 15% to which we have been sub[je]cted during the past year had significant re[s]ource and productivity effects in agriculture? [W]hen I started to write this paper I was not [s]ure how I would answer this question. Was I [m]ore sure when I finished? I leave it to you to [ju]dge.

The first issue that I address is what has [h]appened to productivity in the economy and [in] agriculture during the 1970s. In considering [w]hat may have happened to the growth of [p]roductivity in agriculture, we should con[si]der that change in the context of the national [p]icture.

The available data on changes in national productivity, whether as measured by total factor productivity or by labor productivity (average labor product) show clearly that national productivity growth has been significantly slower since 1973 than in the years before. What is much less clear is why the slowdown has occurred.

What do the data show? Table 1 gives data on total factor productivity for the private domestic economy and selected segments. There can be little doubt that productivity growth after 1973 was at a lower rate than in any other period since 1948. Table 2 provides similar data on labor productivity, and the general picture is the same as for total factor productivity.

There are those who argue that the productivity slowdown started before 1973. Tables 1 and 2 give some support for that view, though the pre-1973 slowdown seems to have been concentrated in areas other than manufacturing.

However, there is little doubt that the sharp break in productivity growth occurred from 1973 on. There are at least two important competitors for explaining the decline. One is that 1973 was the year that oil prices were increased substantially. Another is that it was in 1973 that we started on a roller coaster of inflation, deflation, and inflation again. Other factors could be the adverse effects of environmental regulations, the low rate of capital investment in the U.S. economy, and the decline in real support of research. After noting how little can be attributed to these factors, Griliches came to the following equivocal but not unreasonable conclusions:

> There remain three interrelated forces: the rise of energy prices, accelerating inflation, and errors in our measures produced by the inability of the existing statistical framework to cope adequately with such changes. To me they appear to be the most likely suspects in this case. The main source of this suspicion lies in the coincidence of timing and the fact that the productivity slowdown appears to be worldwide, and not just restricted to the United States. Hence, any explanation for it must be based on factors that are not unique to recent U.S. history. (pp. 12–13)

Table 3 shows quite clearly that the decline in productivity, as measured by labor productivity in manufacturing, has not been only an American phenomenon. Of eleven high income countries, all but one (Germany) had a decline in labor productivity in manufacturing in 1973–76 compared to 1970–73.

Agricultural Productivity

In recent years there has been concern that productivity growth has slowed in agriculture. The National Academy of Sciences expressed its concern on this issue in *Agriculture Production Efficiency*. That study concluded that while there was inadequate evidence to support the conclusion of declining agricultural productivity (through 1972 or 1973), there were some trends pointing in that direction.

Have the concerns noted in the Academy report materialized? Table 4 indicates that the answer seems to be in the negative. I say "seems to be" because the inadequacies of our data base make it difficult to be quite certain that the growth of agricultural productivity has remained unchanged in recent years compared to earlier periods. Stated briefly, our currently available total factor productivity measure for agriculture suffers from three significant defects: (*a*) a failure to measure most changes in the quality of inputs, especially labor and machinery; (*b*) the use of base periods for weighting inputs that are too far apart in time; and (*c*) the failure to adjust output measures for climate changes. Other problems or difficulties are detailed in an excellent report of a task force of the AAE/ Given these difficulties, one must be quite ci cumspect. If one accepts the data as they ar recognizing the qualifications, certain concl sions follow:

(*a*) The growth of total factor productivi in agriculture during the 1970s was at least a high as for the two decades 1950–70. Produ tivity growth was higher during the 1950s tha during the 1960s but the average for the tw decades was essentially the same as for tl 1970s.

(*b*) Agriculture has not suffered the si nificant decline in either total factor producti ity or labor productivity growth that has o curred in the nonfarm economy, either tl total or private, since the mid-1960s.

(*c*) There does not appear to have been ar significant decline in the rate of growth of a ricultural productivity after 1973, in contra to what occurred in the rest of the econom Thus, agriculture appears to have escape the sharp decline in productivity evident in tl nonfarm economy after 1973.

There is a rough independent measure growth of productivity in agriculture, name the change in output to input prices. This me sure suffers from whatever defects there ma

be in the price indexes used, but avoids some of the difficulties of measuring input quantities. It introduces, however, the difficulty of comparative resource returns in agriculture and the rest of the economy. It should be noted that change in the relative output-input prices in agriculture is not a measure of the absolute change in total factor productivity but of the change in relative factor productivity. If real resource returns in the economy were increasing at, say, 2% annually, and if the output-input price index for agriculture declined by 0.5% annually, the growth in agricultural productivity would be 2.5% annually.

The use of the measure assumes that the return to agricultural resources increases at the same rate as in the rest of the economy. If the returns to agricultural resources (labor, land, and capital) increase relative to the returns elsewhere in the economy, the decline in the output-input farm price index would underestimate the increase in agricultural productivity.

From 1960 to 1970 the adjusted parity ratio (1910–14 = 100) declined from 82 to 77, or by 6%. From 1970 to 1979, the decline was from 77 to 73, or by 5%. During each of these two decades, the returns to agricultural resources increased relative to similar resources in the rest of the economy. A rough indication of the improvement was the increase in the ratio of per capita disposable incomes of the farm population to the nonfarm population during the two decades.[1] During the two decades, the

increase in the ratio was from approximately 55% in 1960 to near equality in 1979, with the improvement in terms of points being approximately 20 during each of the two decades. It is true that much of the improvement in the relative incomes of the farm population has been the result of a more rapid increase of nonfarm than of farm income. But the farm production activities of the rural farm population adjusted and apparently adjusted very well to the labor force changes associated with the increased importance of nonfarm employment of members of farm families.

These rough comparisons are consistent with the view that agricultural productivity has been maintained at a relatively high growth rate for the past two decades. In addition, there seems to be no support for the view that productivity growth in agriculture was lower in the 1970s than in the 1960s.

Whatever factors may have been responsible for the slowdown in the growth of productivity after 1973 in the United States and other economies seem not to have had much effect upon agricultural productivity in the United States. Or if there had been some effects, the effects were not large enough to have been caught by our inadequate measures of productivity growth. We perhaps have more of a puzzle on our hands, because U.S. agriculture apparently has escaped unscathed from the dramatic economic events that have occurred since 1972, than would have existed if productivity growth in agriculture had slowed significantly.[2]

[1] This measure is a rough indication since no effort is made to determine the amount of resources per capita in agriculture and in the rest of the economy. Thus, it is possible that resources per capita increased much more in agriculture than in the rest of the economy, though I doubt if such a change could account for much of the improvement in relative incomes.

[2] At this meeting last year, Vernon Ruttan gave a paper with a similar title, "Inflation and Productivity." While there are a number of similarities in our presentations, Ruttan is significantly more pessimistic than I am concerning recent and future productivity growth in agriculture (p. 901).

In the longer run, there is likely to be some effect of national productivity growth upon agricultural productivity growth. While the current episode shows that this long-run potential has so far not had adverse effects upon our agriculture, it would not be safe to assume that the lack of effect can go on indefinitely. In any case, farm people realize the benefits of productivity growth primarily through the increasing value of human effort. Slow or nil productivity growth in the rest of the economy means slow or nil increases in real labor earnings and thus in the alternatives available for the use of the human capital of farm people.

Expected Adverse Effect of Inflation

Why should we expect that inflation would have an adverse impact upon agricultural productivity or output? There are three reasons why negative effects may exist. One is that the rate of inflation is not correctly anticipated. A second reason is that a change in the rate of inflation may have effects on the prices of some or most agricultural products relative to input prices. Finally, the policies and interventions by government in response to the inflation may have inhibited the appropriate responsiveness of the markets. Each of the reasons implies that inflation increases the degree of uncertainty confronting farmers—uncertainty about prices and availability of inputs since the government may impose price ceilings or force the rationing of credit or specific inputs.

The economy of the United States does not have many of the institutional relationships that permit it to exist moderately well with inflation. We still function with long-term bonds and mortgages with fixed interest rates. But there is an indication that the sharp and generally unexpected rate of inflation has led to the introduction of a number of modifications of debt instruments. These include variable rate mortgages, rollover mortgages, and the various certificates of deposits tied to short- and intermediate-term treasury security rates. I do not know if there have been variable rate or rollover farm mortgages written during the past year, but such a possibility must certainly be under consideration by some financial institutions.

Inflation and Resource Allocation

For a rate of inflation—say in the range of 5% to 20%—it is unlikely that the errors in resource allocation due to incorrect anticipations will have a significant impact upon the real output level or productivity. True, some, if not most, asset prices will need to be readjusted as the true rate of inflation is revealed, but actual resource misallocations will have been quite small, especially in the short run of one production period. I am not saying that the effect is nil; certainly one would not expect such a statement from the author of *Forward Prices for Agriculture*. But the uncertainty created by variable inflation rates is an addition to existing uncertainty rather than an entirely new phenomenon. Thus, we can hardly expect that the added effects of variable inflation upon uncertainty could be of sufficient magnitude to be picked up by our imperfect measures of output and productivity.

I know of but one study that may throw some light on the adverse productivity effect of very high rates of inflation. Unfortunately, the agricultural area involved was afflicted with civil disturbance as well as a high and apparently unexpected rate of inflation. Briefly, Dittrich and Myers obtained access to detailed farm management data collected by the Japanese for three villages in North China for various years from 1937–40. These data were used to fit production functions, which were then used to estimate the efficiency of resource allocation in the different villages and years. In one village data were available for three consecutive years. In 1937 it was estimated that the actual resource allocation compared to an *ex post* reallocation of resources resulted in an income loss of 1.4%. Between 1937 and 1938, farm prices increased by 21%; the income loss due to resource misallocations was 3.3%. Between 1938 and 1939, farm prices increased by 136%; the income loss from resource misallocations was 17.5%. The authors concluded: "The findings . . . suggest strongly that the peasants of these farm surveys—operating within a framework of traditional agriculture and private ownership of land—were able to allocate scarce resources fairly efficiently. This was true as long as economic conditions reflected by rising farm prices did not change very rapidly" (p. 895).

As a net debtor in terms of financial assets, farmers usually gain from an unexpected in-

crease in inflation rates. However, this benefit is through an increase in real wealth and has rather little effect on current output and productivity.

Farm Output Prices

The second reason for an adverse effect of inflation is that the fact of largely unanticipated increase in inflation may result in adverse changes in relative prices and thus reduce output. This effect may arise where the domestic prices of major farm products are significantly affected by international market conditions. This is the situation for many U.S. farmers. Unless the U.S. exchange rate falls, an increase in the rate of inflation in the United States relative to the weighted inflation rate in the export destinations will not result in an increase in the absolute price of U.S. farm products. While in the long run purchasing power parties are likely to be reflected in exchange rates, in the short run relative exchange rates can move quite independent of relative inflation rates. This has clearly been the case for the dollar exchange rate since last October and especially from January 1980. When real interest rates rose absolutely and became significantly real, the exchange values of the dollar increased significantly. Between January and April 1980, the value of the dollar increased 13% in terms of the Deutsche Mark, 12% in terms of the yen and 6% in terms of the pound. But, when interest rates fell in April and the U.S. inflation rate appeared to be on the way to stabilization or decline, the exchange rate for the dollar fell and by July has returned to approximately the levels of a year earlier. Consequently, during the period of high absolute and real interest rates from December 1979 through April 1980, farmers were faced with high capital costs and declining real product prices. Some product prices fell in absolute as well as real terms, though a partial source of the absolute declines for the grains and soybeans may have been the U.S. suspension of grain sales to the Soviet Union. But even if there had been no suspension of grain sales, the prices of grain and other export products would have been under pressure due to the strength of the dollar in response to the inflow of funds attracted by high short-term interest rates. Later, starting in April and May, there was an outflow of funds as U.S. short-term interest rates fell; the dollar lost value in the foreign exchange market, and the net effect was to provide some strengthening of the dollar prices of major export products compared to what they otherwise would have been. In the context of circumstances in 1979/80, high interest costs were not offset by farm prices of the major export product rising at approximately the same rate as prices generally; in fact, quite the contrary occurred. High relative U.S. interest rates put downward pressure on the domestic prices of many farm products for a period of several months. These were critical months because many planting decisions had to be made during the period.

Since the slowdown in the inflation rate has been associated with a recession-induced decline in demand for the farm products with positive income elasticities of demand, the potential positive domestic price effect of the decline in the U.S. exchange rate has been at least partially offset by domestic events. The U.S. market for feed grains and corn is sufficiently large that changes in the domestic market can affect international market prices.

It is probable that the consequences of varying and unanticipated changes in the rate of inflation have had some small negative effect upon agricultural output and productivity. But these effects have been too small to be reflected in our measures. Not all of the consequences of the inflation-dominated events of 1979 and 1980 will be felt in the short run; both farmers and financial institutions will almost certainly modify their behavior for some time to come.

Governmental Policies

I will not dwell on the third reason for an adverse effect of inflation upon output and productivity—namely, governmental policies instituted in response to political demands to "do something about inflation." The sharp increase in interest rates, and the probable severity of the 1980 recession, resulted from an unwillingness of the administration to take appropriate action to reduce inflation before late 1979. By then, circumstances demanded that drastic action be taken by the Federal Reserve System. The drastic action taken will have ramifications upon prices and output for all of 1980 and probably well into 1981. One can only hope that since we have received the shock, it will not be all for naught because of a

rapid shift from contraction to expansion in the money supply.

Slow Economic Growth

Far, far more disturbing than any of the effects of inflation upon productivity in agriculture is the slow rate of growth that has afflicted our economy for the past decade. Sooner or later, and probably sooner, the competitive position of U.S. agriculture in world markets will be eroded by the slow growth of our economy. Agriculture's strong position in world markets is the result of efficient and competitive markets for inputs and outputs. The dynamic nature of American agriculture is due to the characteristics of our farm operators, the investment in research, and the rapid translation of research results into useful inputs produced at competitive prices (Johnson). One important advantage of U.S. agriculture has been an efficient, low cost transportation system to move products from the farm to the city with reasonable dispatch, and remarkable responsiveness to the rapid growth of exports. But important components of the system, particularly the railroads, appear to be on a path to disintegration at worst and much higher costs at best. We seem to be paying the price for a regulatory atmosphere that has never had the capacity to look more than a year or so into the future or to understand that the sources of competition for rail transport have changed in a century. Agriculture has not been without fault in the disintegration of the rail system—it has long pressed for low rates in the forlorn hope that someone else would pay to keep the system in a state of good condition and repair.

Inflation and Value of Assets

Earlier, I noted that farmers, as net debtors, gained from unanticipated increases in the rate of inflation. I gave no emphasis to this gain, noting that it did not significantly affect resource allocation. This is not strictly correct, since wealth is a variable that affects a number of decisions, such as consumption-savings or the form of investment or the desirability and availability of credit.

There is a potential effect of inflation that I have not mentioned, namely, the effect of farm land being considered one of the few good inflation hedges. Farm land prices have increased in real terms for the last four decades and have done so almost every year. However, during the past twenty years there seems to have been little relationship between the rate of inflation or the change in the rate of inflation and the size of the increase in the real value of farmland.

The price behavior of farmland does not appear to differentiate it from other types of real estate. Housing prices appear to have behaved in approximately the same manner as agricultural land prices. The only possible difference is that farmland is a major production asset for agriculture and, except for mining and forestry, this is not the case for other types of production. Thus, to the degree that farmland has been an inflation hedge and part of its current price so reflects, the acquisition of land becomes more difficult for those who must acquire it by purchase. But except for the greater difficulty of acquisition, primarily because our credit system does not provide for 100% loans, the fact that farmland is an inflation hedge is a disadvantage only if it should cease to be such a hedge. At that time, the owners of land would suffer a capital loss.

The very large real capital gains in agriculture during the 1970s have perhaps been an important factor in the ability of farmers to adjust to and to overcome the unanticipated events of the decade. In terms of 1967 dollars, the value of farm proprietors' equities increased by \$110 billion, or almost 50% (Melichar and Waldheger, p. 34). The real value of liabilities increased by less than \$22 billion. While there have been numerous claims that farm operators who have acquired their farms since 1972 have suffered such severe financial problems that increased foreclosures were inevitable, data through 1979 show no increase in the percentage of farm real estate sales due to foreclosures (Melichar and Waldheger, p. 57). The situation in 1980 and 1981 may be different, given the sharp drop in farm income that is likely to occur in the second half of 1980.

One reason that farm financial troubles have not dominated the agricultural concerns in recent years has been that during the 1970s real interest rates paid on all farm mortgages have been significantly negative. During the 1970s, prices received by farmers increased at an annual compound rate of 9%; interest rates on outstanding mortgage debt averaged about

7%. And it was not until 1979 that short-term interest rates paid by farmers were significantly higher than the annual rate of increase of farm product prices.

Concluding Comments

The inflation experienced by the United States during the 1970s has not had a measurable impact upon agricultural production or productivity. This statement should not be assumed to mean that inflation has had no effect, but simply that our measures are not sufficiently refined to pick up what effects there may have been. The prices of major export products were erratically affected by the high rate of inflation in 1979/80, the monetary policies that resulted in high rates of interests and a short-run significant increase in the dollar exchange rate.

Some of the potential adverse effects of inflation on resource use may have been offset by the positive transfers received by agriculture as a result of land's role as an inflation hedge and the negative real rates of interest that have prevailed in most years since 1972. Since agriculture is a very capital-intensive sector of the economy, its output may have been favorably affected by a low real cost of obtaining and holding capital.

The most alarming aspect of the performance of the U.S. economy since 1973 has been the low rate of productivity growth and the modest or nil growth of real wages. American agriculture is highly dynamic and progressive, but much of that dynamism depends upon the way in which the rest of the economy functions. When the rest of the economy is sluggish and floundering, eventually agriculture must be affected adversely.

Inflation, Agricultural Output, and Productivity: Discussion

John E. Lee, Jr.

A year ago Vernon Ruttan stood before you and stated that productivity growth in agriculture had definitely slowed and that inflation was partly responsible. Today, D. Gale Johnson stood before you and said productivity growth in agriculture had not slowed—was in fact growing faster than in the 1960s—and that inflation has had no measurable impact. Clearly the issue is not resolved and further investigation is in order.

A general complaint about both the Ruttan and Johnson papers is that while they contain some very interesting and useful observations, neither offers a rigorous analytical explanation of the cause and effect relationships between inflation and productivity. Thus, the value of Johnson's ideas will be enhanced if they inspire other economists to trace analytically and systematically through what theory suggests the impact of inflation should be on output and productivity, and then test those theoretical constructs against the evidence available.

Johnson's paper as well as the one by Ruttan reflect two rather general problems for the profession. The first is that the data and measures needed to trace the relationships in question are indeed less than perfect. The other is that as a profession we have done so little rigorous research on the subject of either inflation impacts or productivity that we are not quite sure what the questions are, let alone how to answer them.

Johnson suggests several reasons for the slowdown of productivity growth in the general economy. No doubt these are all contributors. I would suggest a few others that I believe are equally important. The first is the widespread emergence of an "inflation psychology." This is a relatively new phenomenon for this country, but I submit that it has had a major and pervasive impact on how people behave with regard to their economic and financial affairs. People save less, borrow more, and shift investments from production processes to appreciable assets.

A second important factor has been the growth of productivity-depressing institutional constraints. Johnson mentions environmental regulations. These are perhaps the most visible. But the examples are much more numerous and arise from the abuse of private power as well as from public policies and programs. The costs associated with these constraints add nothing to output. But they make the process of doing things slow, frustrating, and expensive.

Productivity also may be affected by a technological maturing process. The history of inventions reveals that technological developments tend to come in bunches. One breakthrough leads to another and a synergistic interaction evolves. Then there is an exhaustion of these developments until there is another breakthrough. There is an S-curve kind of effect with an accelerating phase and a decelerating phase. In a large and complex technological society there are always many subordinate S-curves which aggregate up to the national technological situation. Each of these may be in a different stage. But there are aggregate variations over time related either to an explosive interaction of subordinate technological developments or to some major event. The pent-up technology from World War II led to an explosion of new developments and a growth in productivity through the 1950s. There was a similar impact from the space program of the 1960s.

No doubt higher energy costs have had their impacts. But one must be careful not to attribute too much to this source. First, theory tells us that a change in relative factor prices should lead to an adjustment in factor mix, but not necessarily to general inflation or a decline in productivity. In fact, we know that the many constraints and market imperfections do not let the adjustments take place perfectly, at

John E. Lee, Jr., is Director, National Economics Division, ESCS, U.S. Department of Agriculture.

least in the short run. And in the real world there may never be a long run—only an endless series of short runs.

The second point about energy as the villain is that the real price of imported oil rose only twice in the 1970s: 1974 and 1979.

If Dr. Johnson's observation is correct that the rate of productivity growth was high in the 1950s, dropped in the 1960s, and rose again in the 1970s, one could hypothesize a number of explanations. A starting point might be to examine where the farm sector is on its aggregate production function and developments that may have caused shifts or changes in that function. Another possible explanation of what happened in the 1960s has to do with the way land is handled in the productivity statistics. Land diverted under commodity programs is included in inputs. Diversion increased in the 1960s relative to the 1950s, thus reducing productivity as measured. Diversion then dropped sharply in the 1970s, thereby increasing the measured productivity. Had diverted land not been included in inputs, the opposite productivity pattern would have resulted, especially since diverted land likely was less productive than land actually used in production.

Johnson suggests as an alternative measure of productivity change, the change in ratio of output prices to input prices. I interpret this to mean that if productivity increases, output prices will decline relative to input prices and the ratio will decline. Decline in this ratio is added to the real rate of returns to resources in agriculture to obtain the total increase in productivity. The empirical measurement problems with this approach are obvious, as Johnson notes. The necessary assumptions are also quite demanding. The ratios of prices received to prices paid can change for a variety of reasons. Tweeten's work suggests that inflation generates a real price effect or a cost-price squeeze, lowering the ratio of prices received to prices paid by farmers. Thus, Johnson's measure would not appear to be useful in the context of attempting to measure the impact of inflation on productivity if the measure of productivity being used has already been distorted or biased by inflation!

It is suggested that we have a puzzle on our hands because U.S. agriculture apparently has escaped unscathed from the dramatic economic events that have occurred since 1972. Perhaps not. I believe it is logical and explainable that productivity in agriculture has been less adversely affected by events since 1972. Energy costs are a smaller part of total cost of production in agriculture than in many other sectors. Events since 1972 have expanded exports, thus increasing utilization of a fixed capacity (land base). Third, capital investment has continued high in agriculture, financed in part by increased debt financing, encouraged in turn by low real interest rates, tax incentives, liberal credit terms, and plentiful supplies of loan funds. Finally, agriculture is still primarily a sector of sole proprietorships (although legally some are incorporated) where operators and families do most of the work and use relatively little hired labor. Despite farmers' complaints about regulation, they are relatively unconstrained compared to nonfarm business, especially the corporate bureaucracies. I really believe this is a significant factor.

Johnson indicates that the United States does not have many of the institutional mechanisms that permit it to exist moderately well with inflation. He suggests that we still function with long-term bonds and mortgages with fixed interest rates. This is not true for the farm sector. Federal land banks which now supply most of the institutional credit secured by real estate, instituted variable-rate mortgages in 1970 and now most of their loans are on variable rates. Even for production credit many banks have, in effect, gone to variable interest rates. They did this by substantially shortening the length of loans, thus requiring more frequent refinancing at new interest rates. With much shorter term loans in their portfolios, banks have also been able to respond much faster this year to changes in directions as well as magnitudes of interest rates. After decades of depending on fixed-rate passbook savings as a source of funds, and lending at fixed rates, agricultural bankers made the transition rapidly and remarkably well to a new world of borrowing via money market certificates with high, and highly variable, interest rates and making production loans for terms shorter than the production season and at rates pegged to the prime rate!

Johnson's explanation of commodity price developments over the past year (i.e., inflation caused high real interest rates, which caused rising value of the dollar which caused declines in export demand) fits textbook theory but does not square with the facts as I observe them. I believe this approach attributes too much to the impact of exchange rates. If one

examines the data carefully, one discovers that we had phenomenally large supplies of grains, but these were offset by stronger than expected export demand. Between July and December of 1979, successive crop reports added 1.1 billion bushels of corn to production estimates. This was nearly three times as much as the 400 million bushels not shipped to the Soviet Union. In addition, we had record large wheat and soybean crops and supplies. But exports continued to strengthen. Weekly shipments of grain from U.S. ports were at record levels. In fact, exports were so strong that we not only seriously under-forecasted the value of export sales but, more impressive, grain prices stayed remarkably (and surprisingly) firm despite the loss of sales to the Soviets and record large supplies. Thus, while grain prices might have been stronger had the value of the dollar not strengthened, I believe it would be difficult empirically to support Johnson's statement that "high relative U.S. interest rates put downward pressure on the domestic prices of many farm products for a period of several months." He goes on to say "these were critical months since many planning decisions had to be made during the period." I believe farmers were as concerned about supply of funds as about interest rates. Moreover, when the plantings data were in there were no discernible effects of high interest rates and fund shortages on acreages planted.

I am sympathetic to Johnson's lament about the erratic and over-reactive public policies, especially monetary policies, for dealing with inflation and the damage this erratic behavior will do to patterns of investment and resource allocation—hence productivity.

I also strongly agree that the slow rate of growth in productivity in the general economy is a far more serious threat to the nation's well-being than the small effects inflation might have had on agricultural productivity. Problems created for the rest of the economy will inevitably have adverse spillover effects on agriculture.

The Johnson paper is stimulating. I believe his general conclusions about productivity to be essentially correct. Moreover, the linkage between inflation and agricultural productivity is of more than academic concern. That will become clearer in the future when the cropland base is fully utilized (no idle acres). In that case, if demand for farm products is increased and if inflation is a concern, productivity growth in agriculture will be the key to whether real prices of farm products will rise (thus redistributing income to farmers and landowners and exacerbating inflation) or fall (thus ameliorating inflation and redistributing income from the farm sector to the rest of the economy and to the rest of the world).

nflation, Portfolio Choice, and the Prices of ,and and Corporate Stock: Discussion

ames P. Houck

he paper by Martin Feldstein presents a ovel approach to asset pricing over time. It eparts from the present value and discounted te-of-return models familiar to most agricul- ral economists. By introducing differential x rates, portfolio balance concepts, and un- ertainty, it highlights demand-side forces hich affect relative prices of land and other ssets in the presence of general price infla- on.

This paper is an excellent example of how a mple, but plausible, model can be used to uminate complex ideas and shed light on atters often befogged by fuzzy debate. It is so an excellent example of how even a sim- e model can become almost unmanageable alytically when uncertainty and covariance e introduced among variables. Feldstein es his mathematics to illustrate economic asoning and make it more explicit. It is to his edit that he did not let mathematics get the pper hand in his paper, but it was a close call, my judgment. In what follows, I will men- on a few rather technical points and then nclude with some general comments about e paper's approach and results.

In order to linearize the rate-of-return ex- essions for land, capital, and treasury bills, l price variables are expressed as rate-of- ange indexes based on previous-period val- s. Then, the various asset prices and the tput price level are expressed relative to a meraire and, later, relative to each other. In der to grasp fully the implications of the odel manipulations, it is important for the ader to understand clearly how the author fines his prices and their changes over time. few more words of explanation on this topic rely would not have been a mistake.

The expected-utility expression in equation) is a standard formula for readers ac- ainted with the literature in this field. It would be to Feldstein's advantage to clarify for others that the 0.5 coefficient is not simply an arbitrary value introduced to simplify cal- culations but a fundamental part of the analyt- ical equation when λ is defined as the risk- aversion measure (Freund, p. 255). It be- longs there.

In my opinion, the introduction of uncer- tainty as it affects rates of change in land and capital prices and their respective marginal products is not as explicit and clear as one might hope. It is a bit too formal as it stands. Some plausible and quasi-realistic examples of factors affecting the relevant variances and covariances would have been enlightening, helping the reader to bridge the gap between the real world and the abstract theory.

On a more general note, I believe that the author should have noted explicitly that the inflation rate (π) is fully exogenous to this analysis. Inflation, in this model, affects rela- tive prices of land and capital, but is not af- fected in return by changes in these prices. There is no feedback. To relax the implicit assumption that inflation falls on this model like rain probably would unleash a hopeless computational tangle, but at least the point should be made.

In a similar vein, the reader also should notice that, while expectations about the rate of inflation are subject to uncertain variation, the inflation rate itself is not a random vari- able. I have a feeling that stochastic fluctua- tion in this variable in the real world is likely to be relatively more important than random vari- ation in some other things, the marginal prod- ucts of aggregates of land and capital, for in- stance.

Feldstein mentions several times in the text that the analytical results which emerge are creatures of four sets of variances and covariances, a differential tax system, and the inflation rate. Land and capital are exactly the same on the supply side; they are fixed. Thus, "reproducible" capital (K) is not reproducible

mes P. Houck is a professor, Department of Agricultural and pplied Economics, University of Minnesota.

at all within the model's context. While relaxation of this constraint transcends Feldstein's current analytical capacity (and mine too), the reader must keep in mind that these theoretical results do not depend at all on the fact that land and any sort of capital are fundamentally different from each other.

Thinking about this point leads me to suggest a partial approach to the matter. Assume, plausibly I believe, that people wish to own land because it is "different." This yen, or yearning, may not be coldly rational, but it does exist and is not random. It is a desire to hold land for reasons beyond productive or speculative returns. One could add a term to reflect this component of land demand to the wealth expression in equation (2), making the land-wealth portion $[(R_L + y_i)\cdot L_i]$, where y_i is the noneconomic measure of "wealth" attributable to holding a unit of land. Expressions could be added to explain y_i either individually or collectively for the society-wide aggregate of the y_i's which would appear ultimately in equation (10).

The marginal productivities of land and capital depend not only upon the amounts used i production but also upon underlying produc tion functions. Consequently, the derivative of equations (33) and (34) with respect to ϕ and ϕ_K illustrate how relative prices adjust a technology changes in a non-neutral way Under Feldstein's assumptions about θ, c, an $dr/d\pi$, an increase in land productivity woul unambiguously increase relative land prices the increase dampened to the extent that risl aversion and uncertainty enter the analysis Considering historic productivity trends, thi relation also may add to the explanation of th recent real-world land price phenomenon.

Overall, this is a good paper. It adds usefu perspective to a controversial area of stud and debate in agricultural economics. But i would be a mistake to argue that the matter i now settled.

Impacts of Federal Tax Policies on Potential Growth in Size of Typical Farms

Charles W. Eginton

Federal fiscal-monetary policy may have contributed to growth in size and declining numbers of farms by encouraging substitution of capital for labor. This paper reports implications of taxation policies for typical farm firms. To what extent have concessionary tax policies such as interest payment write-offs, depreciation allowance, and investment tax credit encouraged growth in size of family farms? To answer this and other questions relating farm firm growth to consumption-savings rates and ownership patterns, a computer model was developed to simulate growth over a thirty-year horizon. Simulations for six typical commercial family farms provided data on rates of growth in discounted net worth and on changes in size, ownership patterns, and in realized taxation rates with and without selected federal income tax features.

Benefits and costs associated with land purchases in inflationary times are unevenly distributed. Farmers who are able to meet the initial cash flow or who already have survived deficit years are more able to afford purchases, thereby accelerating the trend toward fewer and larger farms. A solution to the eventual cash flow shortfall has been suggested by Melichar's finding that increases in land prices will be consistent with productivity increases. Both Tweeten (1980a) and Melichar emphasize the importance of capital gains in the farmer's balance sheet. Tweeten shows that the existence of capital gains as deferred earnings allows the cash flow balance to offset the inflation-induced high mortgage interest rates. He has further shown that preferential tax treatment on capital gains will cause a shift to and from alternative investments by high-income investors.

Tweeten demonstrates that national inflation defers returns and raises immediate costs of farmland, thereby contributing to cash flow problems. Melichar showed that the cash flow problem is exacerbated by land earnings increasing faster than inflation, transforming farmland into a "growth stock." The result is that inflation tends to favor growth of farming units with sufficient equity positions to weather cash flow squeezes. Federal income tax provisions influence cash flow and, depending on the tax bracket and concession, affect the growth rates of farms.

A deterministic simulation model was developed to analyze farm growth. The model is designed to use USDA "Typical Farm Data Series" for 1979. These estimates of typical farm sizes, farm enterprises, labor requirements, land prices, and machinery complements were provided by Fawcett. From this data base, the model simulates thirty years for a farm operation oriented toward growth. Net taxable farm income is calculated using a 4% return-to-equity estimate developed by Tweeten (1979), and an operator labor-management return calculated within the model. Federal taxes are deducted from taxable income along with the family's projected living expenses and mortgage payments. The resulting annual cash flows are then used for growth. To determine the effects of various tax policies, after-tax incomes can be calculated with and without the tax feature under study. This approach allows estimation of the impact of a specific tax policy and comparison of the relative impacts of different tax features.

Numerous studies have assessed the impact of farm-related public policy on the structure of agriculture. Impacts of national fiscal-monetary policies on farm structure are now commanding attention. This study extends the research to examine interaction between inflation and taxation as forces changing farm structure and composition. Is the ideal of an owner-operator and family providing most of the labor, management, and capital for an economic farming unit doomed? Tweeten reports (1979) a chief obstacle to the family farm

Charles W. Eginton is a graduate research assistant, Department of Agricultural Economics, Oklahoma State University.

ideal is obtaining sufficient capital in the face of cash flow problems created by inflation. To show that the family farm ideal is still viable, for those fortunate enough to have adequate initial net worth, a zero initial-year cash-flow position was determined for the economic unit farms of the study. The initial tenure position was determined from a cash flow equation.

The cash flow equation is

> income from land [.04 × (value of acres owned and mortgaged)] + operator and family labor returns [2,600 hours × (farm labor wage rate)] + operator management return [.07 × (cash receipts)] + returns to investments in machinery [equity in machinery × (value in use of machinery complement)].

The cash outflow equation is

> living expense [$12,600] + mortgage payments [mortgage payment per acre × (1-equity requirements) (acres owned)] + federal income and self-employment taxes.

For the zero-cash-flow starting position, the inflow and outflow equations are set equal and solved for the number of acres owned. The result shows the maximum number of acres to which the operator can obtain title, subject to equity and other constraints listed in the equations. Remaining acres in the economic unit are rented. Inflation has increased the value of an economic unit providing full-time labor for a farm family to the point where a full-time farmer must be a high wealth individual to survive in farming.

The initial values of the six economic units in 1979 ranged from 1–2 million dollars. By using rental strategies to control enough land to fully use available labor and maintain a 30% equity in machinery, the entry level farmers on these six units needed an average of $206,500 in initial net worth. This initial net worth invested in farming provided a labor-management return of $12,600 with a zero cash flow in the initial year. Holding real dollar consumption at this level for thirty years, the firm applies all additional income to growth. From this high risk position of maximum leverage, the farmer can rapidly become a high income earner due to returns to capital gains on equity. As farm incomes become larger, the values of tax concessions increase because of graduated income tax rates. The importance of these tax concessions is further enhanced by inflation. The high income needed to realize large benefits from interest payment write-offs was met by typical family-operated economic units considered. These family farms are sufficiently capital-intensive to realize sizable benefits from depreciation allowances and investment tax credits. All of these tax benefits require high income and/or wealth available for investment. Capitalization of these tax benefits into the prices of agricultural inputs has placed low income, entry-level farmers at a severe disadvantage. Expansion of farm size as depicted by the growth in typical farms shown herein means fewer farms, although changes in size and numbers are exaggerated because growth tends to be at maximum levels unconstrained by risk, high consumption levels, competition among buyers for land, and other such factors.

The results of three experiments on six farms are reported in tables 1–6. The zero initial-year cash flow, minimum equity part-ownership starting position is used as a benchmark for comparison. The growth patterns and rates are tabulated along with the effective federal income tax rates for the initial and final years of the simulation. The constant dollar value of the estate transferred after inheritance taxes is reported as a percentage of the initial net worth to measure capacity for continuation of the typical family farm from generation to generation. The three general experiments, or alternatives to the baseline, reported here relate to (*a*) initial tenure, (*b*) consumption pattern, and (*c*) tax policy.

Baseline Case

Six typical commercial farms were chosen from a USDA typical farm series (Fawcett and Thornton). Space limitations precluded reporting results for all twenty farms in this data series. The farms used in this report represented a cross-section of the agriculture sector and include most of the major crop and livestock products. Because the concept of the family farm is basic to this study, all of the farms chosen have annual labor requirements of approximately 2,600 hours. Simulations were computed for various inflation rates, but all of the simulations reported here assumed a 6% average rate of inflation over thirty years and a real rate of interest of 3%. All mortgages are constant-payment, thirty-year, 9% loans. Income is generated from returns to equity, labor, and management.

Because of the high net worth requirements, it is presumed that the baseline farmer begins operation of the economic unit at age 35. This

lows time to accumulate the machinery and ıpital required to operate an economic unit ;ing a rental-ownership strategy. This rela- vely late start has implications for the estate ansfer. It is assumed that the farmer survives s thirty-year growth horizon, but no more. ederal income tax provisions and tax rates ıdexed) for 1979 apply to the entire thirty ;ars. The farming operation is transferred to ıe next-generation heir at 1979 estate tax tes indexed to inflation. (Or, two heirs re- iving half as much each could marry two ;irs with like inheritance to form a farming ıit.) The question considered was: Can a owth-oriented farmer start a family member an initial position equal to or better than his vn initial position?

To compare real net worth for various years ıder an inflationary scenario, dollars are dis- ›unted back to the initial year (1979) in tables -6. The percentage of annual change also is re- ›rted as a ratio of constant dollar values. The sults for the baseline cases show the dis- ›unted real net worth for all the farms grow- g at 6.3%–6.8% rates. The Oklahoma farm able 1) and the Illinois farm (table 3) had the ghest growth rates and experienced the eatest increases in taxation. If estate taxes e indexed for inflation as in the baseline ıse, they do not appear to be confiscatory. ach of the baseline farmers was able to trans- r a larger equity, and hence capacity, to form 1979-type economic unit than he began with. f course, alternative assumptions concerning ımber of heirs change the results. As the rmer expands, higher income forces him to higher tax brackets. The current grad- ıted income tax has the effect of slowing ›wn the rate of growth even when indexed r inflation. This is shown by the consistently wer growth rates for the later years of the nulation.

ıitial Tenure Experiment

he baseline scenario featured a part-owner veraged to the furthest extent permitted by ısh flow. Different initial ownership positions fect growth rates for all farms studied. The ıtes of growth in discounted net worth appear be correlated with the degree of initial verage. The greatest rate of expansion in net orth is for an initial full renter. Both the full ›nters and the zero-cash-flow baseline farmers were able to gain ownership (though not necessarily with full equity) of an economic unit within the thirty-year growth horizon. The full renter consistently could remain in the lower tax brackets, while the full owner's growth was restricted by higher tax rates. The very high initial net worth of the full owner combined with high estate tax rates reduced the percentage of initial net worth transferred. The greater absolute increase in net worth and acres for the full owner supports the widely held view that the established owner-operator is in a position to outbid competitors for land.

Alternative Consumption Experiment

In this experiment the baseline case of constant minimum consumption levels regardless of income was modified to allow consumption to increase with income. The consumption function used specified 70% of the cash flow surplus for additional family spending beyond the $12,600 minimum level. The increased consumption reduced investment rates and annual cash flows thus limiting the farmer's ability to service additional mortgages. This change had a greater effect on firm growth than any other changes from the baseline case. In four of the six farms, increased consumption levels prevented growth beyond the initial family size. Additional consumption reduced the number of acres mortgaged in the thirtieth year of the simulation of the Minnesota farm (table 2) from 348 to 62. The dampening of growth would have been more pronounced with higher consumption had not lower federal taxes attended the high-consumption scenario. Because of space limitations, only selected results are presented here, but other data show large combined effects of consumption and tax policies on growth.

Alternative Tax Policy Experiment

Four tax policy alternatives illustrate the importance of various tax concessions to farm growth. The baseline situation was simulated with all available tax advantages in 1979 (selected alternatives such as cash accounting and income averaging were omitted because they would have little impact in the deterministic simulation used herein) and then rerun with one tax advantage eliminated. ffering value distribution between real and ɔnreal estate assets among the typical farms fluenced the sensitivities to changes in tax ɔlicies. Capital improvement-intensive farms ɪeanut, table 4 and hog, table 5) respond ore to depreciation and investment tax cred-ɜ, while land-oriented farms derive relatively ore benefits from interest payment write-ffs. Interest payment write-offs were shown be extremely important for all farmers with :pansion opportunities. The value of the tax ɪncessions is most easily seen by the effect ı the federal income tax rate paid in the final ɜar of the simulation. Using this measure, the rgest tax decrease would result from index-g income tax rates. The Washington farm able 6) shows a decrease from 194.8% to ɔ.3% effective income tax rate. Removing ɪy of the existing tax advantages would in-ease the effective tax rates for farmers. terest payment deductions appear to en-ɔurage expansion in acreage, while deprecia-ɔn and investment tax credit benefits en-ɔurage the substitution of purchased capital r other inputs.

ımmary

ntry-level family farmers failed without tax ɔncessions. Termination of favorable tax eatment would mean trauma to a financially eak owner who purchased farmland with ex-ɜctations of continuing tax benefits. Of the x experiments, interest payment write-offs ıd the greatest effect on rates of farm growth ɪ subsidizing leveraged purchases of land, us accelerating the trend toward fewer and rger farms. Upward adjustments in real farm ze necessary to realize a given labor-anagement return in the face of changing chnology and the growing opportunity cost farm labor are not considered in this report. igher growth rates permitted by utilization of deral income tax provisions increase com-ɜtition for farms, crowding out some existing rmers. The established full owner is in the est position to compete for land, but progres-ive tax rates appear to diminish this advan-ıge. An alternative worthy of research is lim-ations on tax concessions such as interest ayment write-off and depreciation allow-nces to set dollar amounts (as investment tax redits are now limited) to prevent continuing inflation from preferentially subsidizing super farms to grow even larger.

The depreciation tax benefit had less impact on the expansion of the land-dominated farms studied; however, the highly mechanized, capital-intensive farms grew at rapid rates due to the depreciation allowance. The net effect over the long run was to encourage the use of capital relative to labor, thus exacerbating the trend to increased size and reduced numbers of farms.

Investment tax credit concessions benefited all farms, with capital-intensive farms benefit-ing proportionally more than the land-intensive farms. Each farm in the study was able to increase its growth rate due to the combination of tax benefits presently avail-able. Growth rates were also found to be highly sensitive to savings rates. Indexed in-come tax rates were extremely beneficial to all farmers. In every case, the effective tax rate in the thirtieth year was decreased by at least 100% by indexing. With the 6% inflation rate results reported here, farmers were able to use the existing tax provisions effectively, thus reducing the severity of nonindexed income tax rates. With higher (currently existing) inflation rates, options to avert very high (maximum) tax rates are diminished.

Finally, implications of estate tax policies for intergenerational transfer of family farm firms were briefly considered. For the experi-ment, the initial ownership position was the most important determinant of value trans-ferred. Consumption patterns during the simu-lation also had a major impact on the relative size of estate and thus on after-tax transfer. Combined effects of high initial net worth and high inflation rates on estate taxes increase the value of indexing inheritance tax rates.

This study illustrates that substantial real capital gains can be expected for farmers oriented to expansion at the expense of cur-rent consumption. Each farm's operation be-gins with control (rent or ownership) of a typi-cal commercial farming unit, with growth measured by accumulation of owned land, first by purchasing formerly rented acres and then by expanding the size of operation beyond the initial family size. Growth is triggered and lim-ited by cash income. The impact that cash flow rather than equity is the limiting factor in firm growth is consistent with previous analysis emphasizing the contribution of inflation to the cash flow problem facing newly established and expanding farmers (Tweeten, 1980a).

Land Ownership Restrictions of the Midwestern States: Influence on Farm Structure

Philip E. Harris

Proponents of the family farm recently have been successful in getting some legislatures of midwestern states to pass laws that restrict the rights of aliens and corporations to control farm land (Morse, Reeves, Harl, p. 61). These laws are not the first to limit aliens in their rights to own real estate (Zagaris, pp. 38–39). For example, the common law rule in England prior to 1870 prevented aliens from acquiring good title to land without the king's approval (Blackstone, vol. 2, pp. 249–50). The reason for limiting rights of aliens made sense in the feudal system that existed when the common law rule arose. In that feudal system, the king granted land to lords (and the lords in turn granted land to lessor lords) in exchange for a commitment to furnish specified goods or services—including service in the king's army. An alien was likely not to have the necessary loyalty to the king to uphold his obligation to provide such services. Therefore, to reduce the risk of conveying land to a party who would fail to perform the services promised, the law eliminated aliens (except those approved by the king) from the class of people that could hold land. The logic behind the current interest in restricting land ownership is not so simple.

The primary objective of current laws that restrict the ownership of farmland by aliens and corporations is to influence farm structure by preserving the family farm (Minn. Stat. Ann. Sec. 500.24 (1), Supp. 1979; S.Dakota Compiled Laws Ann. Sec. 47-9A-1, Supp. 1979; Neb. Rev. Stat., Sec. 76-1501, 1976). There are important legal and practical limitations to the effectiveness of restrictive laws in attaining that objective. Some of those limitations are discussed in the second part of this article. The first part of this article summarizes the laws of the midwestern states that restrict the rights of aliens and corporations to control farmland.

Land Ownership Restrictions

The following are definitions of some key terms as used in this article.

A "family farm" is a farming unit that is owned and operated by people who are closely related by blood and/or marriage. A corporation, or any other business entity, will be included in the term "family farm" as long as the entity is engaged primarily in farming and is controlled by members of a family. The characteristic that most clearly distinguishes a family farm from other farms is that the members of the family have management control. That characteristic would be seen by most proponents of the family farm as an essential element without which many of the benefits of family farms would be lost. Another characteristic that distinguishes most family farms is that the majority, if not all, of the labor is performed by members of the family. While this characteristic is probably not as universally important to proponents of the family farm as the management characteristic, many people would be less favorable to protecting a farm where more than one-half of the labor was supplied by non-family members than to protecting farms on which family members provided most or all of the labor. The final characteristic that sometimes distinguishes a family farm is ownership of the farm land by the family. This characteristic is less common and probably would be viewed by most proponents of the family farm as not an essential element as long as the family farmer is assured of the availability of land to farm.

Philip E. Harris is an assistant professor of agricultural economics and assistant professor of Agricultural Law-Extension at the University of Wisconsin and member of Wisconsin, Iowa, and Illinois bars.

Helpful comments by William D. Dobson, Marvin B. Johnson and D. David Moyer are gratefully acknowledged.

"Corporations" will include corporations formed under the laws of any jurisdiction for the purpose of making a profit except those that are included in "family farms" as defined above.

"Aliens" will include only those people who are not U.S. citizens and who live outside the United States. Therefore, "resident" aliens—citizens of other countries who live in the United States—are not included.

Laws of Midwestern States

The restrictive laws enacted by the legislatures of the midwestern states are quite diverse in their approach to limiting corporate and alien ownership of farmland. The following summary of the laws of thirteen midwestern states is intended only to provide an idea of the types of restrictions used. Morrison and Krause, and more recently, Morse, Reeves, and Harl have thoroughly compiled and discussed the restrictive laws of all the states.

The following table shows that eight of the states whose statutes were examined directly prohibit corporate ownership of farmland and ten states either prohibit alien ownership of farmland or limit the amount aliens can own. Six states include businesses controlled by aliens in their prohibitions. Four states prohibit leasing farm land by aliens and corporations and seven states prohibit corporations from engaging in farming.

The exceptions to those restrictions are too numerous and varied among the states to be catalogued here. A few examples will be illustrative. The most common exception is for corporate ownership and use of farmland for research, production of seed stock, or similar activities. Some states allow corporations or aliens who owned land on the effective date of the law to retain the land they owned and, in some cases, to acquire more land to accommodate a reasonable rate of growth. Most of the states provide a period of time for an alien or corporation to divest land they are prohibited from owning or to become eligible to own the land.

In addition to the above restrictions, seven of the states require corporations, aliens, and

Table 1. Summary of Laws of Thirteen Midwestern States Restricting Agricultural Land Ownership

	Laws				
States	Prohibits Owning Agricultural Land[a]	Prohibits Leasing Agricultural Land	Limits Amount of Agricultural Land That Can Be Owned	Prohibits Farming	Requires Reports[b]
Illinois	A[c]				
Indiana			A[c] (320 A.)		
Iowa	C, A, AB	C			C[d], A, AB
Kansas				C	
Michigan					
Minnesota	C, A, AB			C	C[d], A, AB
Missouri	C, A, AB	A[e]		C	C[d], A, AB
Nebraska	C[f], A[c], AB				C[d]
North Dakota	C[d], A, AB			C[d]	A, AB
Ohio					A, AB
Oklahoma	C[g], A	C[g]		C[g]	
South Dakota	C	C	A (160 A.)	C	C[d], A[h]
Wisconsin	C		A, AB (640 A.)	C	

Note: "C" indicates the state has a law that applies to all corporations except family farm corporations unless otherwise noted; "A" indicates the state has a law that applies to nonresident aliens unless otherwise noted; "AB" indicates the state has a law that applies to businesses that are controlled by nonresident aliens.

There are a myriad of minor exceptions to the general prohibitions in the various states such as a divestment period, grandfather clauses, experimental uses, and others.

These reports are required of entities owning agricultural land and are in addition to annual corporate reports which are required by all of the states.

Resident aliens are subject to the law.

Family farm corporations are also subject to the law.

Law applies only to lease for more than ten years.

Law applies to all corporations that are incorporated under jurisdictions other than Nebraska (including family farm corporations) but does not apply to any corporations that are incorporated in Nebraska. Nebraska corporations cannot be controlled by aliens.

Family farm corporations that are incorporated under jurisdictions other than Oklahoma are subject to the law.

South Dakota just monitors reports required by the federal Agricultural Foreign Investment Disclosure Act of 1978.

alien-controlled businesses that are legally holding agricultural land to file an annual report detailing the background of the owners and their use of the property.

Limitations of the Laws

The major legal limitations on the states' restrictive laws are the federal constitution and international treaties (Morrison, p. 639). Morrison concludes that state laws which restrict the rights of resident aliens (e.g., Illinois, Indiana, and Nebraska) are less likely to survive a constitutional attack under the equal protection and due process clauses of the fourteenth amendment than laws which restrict the rights of nonresident aliens and corporations.

The reason for that distinction is that land ownership for a resident alien is a basic need similar to welfare benefits, employment by the state, and eligibility for a profession which the U.S. Supreme Court has held cannot be withheld on the basis of alienage. By contrast, nonresident aliens and corporations do not have the same basic need to own U.S. land and therefore can constitutionally be discriminated against if the state can show a "rational relationship" between those classifications and a legitimate state interest (Morrison, pp. 642–43).

There is a rational relationship between the two classifications (aliens and corporations) and the law's purpose of influencing the local economy. However, the state has a legitimate interest in influencing the local economy only if the federal powers over foreign relations and foreign commerce (U.S. Constitution Article I, Sect. 8) do not preempt the states' powers in those areas. Morrison concludes that the simple exercise of mechanical rules (such as the exclusion of aliens from ownership of land) has not been preempted by federal foreign relations activity (p. 649). Nor has the federal government preempted the foreign commerce field since it has ratified treaties which presume the validity of state legislation restricting the ownership of real estate (p. 652). Therefore, state laws restricting resident aliens' ownership of farm land are very likely to be held unconstitutional if tested in the courts, but such an attack would not invalidate the portion of the restrictive laws that limit the rights of nonresident aliens and corporations.

Treaties entered into by the United States are a part of the "supreme law of the land" (U.S. Constitution, Art. VI, para. 2) and thus override inconsistent state legislation. Many of the existing treaties grant rights to conduct business and to acquire land necessary for the operation of the permitted business. However, most treaties reserve the right to limit or exclude alien activity in exploitation of land which, if exercised, would validate restrictions on alien ownership of farmland. Furthermore, the treaties often expressly recognize the laws of states regarding their land. Therefore, state laws restricting alien ownership of farmland are likely to be consistent with treaties and not overridden by them.

Practical Limitations

Legal avoidance and illegal evasion. Laws restricting alien ownership of farmland can be legally avoided if aliens are not also prohibited from owning a controlling interest in a trust or business that owns farmland. Even if an alien is legally forbidden to own farmland indirectly, the law is difficult to enforce if several layers of corporations or fiduciaries are used to hide the identity of the beneficial owner. The same problem arises if a corporation is the beneficial owner of farmland. Iowa has attempted to solve this problem by requiring all conveyances of agricultural land (including leases for a period of five years or more) to be recorded and the beneficial ownerships of such conveyances to be disclosed (Morse, Reeves, Harl, p. 109). Zumbach and Harl discuss the limitations on a state's ability to pry information out of corporations that are incorporated in other states. They conclude that a federal reporting system (such as the Agriculture Foreign Investment Disclosure Act of 1978) would be more effective in penetrating the layers of corporations and fiduciaries to determine the beneficial owner (pp. 325–31).

Supply of family farmers. Proponents of the restrictive laws are likely to think that the income of family farmers will be increased by the laws as well as the number of family farms. They probably reason that the restrictive laws will reduce the price of land and therefore increase the net income to family farmers, which is the remainder of the revenue from farm products after the costs of all farm inputs are subtracted. The ability of restrictions on farmland ownership to raise the income of family farmers depends upon the elasticity of supply of family farmers.

It is reasonable to assume that the elasticity

of supply of family farmers is quite high. There is an annual flow of farm youth from Midwest farms to full-time off-farm jobs (Abourezk, p. 500). Because of this flow, the farm sector would not have to attract people from other lines of work to increase the number of family farmers but simply retain more of the youth who otherwise would leave the farms (Johnson, p. 182). These youth, already trained to operate a farm, are likely to be responsive to an increase in net farm income.[1] The high elasticity of supply of family farmers means there will be a large increase in the number of family farmers as a result of a small increase in net income of family farmers. The retention of youth who otherwise would have left the farm will continue until their competition for the net income from farming has driven that net income back to the level where farm youth at the margin would again be indifferent between leaving or staying on the farm.

The form which the competition among farm youth would take is in bidding for other factors of farm production until the costs of the other factors rise to the point that net income is reduced to the level stated above. Therefore, if the elasticity of supply of family farmers is high, barring or limiting alien and corporate purchase of farm land will have little effect on the net income of family farmers.

Motives of alien investors. The restrictive laws also may be less effective than expected because the threat to the family farm is less than expected. While this is not a limitation of the laws themselves, it should be considered with the other limitations so that the effect of the laws is not overstated. The issue is whether the motives of alien investors are compatible with family farming.

Before analyzing that issue, two factors that affect the current market value of farmland are delineated and discussed—the flow of income from the land and its expected value in the future. Those two factors are not independent since future value depends upon the expected flow of income in the future, which is correlated to the current flow of income. Despite their lack of independence, the two factors will be treated separately in this analysis because they provide independent reasons for purchasing farmland. The flow of income will be referred to as the productive value of farmland and the expected future value will be referred to as the speculative value of farmland.

The productive value and the speculative value of a given piece of land do not necessarily have to be owned by the same entity. For example, an investor could purchase fee title to farmland and lease it on a long-term basis to a farmer. The rental rate would reflect the land's productive value, while the purchase price would reflect the total of the land's productive, speculative, and other values. The investor could sell the speculative interest at any time by selling his fee title, subject to the rights of the farmer as lessor. The farmer could sell the productive value at any time by assigning the lease to another party. Therefore, for a given piece of land, its speculative and productive values can be severed from each other, transferred from one party to another, and recombined as the supply of and demand for them dictates.

The argument that aliens and corporations push farmland prices high enough to bar new family farmers from entering the industry implies that both the total price of land is too high and that the cost of severing the productive value from the speculative value is also too high. However, the transfer cost of acquiring the productive value of land from an investor who is only interested in the speculative value should not be prohibitive. The only parties involved in the transaction are the farmer and the investor. The investor will be concerned that the quality of the land is not diminished by the farmer's overuse or lack of care of the land. That problem could be dealt with in a two-party contract by stating a standard of use and care with which the farmer must comply or be liable for the resulting damages. The farmer will be concerned about having the right to farm the land for a period long enough to justify investing in equipment to farm the land. As the length of the agreement is increased, the farmer will acquire more of the speculative value because he or she will acquire the right to more of the future production on which the speculative value is based. Arriving at an agreeable length of time should not be an insurmountable problem, however, because the investor's time horizon is likely to be as long or longer than the period necessary to justify the farmer's investment in equipment. Furthermore, both parties can reserve the right to transfer their interest in the land to a third party.

[1] Johnson cites (on pp. 186–87) a study by Edward W. Tyrchniewicz and G. Edward Schuh of Purdue University which estimated the long-run elasticity of supply of unpaid family farm workers to be −3.26.

Perhaps potential new farmers would choose not to farm if they were not assured of having their land to farm for the period required to justify their investment in machinery. While the risk of having to find new land to lease or to change careers if their lease were not renewed certainly would reduce the attractiveness of farming, it would surely not be an absolute bar to farming since most of the alternative careers available to potential farmers have some, if not more, risk of being unavailable within the same period of time. For example, the changing supply of and demand for construction workers, engineers, or lawyers could force people in any of those careers to find employment in a different location or a different occupation.

The severability of the productive and speculative values of farmland is important in analyzing the compatibility of alien investment and family farming. To the extent aliens purchase land as an investment and not as a means of acquiring the commodity produced on the land, they will be interested only in maximizing the return on their investment.[2] Because aliens by definition do not reside in the United States and therefore cannot farm the land personally, their alternatives for realizing the productive value of their land are to (*a*) manage the farms themselves or by an agent and hire the necessary labor to farm the land, (*b*) rent the land on a crop-share basis, or (*c*) rent the land for cash. Given the investor's distance from the land, a cash lease would be the least expensive to supervise and for that reason may be the most attractive alternative. If the alien investor does choose to lease the land for cash and is willing to lease it for the period of time necessary to justify the investment in machinery, the alien investor is very little threat to the family farm. A crop-share lease takes some of the management away from the family farmer but for most of the proponents of the family farm, it probably leaves enough management with the family to satisfy the desire to preserve the family farm. Therefore, if the alien investor rents the land either for cash or a share of the crop, the fact that the land is owned by an alien rather than the family farmer or another American has little effect on the existence of the family farm (Currie et al.).

[2] Currie et al. found no desire among the foreign investors in Iowa farmland they surveyed to acquire the commodities from the land for foreign consumption (p. 129).

If the alien investor chooses to manage the farm and hire the necessary labor, the management of the farm would be severed from the labor to such an extent that most proponents of the family farm probably would consider the essential characteristic of the family farm to have been lost. Therefore, if a sufficient amount of land is purchased by alien investors and if a sufficient portion of them manage their land directly, then alien investors would pose a threat to the family farm. The portion of American farmland which alien investors must own and manage to become a serious threat to the family farm is subject to debate. Some ownership and management of farmland by aliens is likely to be compatible with family farming since working on an alien investor's farm may supplement the income of young family farmers during the years when they have more labor than can be effectively employed by their own capital and management.

Therefore, to the extent alien investors in American farmland are interested only in the return on their investment and do not manage the farm themselves or by an agent, they will have little effect on family farms. Consequently, the main effect of laws restricting alien investors in farmland would be to allow the family farmer to be an investor in land as well as a farmer. As Atkinson and Jones suggest (p. 62), with the increase in the size of farms, the assumption that the ownership and operation of family farms must be in one entity may no longer be valid.

Conclusion

There are some important limitations on the effectiveness of restrictive land ownership laws in preserving the family farm. Restrictions on resident aliens' rights are likely to be unconstitutional under the equal protection clause. The rights of nonresident aliens and corporations do not receive the same level of constitutional protection. Therefore, restrictions on the rights of nonresident aliens and corporations to own farmland are likely to survive a constitutional attack. While international treaties override inconsistent state law, state restrictions on farmland ownership are likely to be consistent with existing treaties and therefore valid.

Aliens can legally avoid restrictive laws if they are not prohibited from owning farmland

indirectly through corporations or fiduciaries. Enforcement of laws prohibiting indirect ownership is difficult on the state level because of the states' limited right to pry information out of corporations organized under the laws of another state. If the elasticity of supply of family farmers is high, the restrictive laws will have little effect on the level of income of family farmers. Finally, to the extent alien investors are not interested in acquiring the ommodity from the farmland and are not in-erested in managing the farm, they pose little ıreat to the family farm. If the threat of alien ıvestors to family farms is low, then laws estricting alien investments will do little to rotect the family farm.

These limitations of the restrictive laws can e explored more thoroughly as data become vailable from the various reporting laws. The mitations may prove to be so great that the enefits of the restrictive laws do not justify ieir cost.

Sociological Aspects of Farm Size: Ideological and Social Consequences of Scale in Agriculture

William L. Flinn and Frederick H. Buttel

The issues of farm size and the wide range of institutional arrangements relating to the scale of agricultural production are among the most interesting areas of interchange between agricultural economists and their colleagues in rural sociology and associated disciplines. The renewal of debate over the structure of agriculture during the past decade raises such broad questions about alternative futures for agricultural organization in this society that representatives from no single discipline—agricultural economics, rural sociology, for example—can provide all the necessary guidance. The purpose of this paper will be to take some necessary interdisciplinary steps by setting forth several sociological observations on the issues of scale and structure of agriculture which are informed by agricultural economics research.

The first portion of the paper discusses a number of ideological and value aspects of farm size. The second section consists of an abbreviated summary of research on the social consequences of farm size and mechanization for farm families, nonfarm people, and rural communities, while the final section advances several observations about political-economic aspects of farm size and their implications for the debate over agricultural structure.

Agrarian Values and Ideological Aspects of Farm Size

One need not be a social scientist to realize the pervasive influence of Jeffersonianism and its ideological descendant, which we term agrarianism. Our previous research (Buttel an Flinn 1975), using a 1971 statewide rando sample of Wisconsin residents, has indicate clear majority support for attitudinal stat ments relating to agrarianism and the famil farm. For example, more than 80% of respo dents agreed that the "family farm is ver important to democracy." Favorable attitude toward agrarianism and the family farm wer most strongly supported among older peopl and among persons with low education fro farm origins and from rural places of res dence. These data, however, reveal some re sons why the "general public" has not fr quently mobilized around the issue of far size and the family farm; these generall favorable attitudes toward the family farm a not strongly held, as evidenced by the fact th majorities or near-majorities of responden tend to "agree" (rather than "strong agree") with pro-family farm attitudes.

It is not surprising that farm operators a even more likely than the general public express values favorable toward the fami farm (Flinn and Johnson). Older, less well-e ucated, and smaller-scale farmers (with sca measured in terms of number of acres a gross farm income) are most likely to agr with statements supporting agrarianism a the family farm. More recent data from Ne York State also indicate that small-scale far ers are more likely than larger-scale farmers disapprove of corporate agriculture and favor prospective government commodi programs that would disproportionately be efit small producers (Buttel; see also Butt Harris, Powers).

Thus, there is an overarching social cla contour to the ideological issues of farm si and the family farm. Small farmers and lo income segments of the general public a more sympathetic with preserving the fami farm and blocking corporate penetration of a

---

William L. Flinn is a professor of rural sociology and sociology and associate chairman, Department of Agricultural Economics and Rural Sociology, Ohio State University. Frederick H. Buttel is an assistant professor of rural sociology, Cornell University.

The authors wish to thank Kenneth L. Robinson, Wallace Barr, Bruce Hall, and Robert Jacobson for their very helpful comments on an earlier draft.

riculture than are relatively privileged farmers and nonfarmers. In addition, there is evidence that positive attitudes toward the family farm and small-scale agriculture are tied to a general critique of the social order as articulated in terms of alienation, powerlessness, and political cynicism (Buttel and Flinn 1976).

Farm Size, Values, and Political Ideology

After a nearly ten-year period of dormancy, rural sociologists have begun to resume their work on the attitudes and ideologies related to farm size and structure. For example, Coughenour and Christenson have empirically examined a variant of the "small is beautiful" thesis by relating farm size to attitudes about personal well-being, community well-being, and perceived adequacy of services. They found virtually no evidence that small farmers are more satisfied than large farmers. In fact, the small differences that do emerge in these data suggest that large-scale farmers express higher levels of perceived well-being than small-scale farmers do. This tendency should not, however, obscure the fact that small operators typically have a high level of attachment to (or a relatively "noneconomic" orientation toward) agriculture (van Es and McGinty). Their sources of dissatisfaction as revealed in the Coughenour and Christenson study do not, of course, derive from negative attitudes about operating a small farm per se, but rather from an inability to support their families from these modest-scale farms.

Two of the more important social and policy issues in agriculture during the past decade are the effects of large agribusiness firms on farmers and the desirability of federal commodity programs. On each of these issues we can see substantial cleavages among farmers from different size-of-farm classes. Data from a random sample of farm operators in Michigan (Buttel, Harris, Powers) have demonstrated that the level of gross farm income is inversely correlated with both cynicism about agribusiness and advocacy of price supports. In general, small farmers are more politically liberal and more cynical about agricultural organization than are large farmers. Large farmers, on the other hand, are much less favorably inclined toward government "interference" in the economy—be it by regulating agribusiness firms, providing social welfare benefits such as public jobs or national health care programs, or undertaking commodity stabilization/price support programs. The tendency for small farmers to show greater favor for federal commodity programs represents something of an irony. Insofar as price supports and related programs may tend to benefit large operators differentially (Schultze, Raup), small farmers, because of their relatively liberal political commitments, may be unable collectively to develop social policies that would be in their own interest (Gardner, Gardner and Pope, Schultze).

Social Consequences of Scale in Agriculture

Much of the work of the pioneering rural sociologists (for example, Kolb and de Brunner) was devoted to determining how relentless increases in the scale of production agriculture had affected rural people and rural communities. Although this research did not return a unanimous verdict, it was substantially colored by a concern that the major forces affecting agriculture did not confer benefits and costs on rural and agricultural people in a socially or economically even fashion. Most of this incipient questioning of structural change in agriculture abated during the late 1950s and 1960s, only to be awakened with considerable vigor in the past decade. This phase largely began with a new edition of the classic work of Walter Goldschmidt on the effects of large-scale agriculture on rural communities in the Central Valley of California during the 1940s. Despite the crucial theoretical and methodological shortcomings of Goldschmidt's work (Goss, Sonka), nevertheless it has remained a fertile source of hypotheses.

Most research on the effects of farm size on rural people or rural communities is closely bound up with issues of mechanization or technological change (see Rodefeld 1980). Historic labor shortages (and relatively high wages) that accompanied the principal surge of agricultural development in the United States (primarily 1935–70) meant that a larger scale of agricultural operations usually was accompanied by deploying labor-saving technology rather than by hiring labor. However, it should be recognized that in several parts of the United States (particularly California), mechanization followed rather than led to large-scale agriculture. Existing large farms in California, many dating back to the Spanish land grants, employed many hired laborers

who only later were progressively displaced by labor-saving machinery (LeVeen).

The social consequences of increased scale and mechanization in agricultural production are, of course, exceedingly complex. First, these processes quite obviously involve both costs and benefits that are differentially captured or borne by societal groups. Because a simultaneous consideration of both costs and benefits (including their distributions across societal groups) has really never been accomplished within the context of a single research design, it is hazardous to generalize about the social consequences of changing scale of agricultural production. Moreover, the consequences of scale and mechanization vary decidedly according to the context—the kind of agriculture, the regional or local economic base, and the class relations among farmers—within which these changes occur (see, for example, Raup). Finally, farm size and mechanization are intimately related to a host of other structural changes in agriculture, and those other changes have independent but concurrent social consequences.

With these caveats, we may note that most rural sociological research on the consequences of farm size has been devoted to identifying two types of consequences: (*a*) changes in the socioeconomic characteristics of farm personnel, and (*b*) changes in the characteristics, especially population size and employment levels, of rural communities. At risk of overgeneralization, available research indicates a cluster of consequences of increased farm size and mechanization for the characteristics of farm people. The most striking and important is, of course, the effect on the numbers of farmers and farm workers. Scale and mechanization generally bring substantial declines in the number of farm people (including owner-managers, family laborers, hired agricultural workers, and their families). The decline in numbers is also generally accompanied by shifts in the types of these personnel; the proportion of family laborers (owner-managers and unpaid family labor) decreases, while the proportion of hired labor increases, particularly in those areas where the transition to large-scale industrial farming is well underway. Primarily because of the greater proportion of hired laborers, the overall characteristics of the farm population tend to shift toward concentration or inequality of land ownership, lower educational backgrounds, lower job and residential stability, lower levels of per capita income, and lower degrees of participation in community institutions such as voluntary organizations, churches, and the political system (Rodefeld 1974; Heffernan; Heffernan and Lasley; Fujimoto; Martinson, Wilkening, Rodefeld). Except for the clear economic gains captured by a shrinking group of larger farmers—whether they be owners or managers of large-scale industrial farms or owner-managers of large-scale family or tenant farms—the overall thrust of these research results is a hesitant or critical posture toward increases in farm size and mechanization.

A more potent critique of increasing scale in agriculture concerns its impacts on rural communities, especially relatively small communities, communities located in the relatively unurbanized "agricultural interior," and communities where inequality in the distribution of social resources such as education has left displaced farm personnel poorly prepared to enter the off-farm labor force (Raup). It is repeatedly observed that declines in the size of the on-farm work force yield declines in the population of rural communities and trade centers greater than the initial loss of farm people (Goss and Rodefeld) because larger farms and increased mechanization tend to undermine the sales and eventually the survival of retail merchants and other small businesses (Sonka and Heady). The trend is aggravated further by the constantly increasing level of sales necessary to support small business operations in rural communities (Ellenbogen). The consequence is the setting in motion of a downward multiplier or spiral of decline that has so far only been partially offset by the recent emergence of net metropolitan-to-nonmetropolitan migration.

Rural sociologists and their disciplinary colleagues thus have drawn a discouraging conclusion about the past and likely future course of structural change in U.S. agriculture. Yet it must be noted that these observations have not necessarily led rural sociologists to decry ongoing changes in the agricultural and rural sectors. Indeed, the center of gravity of the discipline until quite recently was one of passive acceptance of these phenomena. It was assumed, for the most part, that these consequences were inevitable and that the discipline should pursue research on compensatory mechanisms—community development, off-farm employment, rural industrialization, more efficient delivery of services—to help

ural residents cope with the adverse effects of ι changing agriculture.

Broader Political-Economic Implications of Scale in Agriculture

A number of incongruous pieces of observaion and evidence demand that rural social cientists adopt an essentiallly political-ecoıomic perspective in order to deal with hisoric and ongoing changes in the structure of J.S. agriculture. The majority of the U.S. population, especially farmers, sees the family arm as the ideal form of agricultural organizaion at the same time that family farms are leclining as a percentage of units and of sales n agriculture (see Rodefeld 1979, Emerson). As a result, there have been several adverse consequences for rural people and rural comnunities. Why, then, have these changes ocurred in the face of supportive social values and readily observable socioeconomic dislocaions attendant to structural changes in agiculture?

One possible answer is that large farm units re necessary to allow efficient production of gricultural commodities, which in turn fosers backward and forward linkages with inlustry and promotes the development of a maure industrial society. This answer must, however, be regarded as a half-truth in light of omparative evidence from other advanced ocieties. A number of industrial countries—otably Denmark, Italy, France, and Japan—ave reached fully industrialized status hrough routes that have not included nearly s much scale, mechanization, and dislocation n agriculture (Singelmann, Newby).

Other perspectives suggest that relentless ncreases in scale and mechanization in U.S. griculture have been due to either public polcy "mistakes," in which agricultural policy dministrators sincerely attempted to sustain he family farm but were unable to do so, or to leliberate attempts by policy makers to anihilate the family farm. Although both major 'ariants of this argument contain a small kerel of truth, each has major shortcomings that imit its utility in understanding structural hange in agriculture or in developing strateies to improve the condition of rural people. Agricultural policy clearly has a major role in he shaping structural change in agriculture Raup, Mann and Dickinson 1980), but the lifferent complexions of the agricultural systems of the United States and Denmark are not likely to be solely the result of different agricultural policies. Had the U.S. government taken a position more favorable or less favorable toward small-scale producers, these policies perhaps might have modified the transformations of U.S. agriculture but would not have qualitatively redirected them (Gardner).

Conceptual Imprecision

Before detailing what we think are more meaningful political-economic categories for understanding increasing scale in U.S. agriculture, we want to comment briefly on some of the limitations of two prevailing "theoretical" categories—scale and the family farm—and, by implication, a third—the corporate farm—that have generally been employed in the farm structure debate. The notion of scale in agriculture has a variety of distinct components that are often obscured when encompassed under a unilinear rubric. Most important, the mere notion of scale essentially ignores the question of social relationships of production. We must be much more specific about the social context of scale in agriculture—its property relations, social relations, labor relations, and technical relations—in order to understand historical and contemporary transformations in agricultural structure (de Janvry).

Many of the same criticisms can be made of the notion of the "family farm." This category is meaningless unless it is defined in historical or normative terms. If collectors of agricultural statistics can tell us confidently that the relative prominence of "family farms" has never fallen below 95%, we cannot say much about change in agriculture except that these "family farms" have become larger and fewer in number. With such an indeterminate definition of the family farm, the notion of the "corporate farm" becomes the only alternative reference point. Because we have defined the family farm so imprecisely, there is often misplaced emphasis on the prevalence and economic power of corporations in agriculture. A misplaced emphasis on corporate farming often leads to an erroneous assumption that if corporations were banned from agriculture, the problems of the family farm would cease to exist. We argue that barring nonfamily corporations from agriculture would have only partial, albeit significant, effects on many of the

consequences of increasing scale in agriculture, as Raup, no friend of corporate agriculture, has warned.

Family Farming As Independent Commodity Production

We believe that the notion of "independent commodity production" must serve as a conceptual benchmark for reaching a historical understanding of the political economy of agriculture. Independent commodity production can be defined as an agricultural production enterprise (or a system, where such production dominates) in which: (*a*) there is family ownership of land and other capital items plus entrepreneurial control of the allocation of this capital, (*b*) the majority of labor is provided by family members, (*c*) the farmer is largely or fully commercial and interacts in competitive factor and product markets, and (*d*) the farm family subsists primarily on farm income and home-produced commodities.

Several important concepts parallel the notion of independent commodity production. The first concept is differentiation, the tendency in a market economy for some family farmers to be differentially efficient and productive, to have unequal access to inherited wealth, and to be unequally able to accumulate profits. Differentiation primarily implies that disparities in the extent of property ownership will tend to increase. Many mechanisms can accelerate differentiation, including the "treadmill of technology" (Cochrane, LeVeen) and state policies biased in favor of more privileged farmers (Mann and Dickinson 1980).

The second concept is reproduction, the extent to which family farmers as a group have the means to reproduce the key relationships of independent commodity production. Reproduction is a logical extension of differentiation because reproduction will be most problematic for those least able to accumulate profits; thus, if families cannot earn sufficient incomes from the farm alone and must rely primarily on off-farm earnings, the family farm is only partially able to reproduce itself.

Differentiation and reproduction together imply a third concept, that of transformation: qualitative changes in the nature of family farming so that substantial numbers of farms no longer approximate the characteristics of independent commodity production. Ther are two extremes of transformation. The fir is the total failure of the farm family to repro duce itself; the family is forced to leave th farm because of very low returns or forecl sure. At the other extreme emerge the types relations earlier (and loosely) called corporat or large-scale industrial farming; enough cap tal is accumulated to dictate that the farme hire labor for most farm tasks on his large scale farm. There are also, of course, interme diate aspects of transformation as the famil farm begins to depart substantially from all c most of the characteristics of independer commodity production. While continuing t be "owner-operated"—the current definitio of supposed family farming—the farm ma nonetheless undergo significant changes in it social relations of production and exchange For example, the logical extension of produc tion contracts, with many entrepreneurial an management functions surrendered to the con tractor, may be the reduction of the famil farmer to a role little different from a "piece worker" (Davis).

One of the major forces leading to the trans formation of independent commodity produc tion is the dualism between farmer and lan owner in a system of private property in ag riculture, even when both roles are largel fused within the same farmer or family. Th most dramatic recent manifestation of th farmer-landowner distinction is the rapid infla tion of farmland prices as the benefits fro technological change and commodity pro grams have become capitalized in the price land. While directly benefiting absentee own ers of farmland, farm owner-managers hav been adversely affected through increase taxes, rents, and interest payments. The onl way a family farmer can benefit from lan inflation is, ironically, by ceasing to become farmer, i.e., by selling out and realizing capit gains through inflated land prices. This is th final and most compelling instance of th heretofore concealed antagonism between th farmer and landowner. Although not so dra matic as rapid land inflation, another impo tant consequence of farmer-landowne dualism is the increasing proportion of U.S farmland that is rented and absentee-owne (Rodefeld 1979). While land rental obviousl is a strategy to reproduce the family far through expansion, the result is a significar transformation in the character of independer commodity production.

The Dialectic of the Family Farm

Even though their farm size structures vary so greatly and their agricultural histories encompass a wide range of farm enterprise types, the social relationships of industry have failed to become fully manifest in agriculture in all the advanced industrial societies. In view of the fact that agriculture is one of the last sectors where a substantial amount of production is organized under relationships akin to the independent family farm, the intriguing question is not why so many have left the farm, but why so many have stayed!

There are several answers to this latter question. Because agriculture in temperate climates is tied to the seasons, there is an inherent excess of production time (when capital is tied up in fixed investments) over labor time. Under these circumstances, production agriculture remains unattractive to large-scale capital except in cases, such as irrigated areas of California, where technological advances allow virtually year-around production (Mann and Dickinson 1978).

Agriculture thus has been left primarily to "family farmers," and the inherent characteristics of farm families as independent commodity producers, once in place on the land, insure a high level of persistence and tenancy. Farm families can be viewed essentially as labor management systems in which the labor of family members is allocated between farm and nonfarm tasks to maximize the economic welfare of the family as a whole. The availability of family labor, generally on an unpaid basis, enables the family farm to absorb market downturns that might drive corporate-operated farms out of agriculture. The family farm also involves immobility of fixed capital, because of a high degree of attachment to the land and to farming as a way of life.

A variety of phenomena thus combine to comprise what we might call the dialectic of the family farm. On one hand, there are constant tendencies toward differentiation, concentration, and transformation of independent commodity production which are accelerated by economies of scale, government policies that reduce risk or perhaps disproportionately benefit large producers, and mainstream agricultural research. On the other hand, there are several factors inherent in the structure of agriculture and farm families (e.g., risk, the nonidentity between production and labor time, internal diseconomies of scale, immobility of fixed capital, and certain aspects of government agricultural policy) that combine to mitigate against the wholesale transformation of the family farm (Stanton, Mann and Dickinson 1978). Returning to our original question of farm size, we can see that scale in agriculture is an intervening variable in this dialectic of the family farm. Scale is at once a mechanism for the reproduction of the family farm as well as a mechanism for its differentiation and transformation. The ability of some farm families to absorb the technical and social changes that lead to scale in agriculture is widely recognized (Nikolitch). This ability does not, however, derive solely from the organizational superiority of the family farm in a narrow sense but rather, at least partly, from farmer "self-exploitation" and exploitation of unpaid family labor, as Lianos and Paris have put it (see also Barkley). Farmers often invest in labor-saving technology and additional farmland in order to remain in agriculture, typically at the expense of current family income (Raup). Yet, there are limits to the levels of technological development that can be absorbed by family-owned businesses. Stanton, for example, contends that the 300-cow herd represents a ceiling of scale for family-operated dairy farms in New York State. More important, as noted by Raup and Breimyer, the large-scale "family" or "larger-than-family" farm made possible by mechanization exhibits a number of vulnerabilities—particularly difficulties in intergenerational transmission and in adapting to market downturns. Their observation is that these large family-owned businesses, rather than small farms, will be most rapidly consolidated into large-scale industrial farms with absentee owners.

W(h)ither the Family Farm?

Increased scale does not imply the disappearance of the family farm, but neither does the increasing scale of contemporary family farms guarantee that these farms will continue to exist in classical form. Indeed, the transformation of the family farm from independent commodity production to a status that combines elements of the role of capitalist (employer of labor) and worker (forfeiting of entrepreneurial functions, off-farm employment, etc.) lies at the heart of some of the adverse effects experienced by rural people and communities.

Public attention recently has been focused on "structure issues" and "structure policy" in agriculture (ESCS), much of this attention having been prompted by nonfarm public interest groups. These groups have presented a strong case that there would be substantial potential benefits that would accrue to returning to a smaller scale of agricultural production, without adversely affecting levels of productivity and economic efficiency. The effects that these arguments will have are difficult to anticipate. On one hand, there has been fostered a long-overdue reassessment of the social costs of American agricultural development. On the other hand, one senses that these groups' overarching image of desirable social change often is a return to some imagined utopia of independent commodity production. In a very practical sense, however, we will not have the option of "going back." The larger economy and society have developed to the point that it is inconceivable that government policy could have sufficient leverage to overcome the forces behind differentiation and transformation of the U.S. agricultural structure (Walker).

While we cannot go back, this does not entirely foreclose possible future options. Nevertheless, this search for options must take account of the realities of the structure of agriculture in an advanced industrial society. Farmers and their spokespersons in public interest organizations must begin to grapple with the dominant forces of the dialectic of the family farm. For example, they must recognize that government assistance to the small farm will not likely be sufficient to alter substantially ongoing trends because of the farmer-landowner dualism discussed previously.

We suggest that one of the potentially most useful areas of activity would be to deal with the role of private property in land in accelerating the transformation of the family farm. Institutional modifications such as land banking and land trusts potentially can enable farmers and their communities to insulate themselves partially from many of the relentless forces of differentiation and concentration that operate through the market for private property in land. There also may be increased potentials for cooperatives in agriculture, perhaps centering around machinery sharing or cooperative operation of on-farm fuel production facilities. Another potentially exciting strategy is the development of local markets for agricultural produce, which could have a useful rural development role as well. However, the question must remain whether farmers will be ideologically predisposed to embrace these unconventional alternatives, as we alluded to at the outset of this paper. In sum, scale and organization of agriculture are political-economic questions that require political-economic strategies cognizant of the major social forces affecting agriculture.[1]

Critical Choices Relating to the Economic Structure of the Farming Sector: Discussion

Emerson M. Babb

In the coming years, important decisions about the structure of the farming sector will be made. These decisions, including making no change in current policies, will be based on facts or perceptions about the consequences flowing from alternative structures. The challenge to our profession, and to other professions concerned with agriculture, will be to provide information needed for decision making on a timely basis. We will be called upon to interpret our stock of research findings and to fill important gaps in our knowledge about farm structure relationships. The paper by Flinn and Buttel contains an excellent summary of the work by sociologists on farm structure and provides a basis for identifying the research that will be needed. Because of its scope, I will direct most of my comments to that paper.

The Flinn-Buttel paper is provocative and grapples with major issues in the farm structure debate. The authors indicate that sociologists would be divided on their interpretations of research findings and implications. Economists likewise will be divided. For example, it is unlikely that contracts have or will transfer virtually all managerial functions to the contractor firm. The consequences of separation of farm ownership and operation and of part-time farming may be less serious than suggested. The authors are gentle in their reminder to economists that the causes and consequences of changes in farm structure are not solely economic. They do not belabor the point that we sometimes take a narrow view of efficiency and ignore externalities.

The paper makes a number of important points. The first relates to the importance of defining what we want to preserve and why. Some of the authors' concerns about changes in structure are an outgrowth of their family farm definition. Second, changes in the overall characteristics of the farm population associated with the changing structure of agriculture may be as important as declines in the number of persons engaged in farming. The impacts of changes in farm population characteristics on rural communities are also important. We probably have directed too much attention to changes in farm numbers. Third, the sociologist's concepts of differentiation, reproduction, and transformation have economic content. In fact, these processes can be simulated. The process of change could be one research area where collaboration among economists and sociologists would be fruitful.

In sum, economists interested in farm structure will want to read the Flinn-Buttel paper. It provides a concise review of research by sociologists and their conceptual frameworks. The reader should obtain a copy of the paper prepared for the session, which is more than twice as long as the published version.

There is general support for Harris's conclusion that alien investment in agricultural land is not likely to threaten the family farm. He argues that land ownership restrictions have little effect on farm income. Income per farm may be affected, however, even if income in the aggregate is unchanged. The restrictions could influence farm size as well as the number of farms. The economic impacts of restrictions placed on corporate and alien land ownership appear to have been minor.

Eginton compares the financial performance of farm firms under alternative tax features using a budgeting process. His results are predetermined by the assumptions used, including the single objective of firm growth (the firm applies all additional income to growth). Projections might be more realistic and more useful if the model were restructured to analyze a variety of firm objectives, contained stochastic elements and permitted variation in assumptions about the firm.

Emerson M. Babb is professor of agricultural economics at Purdue University.

Critical Choices Relating to the Economic Structure of the Farming Sector: Discussion

Rulon D. Pope

Vo one can deny that structural issues are motionally charged, and there appears to be videspread concern that current changes are ot in the public interest. Further, as Flinn and Buttel indicate, there are interesting alliances etween farm and nonfarm groups interested in amily farms and related issues. It is ever be- ore us whether these concerns reflect a sub- tantive disenchantment with current institu- ions and policies, or whether the temporary osers in the tide of changing economic condi- ions are vocalizing their frustration. One is urious how these concerns respond to farm ncomes, as well. Judging from the perennial st of symposia, invited, and selected papers n structure, professional interest is inelastic nd structure will be of continuing concern in gricultural economics.

In a broad sense, all three papers deal with ne heart of the structural issue: the social and conomic characteristics of operators and wners, the number and sizes of farms, and ne ownership and control of resources. Each f the authors is to be commended for choos- ig timely and interesting aspects of the struc- ure issue.

Considering initially the Eginton paper, ough few details are given, it appears to be a icromodel of a cash-flow-constrained firm hich has few strategic choices to make. The onclusion that "tax concessions" encour- ged survival and expansion of farms is not nanticipated. Yet, one may question whether model with 6% rate of inflation and a sure ositive rate of return on assets with exoge- ously rising land prices has relevance to farm rowth issues under various taxation policies. hough I believe much could be discussed garding the strengths and weaknesses of the pproach, I would like to focus on the word concession" as used throughout the paper, emplified in the following quote:

> An alternative worthy of research is limitations on tax concessions such as interest payment write-off and depreciation allowances to set dollar amounts (as investment tax credits are now limited) to prevent continuing inflation from preferentially subsidizing superfarms to grow even larger.

It follows from competitive theory that profits may be taxed without distorting input use. Such a tax would imply input usage where the value of their marginal products equals input costs. Given a fixed marginal tax rate, this can occur only when each input's cost is subtracted from revenue and then taxed. What is the cost of capital? Theory suggests that interest plus depreciation costs must be included. I would argue that including a deduction for interest rate is not a "concession" promoting growth of farms. Reduction or elimination of the provision would lead to insufficient farm demand for capital. This in turn may lead to a rise in the rate of return to capital and a reduction in the wage rate as the capital/labor ratio falls. Thus I would disagree with much of the thrust of the conclusions of the paper.

The paper by Harris also treats an interesting and important topic. Some data are helpful in seeing the topic in perspective. More than half of all land in farms was operated by part-owners and this number appears to be increasing (Banks). About 30% of the farm and ranch land is owned by 1% of owners. Sole proprietorships and husband and wife owners account for about two-thirds of all private holding. Non-family corporations hold 2.4% of the farm and ranch land. Concerning the residency of purchasers of land, surveys indicate that 80% of the acreage purchased involved tracts from the same county as the purchaser, 14.5% from another county, 5.5% from another state, and .05% from outside the United States (USDA). The data also suggest that most of the states which have enacted legislation restricting ownership have a low incidence of either corporate (widely held) or alien ownership.

ılon D. Pope is an associate professor of agricultural economics, exas A&M University.

Since the above data suggest that the economic impact of alien or corporate ownership (or restriction) is relatively low, it remains difficult to explain the actions of states passing this legislation on the grounds that farmers were feeling a measurable rise in land prices. Presumably, separation of ownership and operator are at the center of these motives. Over half of the U.S. land is already operated by part-owner farmers, suggesting widespread separation between ownership and operation. Further, returning to the Eginton model, if farms are constrained from efficient choices due to a cash flow constraint, then corporate and alien investment can be a boon to the food sector, as was foreign investment in the United States during the early and mid-nineteenth century.

It is not feasible to discuss the many possible motivations for these investors' recent attention to agricultural investment in the United States. Clearly, tax policies, exchange rates, expected incomes, and inflation rates are among the macroeconomic variables of interest. These must not only be considered with respect to the United States, but with respect to the entire international portfolio of investments (see Nuckton and Gardner, and Rausser, Schmitz, Warner, for a discussion). However, with the recent slowing in the rate of land appreciation, it will be interesting to see if there is a change in the magnitude of these investments.

The Flinn and Buttel paper is excellent and should raise our awareness of sociological issues, observations and perspectives. There is much for agricultural economists to ponder and debate in this paper regarding farm size: this is usually the case when we consider a broader social science perspective than our own. This debate should be centered on discussing pragmatic alternatives. As Friedman's "Free to Choose" exemplifies, we may disagree on means more violently than the goal. Finally, not only are our perspectives different, but our epistemological approaches differ as well. I believe most economists would be cautious in the interpretation of attitudinal surveys but have more faith in revealed preference. Yet these data are useful and it is important for economists to try to understand, e.g. why small farms support farm programs with more enthusiasm than larger farms. Why do low income urban dwellers support family farm notions when, relatively, they may have the most to lose from a policy which may raise food prices? It appears that economists will have little impact on policy unless we understand the issues from a sociological, political and economic perspective.

Our Energy Transition: The Next Twenty Years

Wallace E. Tyner

About 150 years ago, Macaulay wrote the following passage regarding the prevailing mood of the time:

> We cannot absolutely prove that those are in error who tell us that society has reached a turning point, that we have seen our best days. But so said all who came before us, and with just as much apparent reason. . . . On what principle is it that, when we see nothing but improvement behind us, we are expected to see nothing but deterioration before us?

It is true that doomsday prophesies have been with us for hundreds of years. Has the time come for us to believe the prophets of doom, or can we see hope for improvement in the future? In forecasting our nation's energy future, there is ample cause for both despair and hope. The hope is premised on our ability to perceive accurately the nature of our energy problem and take prompt, effective actions to solve it. My own beliefs, which are reflected in the remainder of this paper, comprise a mixture of optimism and pessimism, which I like to characterize as guarded optimism.

Our current situation is that we are in an energy transition from petroleum fuels to alternate energy sources. The notion of energy transition is not new to our country. We have been through two previous energy transitions—one from wood to coal and the second from coal to oil and natural gas. Through the 1880s, biomass (primarily wood) was the major energy source in the United States. From the 1880s through the mid-1940s coal was the dominant energy source, and oil and natural gas have been the major energy sources since then. (Today, oil and natural gas constitute about three-fourths of our total energy consumption—one-half oil and one-fourth gas.) In the previous energy transitions, first coal and then oil and natural gas became the fuels of economic growth. The previous transitions involved not so much substitution of one source for another, but the use of the new energy source for new economic activity. That is the fundamental difference between our previous energy transitions and the current one. In the current transition, much of the attention is focused on decoupling economic growth and energy consumption (energy conservation) and on developing unconventional energy sources like oil shale, coal liquids, and biomass to substitute for oil. The era of cheap energy to fuel economic growth is gone; the question is what will the transition away from that era look like. That is the subject of this paper.

Because of all the interest in this energy transition, there have been a host of major multimillion dollar studies on our energy transition published in the last few years. The major ones are included in the references to this paper. While I have reviewed these studies in preparing this paper, I cannot discuss the results of each because of space limitations. Rather, I will reference specific points adopted from each study.

My procedure in addressing this very complex question in such a brief paper will be to first discuss the technical and economic potential of some major energy alternatives and then to integrate the separate pieces into a personal view of this transition. Once this is completed, I will discuss some of the policy issues related to the energy transition.

Conservation and Energy Consumption

Forecasting demand for anything twenty years into the future is always difficult, but forecasting energy demand twenty years hence borders on soothsaying. From the 1920s through

Wallace E. Tyner is associate professor, Department of Agricultural Economics, Purdue University.

the 1960s the real price of energy fell, yet the energy gross national product (GNP) ratio also declined during that period (Resources for the Future). That is, even with declining energy prices, the use of energy per unit of GNP fell with GNP growing at 3.1% and energy consumption growing at 2.5%, or 80% as fast. In the 1970s energy prices began rising in real terms, so we would expect the energy/GNP ratio to decline reflecting the higher energy prices. The question is how much will it decline over the next twenty years. To accurately answer this question we would need to understand thoroughly the feedback relationships between energy and GNP and to have reliable price and income elasticity estimates for each major energy source. (The CONAES study does the best job of estimating these elasticities and incorporating them in demand projections.) Furthermore, we would need to make assumptions about the rates of development and adoption of new energy conserving technologies.

One major problem in obtaining good long-run elasticity estimates is that much of the change in energy consumption requires a turnover in capital stock, which takes place over a long time period. We have yet to see all the conservation impacts on our economy resulting from the 1973 oil price increase. Turnover of the automobile fleet takes about eight years, and the housing stock is replaced in approximate fifty-year cycles. We have hardly begun to see the energy conservation induced by the 1979 oil price increases. In addition, energy-pricing policy is shifting from regulated prices to market prices and that impact is yet to be felt. Because these changes take so long to occur, we have no reliable statistical base from which to make demand projections.

Since the early 1970s, there has been a general decline in the level of all energy demand forecasts (table 1), regardless of the bias of the forecasters. The 1972 forecast of the low-growth advocates is about equal to the 1978 forecast of the high-growth advocates. None of these forecasts incorporate the doubling of oil price in 1979. Even if we disregard the two extreme groups of forecasters ("Beyond the Pale" and "Superstition") and seriously consider only the middle two groups (table 1), the difference amounts to about 30 quads or 15 million barrels of oil equivalent per day in 2000, which is 38% of our 1979 energy consumption. My own belief is that energy demand will increase in the range of 0 to 2.0% per year, with a most likely range of 1.0% to 1.5% per year. This implies a year 2000 energy consumption of 78 to 115 quads, with a most likely range of 95–105 quads.[1]

My forecasts are at the low end of "conventional wisdom," because I believe price-induced conservation will occur at increasing

[1] In arriving at these figures, I assume GNP will grow 2.0% to 2.5% per year, real energy prices will increase 2% to 3% per year, the income elasticity of energy is 1.0, and the own-price elasticity of demand is −.25 to −.50. These assumptions are consistent with the modeling results from the CONAES study (pp. 529–612). The 95 and 105 quad demand levels are lower than the RFF study and within the range of values used in the CONAES study. The EXXON forecast for 2000 is about 101 quads.

Table 1. Energy Demand Forecasts

Year of Forecast	Beyond the Pale	Heresy	Conventional Wisdom	Superstition
1972	125 (Lovins)	140 (Sierra)[a]	160 (AEC)	190 (FPC)
1974	100 (Ford zeg)	124 (Ford tf)	140 (ERDA)	160 (EEI)
1976	75 (Lovins)	89–95 (Von Hippel)	124 (ERDA)	140 (EEI)
1977–78	33 (Steinhart)	67–77 (NAS I, II)	96–101 (NAS, III, AW)	124 (Lapp)

Note: Amory Lovins put together this table showing the downward drift in forecasts. Figures represent total U.S. energy demand in year 2000 or 2010.

ates in the future. Auto fuel economy will icrease even faster than government standards, and retrofitting will increase conservaion in the industrial and residential sectors.

iergy Supply

efore discussing each of the major supply itions, I will provide an overview of our curnt consumption, reserves, and energy reurces. Several important points emerge om examining our energy reserves and reurces (table 2). First, the magnitude of the serve and resource numbers clearly demonrates that we have huge amounts of energy serves and resources relative to our current nsumption. Our reserves could last from 70 170 years and resources could last from 250 320 years, assuming energy demand ineases at 1% per year and that we maintain r current level of import dependence.

Second, our energy problem is one of the screpancy between the forms of energy we e consuming and the forms we have in rerve domestically (table 3). Half our conmption of energy is oil and one-fourth tural gas, but our reserves of these sources e no more than 7% of total reserves. Our ergy problem is really the national security oblem of being dependent on the rest of the orld for half our liquid fuel needs. The ergy problem is best characterized as the nsition from our current patterns of energy pply and demand to patterns offering a bet- match between social cost and social value. (Included in social cost would be items such as the national security externality, environmental externalities, and risk premiums associated with some of the energy sources.)

Third, the extent of our energy reserves and resources depends critically upon whether or not the fast breeder reactor is developed. Uranium reserves and resources are multiplied by 60 to 100 times with the breeder reactor. In addition, we have vast reserves of thorium which can be used in a breeder cycle. However, large uncertainties remain and safety, waste disposal, and proliferation problems are not resolved for nuclear power.

Another point of interest regarding the reserve and resource numbers is that they do not include renewable resources (flows) such as solar, hydropower, and biomass. Use of renewables for a portion of our energy consumption would extend the stocks beyond the time periods indicated above. Potential for the major renewable resources will be discussed below.

Coal

With the recent publication of the WOCOL study and the Venice summit pronouncements on coal, interest in the future potential of coal is quite high. The WOCOL study estimated that coal could provide one-half to two-thirds of the increase in world energy consumption over the next twenty years. In line with the CONAES, RFF, OTA, and WOCOL studies, I estimate that U.S. coal production could grow at an average rate of 4%–5% per year

ıble 2. U.S. Energy Reserves and Resources

	Reserves			Resources		
source Type	Amount	% with LWR	% with FBR	Amount	% with LWR	% with FBR

between now and 2000, which means that 2000 coal production would be 2.2 to 2.7 times the current level. Coal could increase from 19% to as much as 36% of total energy consumption by 2000. Coal exports may increase also.

However, the use of coal, whether it is directly combusted or converted to liquid or gaseous fuels, causes environmental problems. In addition, high levels of coal use may strain capital or equipment markets, cause transportation bottlenecks and social disruptions like the boom town growth in the West. Environmental problems include land reclamation, CO_2 effect, acid rain, air pollution, water pollution, and destruction of scenic beauty. Economically, coal-generated electricity compares favorably with oil-generated power even when all environmental control costs are included. For example, in Japan, where environmental control laws are strict, imported coal costs about $45 per ton and environmental costs add $35 a ton for a total of about $80 per ton compared to a cost of about $165 a ton for fuel-oil power generation. Comparison of coal to nuclear power is not so simple, and the answer depends very much on the assumptions used in the analysis. Generally, however, coal-generated power is as cheap or cheaper than nuclear power. The decision on the extent to which each will be used depends as much on the evaluation of nonmarket costs as on market costs.

Coal can substitute for liquid and gaseous fuels in several ways. We normally think of the most direct route technically, which is to liquify or gasify the coal. The CONAES study estimates that coal liquid and gas production in 2000 would be 2.3 and 3.5 quads, respectively, under the business-as-usual case. (No coal liquid or gaseous fuels are being produced commercially today in the U.S.) For the national commitment scenario these level reach 4.7 and 4.5 quads. Current estimates fo coal liquids cost range between $40 and $6 per barrel. Coal liquids plants will require a billion capital investment. High BTU coa synthesis-gas costs range between $3 and $ per million BTUs (1,000 cubic feet).

Another means of using coal to substitut for liquid fuels is by converting to electri vehicles and trains for motive power. Railroa electrification is one means of substitutin electricity generated by domestic coal or nu clear sources for diesel derived from importe oil. Assuming 1,000 route miles per year (new electrified track and a 2% annual growt in freight, preliminary research results ind cate that the oil savings by 2000 would b about 100,000 barrels per day or the equivalei of two syn-fuel plants.[2] The capital investmei required to achieve this savings is roughly th same as for an oil shale syn-fuel plant- $35,000 per barrel of daily capacity. Howeve the operating cost is considerably lower tha for a syn-fuel plant.

Use of electric vehicles also would brir about substitution of coal or nuclear power f(imported oil by displacing gasoline. By th year 2000, electric vehicles could achieve a oil savings of about 500,000 barrels per day, (ten syn-fuel plants (1 quad). The capital co in new plant and equipment for achieving th savings is estimated to be about $31,000 p new daily barrel of oil saved. Electric vehicl are projected to be competitive at gasoli costs slightly less than $2.00 per gall(($1980). (These preliminary results also con out of the Purdue energy transition study.)

[2] These are preliminary results from an ongoing study of energy transition by an interdisciplinary group at Purdue Univ sity. The unit of syn-fuel plant is a convenient measure to comp alternatives because many energy planners think in terms of t unit, which is about 0.1 quads/year.

We can expect to see increased efficiency in oal power generation over the next twenty ears by the successful development of echnologies employing cogeneration, fluidzed bed combustion, and Magneto-hydroynamic (MHD) coal power generation.[3] Inreased power generation efficiency will both ower the cost and reduce the primary energy equirement of coal-based power.

)il Shale

As indicated above, this nation has vast reources of oil shale, but the development of hale likely will not come close to the resource otential. The constraints on oil shale develpment will be environmental and social. The)TA oil shale study concluded that a 400,000 arrel per day (eight plants) industry could be eveloped by 1990 without serious difficulties, out that a 1 million-barrel-per-day industry vould unavoidably violate environmental air quality standards and cause serious economic and social disruption to the producing areas. Apparently, the environmental, economic, and social systems can accommodate a certain evel of development, but once this threshold s reached, the social costs of further develpment increase rapidly.

A 50,000-barrel-per-day oil shale plant is projected to cost $1.7 billion or $34,000 per daily barrel of capacity. Oil shale costs are projected to range between $35 and $60 per barrel depending on the crude oil price increase and rate-of-return used.

Oil and Natural Gas

The CONAES study projects U.S. oil production to range from 12 to 20 quads in 2000, depending on the level of national commitment to increased oil production. Most other studies project domestic oil production in 2000 including enhanced oil recovery to be lower than the 1979 production level of 17 quads. Domestic gas production in 1979 was about 19 quads. Domestic production of natural gas for 2000 ranges between 7 and 17 quads in the CONAES study.

Solar

The Harvard study projects solar energy to provide 4 quads by 1990. Solar energy utilization in the CONAES study is .0, 4.0, and 7.7 quads in the three scenarios. Direct use of solar is often more expensive than conventional sources. Without substantial economic incentives, solar energy will remain quite low over the next twenty years.

Nuclear

Nuclear energy is a large question mark for our country for the next twenty years and for the next century. The energy potential from nuclear energy is very high, yet so are the perceived social and environmental risks. The CONAES estimates for nuclear energy for 2000 are 12.5, 29.5, and 27.5 quads. Current nuclear power generation is about 3 quads. Even the CONAES business-as-usual case entails a quadrupling of nuclear power by 2000. Whether nuclear power will achieve that level or anything higher is an open question.

Biomass

The biomass energy category includes a wide variety of sources including wood, forage crops, crop residues, grains, and municipal solid wastes. Wood currently supplies about 2 quads of energy primarily in the forest products industry. The OTA biomass report attributes the highest potential within the biomass category to wood followed by forage crops. (Municipal solid waste was not included in this OTA report.) The most immediate biomass potential is for ethanol for gasohol from grains. Recent projections for ethanol capacity are for 60,000 barrels per day oil equivalent (1.2 syn-fuels plants) by 1983 (Meekhof, Gill, Tyner). By 1990, ethanol capacity could be 2 billion gallons per year of 145,000 barrels per day oil equivalent (about 3 syn-fuels plants or .3 quads). Whether or not grain alcohol production will increase beyond that level will depend on the impacts alcohol production has on feed/food prices and the policy response that occurs. Current research results indicate that alcohol production levels substantially higher than 2 billion gallons could cause corn prices to increase substantially (Meekhof, Tyner, Holland). By the mid 1980s, most authorities believe that cellulose conversion technologies will be commercially available to produce ethanol from crop residues, forage crops, wood, or municipal solid waste. It is too early to tell whether cellulosic biomass will be gassified, directly combusted, or converted to methanol or ethanol. The CONAES

[3] Magneto-hydro-dynamic power generation probably is more than twenty years away from commercialization, but has a good potential for the next century.

biomass estimates for 2000 are 0.1, 1.9, and 5.4 quads. (These figures exclude 2 quads of wood energy not currently included in U.S. energy statistics.) The most likely sequencing of biomass resources is an initial surge in grain alcohol followed by greater use of wood, municipal solid waste, and other cellulosic sources later in the 1980s.

Time Phasing of Supply Alternatives

In the very near term, the next five years, the most important changes in our energy picture will be increased conservation and ethanol production from grain. The 1979 oil price increase plus the phased deregulation of domestic oil and gas will induce much greater conservation than has occurred in the past. Within the next five years, there will be no commercial syn-fuels production from coal or oil shale, little use of electric vehicles, small increase in nuclear power, and a very low growth in solar energy. It takes six years to build a syn-fuel plant and ten to twelve years to bring a nuclear power plant to completion. A grain alcohol plant can be completed in two years, and I expect to see the equivalent of at least two syn-fuel plants of ethanol before the first coal or oil shale plant comes on stream.

Over the next decade, syn-fuel plants will come into production as will electric vehicles and rail electrification. By 1990, savings due to rail electrification likely will be less than one syn-fuel plant equivalent, but electric vehicle savings could be about three syn-fuel plants equivalent, roughly the same as biomass alcohol production. Oil shale syn-fuels could be as much as eight plants with roughly the same amount from coal gasses and liquids. By 1990, methanol from coal will be in production with the major use probably for turbine electric power generation (displacing fuel oil) for peaking power. Methanol from coal will grow fairly rapidly for stationary plant energy needs and perhaps for motive power as well.

In the 1990s, syn-fuels from coal will grow fairly rapidly along with solar, biomass, electric vehicles, and nuclear power. During the next two decades the absolute level of our dependence on foreign oil will decline very little, but the percentage of our dependence could decline from about 21% of total energy today to 13%–15% in 2000.

Because of the long lead times involved in the development of the energy alternatives, we face several critical choices in the next few years that will influence our ability to make the transition away from oil to other energy sources. We have already begun to deregulate oil and natural gas prices—steps which are absolutely essential if we are to achieve the conservation and alternative fuels development levels outlined in this paper. I think we should go further and place a tax on crude oil to internalize the national security externality caused by our dependence on oil. A crude oil tax would reduce demand growth as well as stimulate development of energy alternatives.

The other major choice we must make over the next decade is between the economic potential, environmental disruption, and societal risks associated with coal power and nuclear power. We will need some of each, but the choice concerns emphasis. I expect we will spend the next five to ten years developing both coal and nuclear power, but during that time we will have to decide how best to handle the externalities and risks imposed by each of these major power sources.

Table 4 summarizes where I think we are likely to be in the year 2000 for two demand levels. Note that I do not expect us to be on either a "hard" or "soft" path exclusively, and I reject the notion that "hard" and "soft" paths are mutually exclusive options. We will have some of each, with the "hard" path being dominant over the next two decades.

When we reach the vantage point of the year 2000, I hope we will be able to look back and see that we have developed to some extent the wide variety of energy sources we have discussed here including oil shale, coal syn-fuels, electric motive power, nuclear power, solar and biomass. If that is the case, we will be in a much better position in the year 2000 to project to 2020 than we are in today. My own feeling (from the 1980 vantage point) is that nuclear and solar energy (perhaps strange bedfellows) will provide much of the growth in energy from 2000 to 2020 and beyond. We may not be able or willing to greatly expand the syn-fuels industry or biomass because of the serious environmental degradation that could occur. Synthetic liquid fuels may be only transition fuels. To the extent that we are not able or willing to expand nuclear power, coal-based power is the most likely alternative. If that becomes the case, growth in coal-based syn-fuel development almost certainly will be limited and conservation and solar alternatives become much more important.

ble 4. Energy Supply and Demand for 2000

source pe	1979 Quads	1979 (%)	2000 (Demand = 95) Quads	2000 (Demand = 95) (%)	2000 (Demand = 105) Quads	2000 (Demand = 105) (%)

rce: Data for 1979 are from Department of Energy. *Quarterly Report: Energy Information*, Apr. 1980. Projection's are the author's.
1979 coal production actually was 17.4 quads, with 1.7 quads exported and 0.6 quads change in stocks. Year 2000 coal numbers ude synthetics.
iomass production and consumption, primarily wood in the forest products industry, currently is not included in official DOE istics. The 2 quads of biomass explains the different between the DOE 78 quads and the 80 quads shown here.
atural gas imports in 1979 actually were 1.2 quads. The figure is adjusted here to make production plus imports balance with sumption.

Clearly, this has been a personal view of our ergy future and the critical choices we face. s I said earlier, I approach the energy transi- n with guarded optimism. I am optimistic cause I see market forces both inducing nservation and increasing energy supplies. etroit is on a crash program to produce fuel ficient autos not because Washington re- ires them to, but because you and I—the nsumer—have required them to. Oil-drilling tes have set new records in the U.S. in 1980 part because of oil price deregulation. We e entrepreneurial activity all over the coun- y in developing and marketing conservation oducts and new energy alternatives. This es not mean that government policy is un- portant. Development of syn-fuels will not cur without government assistance—at least tially because the private risks are too great. so, weighing externalities and societal risks ainst private costs must be accomplished in e political arena. We as economists have a emendous educational role to play in this gard to convey the nature and importance of ese critical energy choices.

Economic Feasibility of Agricultural Alcohol Production within A Biomass System

Donald Hertzmark, Silvio Flaim, Daryll Ray, and Greg Parvin

From 1980 to 1990, the United States will face . situation of continuous decline in domestic production of petroleum from conventional ources. At the same time that our depenlence on imported oil becomes more severe, he use of lead and other octane boosters that ubstitute for energy and feedstock in the reining of oil will diminish to zero. Fossil-based ynthetic fuels are a likely alternative—but nly in the long term, beyond 1990. For the ext ten years, ethanol will be the only synhetic fuel commercially available in sigificant quantities. Moreover, the likelihood hat a large portion of coal-based synthetic uels will be alcohols or low octane gasolines nakes ethanol a compatible component of the ation's fuel system for the foreseeable future. This paper discusses technical and economic easibility, energy requirements, product ecoomics, and policy issues of producing ethanol rom renewable sources.

Technical and Economic Feasibility

The two major technical features of the production of fuel ethanol from grains and sugars re the grain handling and the actual fermentaion and distillation of the fermentable sugars. n the beverage process, the entire grain is ent through the cooking and fermentation cyle. The residue that comes from the distillaion columns is a fibrous (7%–8%), highrotein animal feed, distillers' grains. The bevrage technique is a fixed proportions proess yielding about 2.5 gallons of "dry" thanol and 16.8 pounds of distillers' grains 26%–30% protein) per bushel of grain input.[1]

The major alternative to the beverage process is the wet milling of corn for the production of oil, meal, feed, and fermentable sugars. This technique yields 2.5 gallons of dry ethanol, 1.7 pounds of corn oil, 11.2 pounds of gluten feed (22% protein), and 3.3 pounds of gluten meal (62% protein) per bushel of corn input (Keim). From a technical standpoint, the wet milling has several advantages vis-à-vis the beverage technique. First, less total volume is sent through the distillation columns, so that the columns may be smaller per unit of ethanol output. Second, the grain-handling and ethanol production parts of the facility are largely separate, so that innovations in either part of the technology can be adopted without a disruption of the rest of the process. And finally, the joint products of the wet milling approach have a greater economic value than the beverage byproduct due to the lower fiber content of the joint feed products compared to distillers' grain.

Both the beverage and wet milling techniques can use either batch or continuous fementation. Distillation can be either at atmospheric pressure or under vacuum. Continuous fermentation reduces fermentation time from approximately forty-eight hours to about eight hours (Chemapec) and lessens capital investment costs. Vacuum distillation produces 199^{+} proof alcohol in the distillation column at 120°F, thereby lowering steam requirements greatly. Most assessments of the energy, capital, and material requirements for ethanol production have been based on the least desirable set of production techniques. That is, the beverage process is assumed with distillation at atmospheric pressure and fermentation of the grain in batch rather in a continuous process.

Donald Hertzmark and Silvio Flaim are senior economists with he Agriculture and Transportation Group, Solar Energy Research nstitute, Golden, Colo. Daryll Ray and Greg Parvin are professor nd research assistant, respectively, in the Department of Agricultural Economics, Oklahoma State University.

[1] Water may be left in the alcohol if it is to be used straight or njected into the engine from a separate tank. Conventional distilation can produce only 95% ("neat") alcohol. Removal of the additional water requires benzene or gasoline distillation or one of several techniques such as selective membranes and molecular sieves.

Non-Feedstock Production Costs and Energy Requirements

Table 1 gives the production costs of alternative technologies. The estimated costs of production appear to converge about 70¢–85¢ per gallon, with lowest values reported by Lawrence Berkeley Laboratories (Maiorella, Blanch, Wilke) and the highest by the Department of Energy and Litterman, Eidman, and Jensen. The Chemapec and the Berkeley processes are extremely energy efficient so their variable cost components are relatively immune to increases in energy costs.

The advanced technologies being developed at the Lawrence Berkeley Laboratories include such improvements on the vacuum distillation and continuous fermentation techniques as flash fermentation and cell recycle. These technologies represent significant advances over existing low energy techniques.

Engineers from the Solar Energy Research Institute have performed an engineering and economic evaluation of an existing farm still in southeast Colorado and have found that the still compares favorably to existing beverage distilleries on both cost and energy bases (Jantzen and McKinnon).

As is evident from table 1, energy consumption is substantially higher for the traditional beverage processes (Keim; Litterman, Eidman, Jensen) compared to advanced or energy conserving processes (Office of Technical Assessment, Chemapec wet milling, Berkeley Lab, and Solar Energy Research Institute). Beverage distilleries for manufacturing ethanol are generally fueled by either natural gas or heating oil (no. 2). A few existing distilleries are fueled by coal or residual oil (no. 6). In almost all cases, these plants consume a significantly greater amount of fuel than is contained in the ethanol that is produced. Using these data, some analysts have concluded that alcohol fuels are merely a means of transforming natural gas or heating oil into an alternative form of high grade fuel. Cogeneration and use of waste materials to satisfy heat requirements provide alternative energy sources which are not reflected in cost or energy requirements in table 1.

The use of steam from power plants or other large energy sources is feasible for the entire ethanol production process except for mechanical drive needs. Using this low-grade energy to assist in producing high-grade energy could result in the net use of 3,000 to 22,000 Btu for the beverage process and 5,000 to 12,000 Btu for the wet-milling system.[2] Even adding energy consumption for growing the corn (36,000 to 72,000 Btu) co-generation of energy would show a favorable effiency ratio, especially since ethanol could provide the equivalent of 100,000 Btu per gallon due to higher combustion efficiency when mixed with lower octane gasoline. Ethanol distilleries have been proposed that would use waste steam of oil refineries (Commerce City, Colo.) or low-grade steam of geothermal reservoirs (Grand Junction, Colo.). Such efficiency compares well to finished fossil products since they must contain strictly less energy than was removed from the earth.[3]

Fossil energy requirements of ethanol production can also be reduced substantially by using waste materials for process heat requirements. Potential feedstocks include forest product, agricultural, and municipal solid wastes. Agricultural materials suitable for supporting an ethanol facility include animal manure from confined operations, food processing and packing wastes, and crop residues. The most advanced conversion technologies for using these materials include anaerobic digestion, gasification, and direct combustion (JG Press, English et al., Levelton & Assoc., Junge). Direct combustion is a low-cost application with many systems commercially available. Capital costs for bale burners are as low as $6,000 for systems in the 5 to 6 MBtu per hour size range (Flaim and Urban).

The principal advantage of agricultural waste materials is low feedstock costs. Propane at 65¢ per gallon (91,000 Btu/gal.) costs approximately $7.10/MBtu, while on-farm collection costs estimates of crop residue range from $8.00/ton (13 MBtu/T.), or 62¢/MBtu (English et al.) to about $16.00/ton or $1.25/MBtu (Duave and Flaim). Costs for residues transported ten miles range from $20 to $30 per ton ($1.50 to $2.30 per MBtu).[4]

At the present time, there are no commercial technologies for the fermentation of lig

[2] These figures are obtained by assuming that premium energ[y] need be used only for mechanical drive and that heat requirement[s] are met from coal or renewable sources. Details may be obtaine[d] from the senior author.

[3] Amidst all the furor over energy use for alcohol production, [it] is generally forgotten that the petroleum-refining industry is th[e] largest industrial gas user.

[4] A good summary of wood waste combustion systems suitabl[e] for direct combustion of crop residues is contained in Levelto[n]. The limitations of using wood waste materials for direct combus[-]tion is reviewed by Junge.

[b] All studies used different accounting conventions. In general, variable costs included fuel and enzymes; fixed costs included capital charges, depreciation, maintenance, labor, and profit.
[c] Batch fermentation and atmospheric distillation.
[d] Energy-conserving distillation.
[e] Collected from several studies.
[f] Flash fermentation, vacuum distillation. A similar, though less advanced process, is currently available commercially.
[g] Based on 20% rate of return on invested capital.
[h] A gallon of ethanol contained 85,000 Btu.
[i] Lower figure is for cellulose feedstocks, higher figure is for grain.
[j] Includes drying of stillage except for SERI farm-still study.

nocellulose (wood and agricultural residues). For these feedstocks, gasification and methanol synthesis is the far more likely route to alcohol fuels than is fermentation with existing technology. For manures and similar organic wastes, anaerobic digestion to methane for possible conversion to either methanol or electricity is the likely means of energy conversion.

Corn Feedstock Economics

The impacts of using corn to produce ethanol fuel on the agricultural sector of the U.S. economy were simulated with a national agricultural policy simulator (POLYSIM). The model contains supply and demand relationships for the major U.S. crop and livestock categories. For the purposes of this analysis, several modifications were made to POLYSIM. A series of equations was estimated to determine the domestic demand for the gluten meal and distillers' grains and the interactions of these demands with other grains and concentrates. Further work is in progress to include export relationships for the byproducts and to integrate the corn, soybean, and cottonseed oil sectors into the analysis. Linear growth in alcohol production was imposed on the model over a five-year period, with final year production ranging from 200 million gallons per year (80 million bushels of corn) to 1 billion per year (400 million bushels of corn).[5] An even split between processes generating dried distillers' grains and gluten feed and meal was assumed.

The preliminary results are summarized in table 2. In the final year of the five-year simulation period, corn prices and acreage increase and soybean acreage decreases slightly, but in general the impacts on the corn and soybean sectors are nominal. Final-year prices for gluten feed, distillers dried grains, and soybean meal for the 1 billion gallon alternative decrease by 26%, 28%, and 7%, respectively. Final-year soybean prices are nearly constant, with reduced supplies offsetting the effects of lower meal prices. However, not accounting for the effects of increased corn oil, production on the vegetable oil market biases soybean prices upward.

Soybean meal exports increase and the value of corn exports also increases. Overall, export earnings increase slightly with the

[5] A 3 billion gallon scenario was simulated. However, the joint produce demand equations contained no export provision. As a result, the joint product prices went below their values as boiler fuels. Simulation of more ambitious levels of ethanol production will need to include export oil joint products.

Table 2. Price Effects of Alternative Ethanol Programs on Selected Agricultural Sector Variables, 1979–83

			1983 Production (million gal./yr.)

Source: POLYSIM; Hertzmark, Ray, Parvin.

ethanol programs. The U.S. balance of trade n agricultural commodities appears to be little ffected by the production of ethanol in the ear term. Net farm income increases only noderately with ethanol production of up to 1 illion gallons by the end of five years.

Sugar Crops

The fermentation of sugar crops such as cane, eets, and sweet sorghum represents an addiional potential for fuel ethanol production. The same facilities that process grains can be sed for sugar crops with some relatively ninor modifications of the front end of the lant. With the exception of the sugar beet, one of these crops produces a joint product or food or feed use, though sugar cane distileries are in general net producers of energy electricity and steam) because of the trenendous volume of bagasse that is produced long with the cane (Adams). The less sophisicated processing vis-à-vis grains and celulose permits lower expenditures on the capial side; however the net cost of production is pproximately the same because of the lack of narketable joint products.

Table 3 presents the net costs of producing thanol under the range of conversion costs iven in table 1 and the feedstock and joint production costs given in table 2. For comparison, it is necessary to know the marginal cost of gasoline. To determine the marginal cost of gasoline, one must distinguish between domestic and imported supplies of crude oil. Domestic crude oil prices vary widely because of federal regulations on its definitions of "old" and "new" oil. Uncontrolled domestic oil is selling for more than $40 per barrel while oil subject to price controls is less than one-third this price (*Oil and Gas Journal*, p. 158). The most expensive imported crude based on posted prices comes from Libya and Algeria, with prices of $36.72 and $34.21 per barrel, respectively. In addition, Algeria charges a $3.00 per barrel exploration fee (*Oil and Gas Journal*). Foreign prices are f.o.b. port of loading and exclude transoceanic shipment and handling charges. At the posted price of Libyan crude, the cost of feedstock for gasoline is at minimum $0.874 per gallon ($36.72 ÷ 42 gal./bbl. = 0.874) excluding transoceanic shipment, handling, and refining costs.[6] These latter charges have been esti-

[6] The naphtha and other light fractions that are refined to gasoline and petrochemicals are more valuable than the heavier fractions. Only one OPEC member, Venezuela, exports naphtha for gasoline rather than crude. Recent prices for Venezuelan naphtha have been about $39–40/bbl (90¢–95¢ per gallon of gasoline). This would increase refinery gate and retail prices to $1.50 and $1.77 per gallon, respectively.

able 3. Costs of Ethanol Production under Alternative Scenarios (in Dollars per Gallon)

	1983 Production (Million Gallons/Year)[a]			1980 Actual (Mid-May Prices)[b]

Tyner's prices for ethanol range from $0.93–1.63/gallon but assume 15% r.o.i. instead of the 20% assumed above (Tyner, p. 15).

mated to be about $24.50 ($1980) per barrel (Flaim and Mount) excluding refinery losses. These average cost estimates combined with feedstock charges make the lowest possible cost for unleaded gasoline from Libyan crude $1.45 per gallon at the refinery gate. This implies a marginal retail price approaching $1.72 per gallon.

For all production scenarios, the price of ethanol is generally below that of marginal gasoline cost. Wholesale prices for wet milling process alcohol are in fact substantially less than for marginal gasoline at the refinery gate. Even with low value joint products as in the 1 billion gallon scenario, ethanol is competitive with marginal gasoline. For the beverage process, the implications are not as sanguine. The generally lower value of joint product and the high capital and energy costs make this technique less attractive for large-scale production compared to the wet milling process. Use of co-generation or waste materials as fuel sources would further enhance ethanol's price competitiveness with gasoline.

Policy Implications

Given the tax exemptions, loan guarantees, and tax credits either enacted under existing legislation or in pending legislation, gasohol development already has received considerable public policy attention. Well-meaning government actions—taken too far—can be inferior to a policy of standing back and letting market forces work. Of course, society has the prerogative of using subsidies to augment private economic incentives to countervail perceived external diseconomies of importing large quantities of oil. External diseconomies of gasohol production, such as increased soil erosion from adding marginal cropland and mining soil due to residue collection for fueling alcohol plants, also require consideration, however. Present and probable future increases in world crude oil prices and current improvements in alcohol production techniques could well justify future investments in alcohol plants without direct government subsidies. Rather than biasing resource use by providing tax exemptions or other subsidies for a specific syn-fuel (alcohol), the government could facilitate syn-fuel research and bear a portion of the risk through loan guarantees; perhaps acting as a demander of last resort.

Crash programs such as promoting and providing incentives for the construction of "a still on every farm" will probably do just that—crash. Farmers who have the grain for alcohol feedstock and the livestock for feeding the byproducts generally do not have the time nor technical expertise to run an alcohol plant seven days a week the year around.

Government farm programs will need to be modified to reflect the use of farm commodities for alcohol feedstocks. In particular, grain reserve targets and acreage diversion programs will need to be managed to accommodate the grain requirements of ethanol plants on an equal basis with grain needs of other consumers and users of grain. Loan rates, target prices, and procurement prices would be nondiscriminatory with respect to the end use of grain.

Energy and the Structure of Agriculture: A Political Economic Analysis

David Holland

The purpose of this paper is to provide an analysis of how the "energy crisis" is likely to influence the direction of future U.S. agricultural development. Emphasis will be placed on examining the main forces that will influence change in organizational type and size distribution of farm units.

In the view of neoclassical economic theory, the structure of an industry ultimately derives from the interaction between competitive market forces, relative price ratios, and a number of quasi-exogenous elements such as economies of scale, available technology, possible government regulations, and time lags in adjustment. From this perspective, the structure of agriculture is simply the outcome of a number of largely independent forces regulated in the public interest through the market. In the model developed in this paper, such a view represents a case of misplaced emphasis, incapable of generating a clear understanding of the principal mechanisms affecting structural change.

A Model of Structural Change in Agriculture

While market forces undoubtedly have an influence on the size distribution of farms at any given time, other forces reflecting essentially underlying distributions of wealth and political power are the more important determinants. To understand the dynamics of structural change in agriculture and the possible impact of energy shortage, the role of the state and role of asset distribution in agriculture must first be discussed.

The Role of the State

Economic activities in America may be classified into two broad categories: activities organized by private capital and those organized by the state (O'Conner). Production and distribution in the private sector falls into two subgroups: competitive industries organized by small business and monopolistic industries organized by large-scale capital (O'Conner).

In the competitive sector, production is typically small scale and markets tend to be regional or local in scope. Capital requirements are low and there is a tendency toward overcrowding. Output per worker is low and wages are low. Competitive sector wages, prices and profits are determined mainly by marke forces. Farming may be seen as a once competitive industry rapidly on its way to los ing its competitive character.

The monopoly sector is characterized by large-scale production. Barriers to entry ar plentiful. In the monopoly sector, marke forces are not the main determinants of wages prices, and profits. Monopolistic corporation have substantial economic power and are abl to administer prices. Wages are determined b worker productivity and the bargaining powe of unionized workers.

The role of the state in this economic syster is to carry out two main functions: accumula tion and legitimization. First, it must assure a economic environment conducive to expar sion of business activity and the accumulatio of capital both at home and abroad. Seconc the state must try to maintain or create cond tions for social harmony. Examples of the fir type of activity are fiscal and monetary polic foreign policy, education and manpower po icy, and investment in physical capital pro ects providing basic infrastructure, such a freeways, airports, and mass transit system Examples of the second type of activity ai insurance against sickness, old age, unen

Helpful comments on earlier drafts were received from Bruce Florea and Phil Wandschnieder. Cheryl Wilkie was helpful in developing the analytical perspective.

ployment, public housing, and, in short, much of what is now known as the "welfare" activities of the state.

The character and policies of the state derive from its legitimization and accumulation functions as the state attempts to resolve the various contradictions introduced by the growing importance of the monopoly sectors. It is not necessary to explore these contradictions in this paper, as they have been well-developed elsewhere (O'Conner). What is important for our purposes is to recognize that behavior of the state is going to be influenced mainly by the needs of the large monopoly sectors of the economy. To the degree that broad national policies are developed that affect farming, the well-being of most farmers will be an incidental consideration.

The Role of the Distribution of Land and Capital in Agriculture

The existing distribution of wealth in farming deserves special attention in our discussion because it is the main determinant of class structure in most rural areas (Gotsch) and class interests. In any rural area in the U.S., some variation of the following structure can be found. At the top of the pyramid are large businesses, large industrial-type farms, and larger-than-family-type farms (Rodefeld). Owners of these resources may reside in the area, but often do not. Next come the small capital owners who provide most of their own labor and management. Examples are family-type farms and small business. Finally there is the great majority of the propertyless, who do not own productive assets and who exist largely through the sale of their own labor.

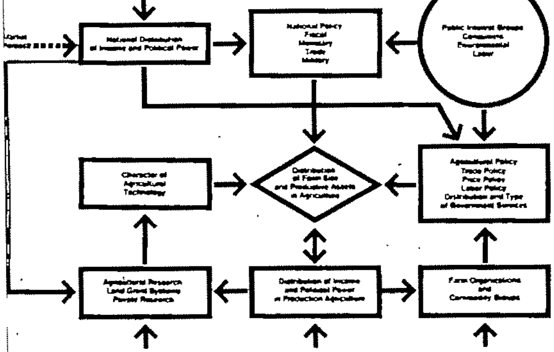

Figure 1. Flow diagram of factors affecting the distribution of farm size in U.S. agriculture

Agricultural development inevitably changes the welfare of each group, and each group desires to influence that development in ways that are beneficial to them. The two main areas in which the distribution of personal income and political power are hypothesized to influence future agricultural development are through the character of technological change in agriculture and the character of overall agricultural policy viewed as not only formal policy legislation, but also as government regulation and the type and orientation of governmental agencies that are supposed to serve agriculture.

Various Components of the System and Their Feedback Effects

A formal model of the determinants of agricultural structural change is presented in figure 1. The distribution and magnitude of personal income and political power in the farming sector (represented in the diamond) is the central element influencing structural change. The distribution of income and power is determined mainly by the distribution of land and capital in farming and the stage of historical development in agriculture. Because large components of farming are still competitive, market forces also have some influence upon agricultural income. Income levels and the resulting political power then become the inputs into the three main feedback loops influencing agricultural structure: capital accumulation, technological change, and agricultural policy.

The character of agricultural technology is viewed as influenced by the type of agricultural research done. To some degree that research will be directed by present and expected future relative price ratios as the induced development hypothesis (Hayami and Rüttan) would suggest. But of greater importance is the issue of who is allowed to define the important problems. Agribusiness, which in figure 1 is treated as in the rest of the economy, and the larger farmer's interests are the most important here. Since the research perspectives of each of these groups are dominated by the large concentrations of capital represented, the problems defined are those of the large agribusiness firms and the largest farmers. Consequently, technological change is focused upon solving those particular problems. As a result much of the research that is done is most appropriate for very large farms.

Even when technology is divisible across farm size, savings to acquire new land and capital will be generated mainly from the profits of larger farmers and agribusiness firms, and pressure for the expansion of farm size can be expected to continue from these sources. It is savings generated from both the absolute magnitude and distribution of farm income which provide the second main feedback loop affecting farm size (denoted by the double arrow between income distribution and asset distribution).

The third feedback loop relates farm income and political influence to the character of the institutions serving agriculture and to farm policy. The current beneficiaries of government services, who are mainly the larger farmers, do not want to see their control of these services passed over to other individuals. Agricultural development in directions that seem to threaten this control will be strongly resisted. To the degree that existing farmers and commodity groups are able to influence policy, the policy that emerges will serve existing holders of agricultural capital and will help to further consolidate the concentration of this capital.

The ability of agriculture to influence only partially the determinates of its own structural change is emphasized by the role ascribed to the national distribution of income and political power. Here competitive market forces have minor influence (indicated by the dotted arrow), with most impact deriving mainly from the underlying distribution of wealth at the national level. This distribution of income and political power guides the activities of the state as it acts in either its legitimization or accumulation aspects. Fiscal, monetary, trade, and military policy at the national level affect both the size and distribution of income in farming which, in turn, directly and indirectly influence the size distribution of farms.

The national distribution of income and political power will also, as indicated in figure 1, have a direct effect upon both the character of agricultural policy and technological change. Inasmuch as the more advanced monopolistic sectors are able to wield more political power, it is not unreasonable to expect agricultural policy and research directions to develop which are conducive to the extraction of large profits from the farming sector by agribusiness corporations.

Finally, the role of the special interest groups associated with the consumer, labor, and environmental movements must be considered. Such groups are largely outside of the main flows of economic and political power in this country and are depicted as such in figure 1. Nevertheless, such groups are viewed as having an influence on both national, and more specifically, agricultural policy, decisions.

Implications of Energy Shortage for Structural Change in Agriculture

Within the framework described in figure 1, it is now possible to return to the issue of the likely impact of energy scarcity on the size distribution of farms. In periods of petroleum shortage it has become clear that a reoccurring problem of advanced industrial economies is the addition of energy-induced inflationary pressures to other inflationary sources as increased energy costs pass through the industrial system (Carter and Youde). In an attempt to fight both inflation and balance of payments problems, anti-inflationary fiscal and monetary policy is pursued resulting in the now all too familiar characteristic of the 1970s—stagflation.

With stagflation as the overall economic picture for the 1980s, the forecast for agriculture that I see is one of an increasingly severe cost-price squeeze. Energy will be allowed to continue to rise in price, while simultaneously the price of wage goods will be held down to the degree possible with a cheap food policy. Lowered rates of economic growth around the world will lead to a lowered rate of growth for U.S. agricultural exports.

Within this general picture there will be attempts to ameliorate the impact of energy price increases through short and long-run technological change and government assistance. All such possible policy programs and research development must first, however, be filtered through the lens of economic class interest. Because existing research and policy institutions are heavily dominated by large industrial-type farm (Rodefeld) interests, it is not likely that the emerging research and policy directions will be directed toward improving the survival chances of smaller and medium-sized farms or the well-being of agricultural labor. An example of this sort of selectivity can be found in a recent work where "realistic and unrealistic" responses to energy shortages are discussed (Buffington and Zar).

Conclusions

Assuming the preceding analysis is correct, the future for the family-type farming in America is bleak indeed. Faced with an intense cost-price squeeze arising to some considerable degree from energy scarcity and the nature of agricultural input and output markets, family-type farms are unlikely to witness the specific kind of research development or government programs that will permit or enhance their viability.

The many contradictions including the energy crisis that now beset agriculture demand that the issue of structural change be treated as a possible policy variable rather than as an exogenous constraint. The goals of an ecologically sound and socially equitable agriculture will require that the agricultural treadmill be stopped. This will necessitate that the role of so-called "competitive market forces" be lessened or eliminated with greater emphasis upon social planning and social control of the food system. Such an accomplishment will in turn require reorientation of research in the land-grant system toward greater emphasis on energy conservation, environmental soundness, and social equity aspects of technological change. The other public institutions supposedly serving agriculture will have to be similarly directed.

While some will argue that the present direction of change is in similar directions, it must be emphasized that change is taking place only within a context that is circumscribed by the class interests of existing concentrations of land and capital. To attempt to make adjustments to energy shortage strictly within the confines of the existing agricultural structure will be very detrimental to family-type farms and eventually to the democratic principles upon which this country was founded.

The type of policy, research, and economic redirection just discussed will not materialize out of thin air. Strong shifts in political alliances will be required. The large number of currently existing family-type farms will have to realize that they are not being well served by the existing set of institutions. They must recognize their endangered position and realize that their present identification and alliance with the interests of large-scale industrialized farming eventually will lead to the extinction of both their living and way of life.

A new political alliance must be forged; not with the agribusiness elite but with the progressive elements of labor, consumer, environmental, and women's groups. Traditionally, these groups have been viewed as enemies of agriculture. What existing family-type farmers are going to have to realize is that agriculture's erstwhile friends have the family farm locked in a death grip and that the only hope for survival lies in breaking the stranglehold.

Critical Choices in Energy: Discussion

Norman Rask

The energy problem has been recognized for several years. Yet, our profession has delayed in making serious efforts to identify and address energy realities. Part of this reluctance stems from an inability to see clearly our energy future. It is generally recognized, however, that we have reached a turning point. A long history of declining relative energy costs and a perceived abundance of oil has been reversed. Now, new sources of energy and new energy use patterns must be developed. Past experience is of limited value in determining the environment within which these critical choices in energy are to be made. It is difficult, for example, to make demand projections without a valid historical base. The relationship between economic growth and energy use, as well as the degree of conservation that can be expected in the future, is relatively unknown. In addition, there are many uncertainties on the supply side, such as the future Irans, Mexicos, Three Mile Islands, and development of new technologies. These are all situations that will alter the conditions as we now see them and, thus, affect our future choices in energy. Within this difficult framework, our panel has made important contributions. In the following discussion, I identify some of these major contributions, suggest some additional points I would have liked to see addressed, and outline a general framework for further study.

The Tyner paper makes a particularly important contribution in presenting a balanced view of the energy transition from the 1980 perspective. I believe the general direction, timing, and magnitude of the energy transition that is depicted is essentially correct. With the excellent frame of reference provided, one is tempted to ask for much more. I would have liked, for example, to see more attention to world versus U.S. situations relative to supply, demand, and price possibilities. It would have been helpful to have some projections on future levels of petroleum prices. For example, will coal liquids, oil shale, and alcohol put an effective price ceiling on petroleum? If so, are we looking at a doubling of 1980 oil prices in real terms over the next ten years, or as Tyner has suggested, will production limits imposed by environmental factors, costs, and water availability restrict production of these alternative liquid fuels to the point that they cannot provide an effective brake on petroleum prices?

A reference to the unique U.S. energy resource base would have been helpful since most other countries of the world face a somewhat different energy transition. Brazil, for example, which imports over 80% of its petroleum requirements and has a large underutilized land base is moving rapidly toward a significant substitution of alcohol for its liquid fuel needs. Brazil also will utilize a significant hydroelectric potential. France, on the other hand, with scarce domestic energy resources, is moving toward a much heavier reliance on nuclear energy. These are two examples that illustrate how individual countries facing different energy and agricultural resource situations will find substantially different paths through the energy transition.

The Hertzmark and Flaim paper is complementary to the Tyner paper. It deals more specifically with agriculture's contribution to meeting petroleum shortages over the next decade. There are two important points in this paper. First, it highlights the fact that biomass alcohol will serve two purposes. It will be both a substitute liquid fuel before the more plentiful synthetic fuels can be produced in significant quantities and also a useful additive to those fuels when they become available. Second, their review of changing alcohol production technology demonstrates that new developments are bringing about substantial improvements in processing technology and energy balances in a short time. I would have liked to see a broader treatment of the food-feed-fuel issue. Simulations were run over too narrow an alcohol production range and too

Norman Rask is a professor in the Department of Agricultural Economics and Rural Sociology, Ohio State University.

short a time horizon to get at the commodity price and land use questions that certainly will arise as we move into a more substantial alcohol program. For example, had the alcohol production levels been extended to five billion gallons annually over a ten-year horizon, the authors may have come to substantially different conclusions concerning the impact on commodity prices.

The Holland paper looks at the potential structural changes in agriculture that will result from higher energy prices. This paper argues that the market power and political influence of large farm units will continue to increase at the expense of small farms as energy costs rise. The resulting inflation and cost-price squeeze will be more detrimental, in Holland's view, to the smaller farmers.

I have two problems with this characterization of the energy impact on agriculture. First, it puts too much of the structure burden on potential income impacts of rising energy costs. The structure question is a much broader issue. Second, as noted above, agriculture is in the unique position of being a supplier of energy, as well. Thus, the cost argument alone misses the positive income effects of alcohol production. In my view these positive income effects likely will outweigh in the aggregate the cost effects of higher energy prices. Certainly there will be some regional differences due to increased transportation, irrigation, and other energy input costs, but agriculture in general should prosper during the next decade.

I turn now to some general interpretations. There are at least three energy realities that will be important for agriculture and for researchers attempting to project the impact of the energy situation on agriculture. The first is that oil and natural gas will be important sources of energy for most planning horizons. Clearly they will be more costly, perhaps as much as \$50–\$60 per barrel at 1980 price levels. This projection has to be conditioned on many unknowns including the degree of conservation that can be obtained in the use of liquid fuels, and the relative quantities of coal liquids, shale oil, and alcohol that can be produced within the constraints mentioned earlier.

A second energy reality is that no new dominant energy source is known or likely to emerge over the next twenty years. The transition period will consist of a composite of energy sources and, therefore, no options should be foreclosed as we attempt to find replacements for oil and natural gas.

The third energy reality is that during the 1980s conservation and alcohol production are the only liquid fuel substitutes that can be provided in significant quantities. Thus, rising oil prices, externality costs of imported oil, and development of new alcohol technologies will all combine to make a modest alcohol industry politically desirable and economically attractive. This has far ranging implications for agriculture. The degree to which alcohol will be called upon to substitute for oil depends on many unknowns including conservation efforts, the political stability of the oil exporting countries, and future petroleum prices.

These general energy realities as they impact on agriculture suggest several areas for research and extension efforts. First, there is a need for public information programs. We clearly need public understanding not only of the energy realities but of the options, the uncertainties, and the relevant policies that flow from these conditions. Most institutions, both private and public, have strong credibility problems in the energy area. Thus, the university has a unique role to play in providing this form of public information.

An important area of needed research is the changing structure of demand for farm products. Demand estimates are especially important for assessing the impact of an alcohol fuels program. The U.S. consumer has tremendous flexibility in adjusting expenditure patterns. The manner in which he adjusts to higher energy prices in both food versus nonfood items as well as the substitution between individual food items will be an important determinant of the demand for farm products. The level of international demand for U.S. farm products will depend on both the income effect on consumer choices in other countries as they adjust to higher energy prices and the supply effect as countries such as Brazil shift to energy crops. This will affect local production of food and feed crops as well as the amount of agricultural products moving in international trade. Because the U.S. is also a major importer of agricultural products, these changes in other countries will affect both our imports and our exports.

Another research area relates to agricultural adjustments to higher energy prices. First, we need to incorporate energy costs explicitly in most research efforts. We have to use cost

sensitivity analysis over relevant energy price ranges, perhaps a doubling of real energy prices over the next ten years. As we look to specific forms of energy, there may be some differences. For example, if we consider marginal rather than average pricing of certain energy sources, a wider energy price range will be needed. This may be necessary also with energy sources that are now regulated and protected. The point is that any research effort that depends on the current price of energy for validity will have only very short-run usefulness.

A second research area under agricultural adjustments to higher energy prices is interregional competition. Transportation costs, energy use differentials by various agricultural enterprises, and the demand changes that will come about in specific regions with energy crop production are all factors that will affect interregional competitiveness. We need to anticipate what these changes will be.

Activities beyond the farmgate will be affected significantly by higher energy costs. Marketing, processing, and consumption activities actually use much more energy than farm production, and we need to study the impact of energy costs on each of these functions.

Energy crop production is the final general area of research emphasis. Many of the points mentioned earlier apply here as well. However, I think there are some specific issues that need special attention. First, with the interest and emphasis on small-scale alcohol production for on-farm uses, we need studies that look at incorporating energy production and consumption into the farm or the firm operation. Second, with rising energy prices and the existing subsidy program, we need to determine the level of subsidy or incentive policies that are needed. Finally, in line with the earlier demand studies, we need to determine the impact of energy crop production on the supply and price of our traditional farm commodities.

These are a few of the important areas that need immediate attention. It is a broad agenda and we have made only a very modest beginning.

Food Aid and Nutrition

John W. Mellor

Four questions should be considered when discussing improving human nutrition through food aid. What is the effect of increased food supplies and the corresponding decline in food prices on food consumption and the nutritional status of low income people? Can market interventions increase the efficiency of a given addition to food supplies for these purposes? What is the effect of reduced prices on food production? And, can market interventions decrease the unfavorable supply effects of consumption-oriented policies?

The two consumption questions address the issue of how to utilize a gross increase in food supply to improve quickly nutritional status. The two production questions deal with long-range effects of food aid on total supplies, consumption, and nutrition.

Objectives

The manifest objective of food aid to improve human nutrition presumably is derived from an underlying objective of reducing poverty, recognizing that poor health is a particularly pernicious aspect of poverty and that inadequate food is a major source of ill health.

Thus, food aid can provide a direct, immediate, and charitable means of reducing poverty. Foreign assistance took on a particularly charitable orientation following the mid-1960s as the result of impatience with the effect of earlier foreign assistance efforts to encourage growth and reduce poverty. Even the production breakthroughs of the "green revolution" tended to be discredited (Griffin). This negative attitude toward growth was reinforced by increasing concern among foreign assistance donors about its environmental effects and, more recently, the amount of energy use it required. The result was increased emphasis in the donor community on direct reduction of poverty. In agriculture, less emphasis was placed on technological change and the purchased inputs that would increase the price responsiveness of food output (Bapna). Perhaps surprisingly, more stress on direct welfare and less on elements that increase price response has not brought about increased support for food aid.

Using food aid to achieve improved nutrition need not reflect solely charitable motivations. The inability to provide adequate food to a large proportion of a country's population in the long run is reflected in an inability to accommodate those people in the political system, leading to narrowly based and unstable regimes (e.g., Mellor 1976, 1979). Thus, improving nutrition through food aid may be consistent with political objectives, but to achieve a wider political base, allocations may have to be made exceeding the narrowly defined poverty group.

Similarly, improvement in food consumption and nutrition of a broadly defined poverty group provides the basis for a stable, low wage labor force, which in turn is conducive to more labor-intensive production (Mellor 1976). In the long run, a strategy to increase employment will shift aggregate consumption toward wage goods, particularly food, to the advantage of food-exporting countries.

Dumping, direct displacement of alternative imports or domestic production, and the replacement by food aid of other forms of foreign assistance may conflict ultimately with nutrition objectives. However, these problems, which are based on different considerations, are not the subject of this paper.

In the period 1971–76, over one-third of food aid went to countries other than those designated as "needy" by the United Nations Economic and Social Council, the World Food Council, the Consultative Group on Food Production and Investment, and other international agencies. Calculations by the International Food Policy Research Institute show

Per Pinstrup-Andersen and Shubh Kumar provided helpful suggestions.

that for the needy nations the percentage of the calorie gap (estimated by FAO) taken up by food aid ranged from 0 to 68%, with no apparent relation between the amount of food aid received and the extent of need. For a number of countries not considered needy, the amount of food aid was considerably larger than the calorie gap. It is clear that objectives other than nutrition have been major determinants of food aid allocations. There has been a tendency for critics to use this evidence of food aid allocated for political reasons to condemn it as an instrument for reducing hunger and poverty.

Market Effects on Price and Consumption

Increasing the total supply of food grains through food aid can have a major impact on nutrition by reducing market price. Use of market forces is administratively simple. Potential drawbacks, however, are distribution of substantial financial benefits to higher income people and discouragement of domestic production.

A change in food grain prices has a large effect on consumption of low income people because they allocate a high proportion of total expenditure to food grains. This is shown by Indian data. Taking into account only the income effect on the bottom two expenditure deciles, a 10% increase in food grain prices brings about a 5.5% decline in real total expenditure (Mellor 1978, p. 6). In the bottom two income deciles, food grains comprise more than half of the total consumption expenditure. Therefore, a 10% increase in food grain prices reduces their expenditure on food grains by 5.9% and their consumption by 6.6%.

A change in food grain prices also has an impact on expenditures on other commodities. Although the absolute effect is small, the percentage changes are large. For example, a 10% increase in food grain prices causes the two lowest income deciles to reduce consumption of milk and milk products by 33%. Similar percentages for other commodities suggest that changes in food grain prices have a major effect on nutrition of the poor, first, because caloric intake that is already submarginal may be significantly reduced and, second, because foods of poorer quality may be substituted for those of higher nutritional value. These substitutions may not be major; nevertheless, they have the potential to reduce the quality of the diet. Because supply can respond so little in the short run, efforts by the poor to switch to lower quality food grains will serve largely to further reduce quality differentials in price.

Using the elasticities implicit in the income effect of a price change, one can calculate the effect on income and food grain consumption of a change in supply—or for commencing or terminating a food aid program. Again, the Indian data show that a 10% decline in food grain supply would cause a 37% decline in real expenditure of the bottom two deciles (Mellor 1978, p. 11). It should be noted that in reality such a large price effect would not occur because indirect effects on employment and incomes resulting from expenditure decline by higher income classes would reduce overall food grain consumption, thereby lessening the upward pressure on prices. But the described effect on consumption is probably a reasonable depiction of the sum of price and employment effects.

Further analysis of expenditure data confirms that change in food grain supplies and prices is an efficient means of affecting consumption of food grains by low income people. Whereas a 10% increase in food grain prices reduces food grain consumption of the two lowest deciles by 5.9%, it decreases food grain consumption of the upper half of the tenth decile by only 0.2%. The absolute real expenditure on food grains is reduced ten times as much for the lowest two deciles as for the upper half of the tenth decile. In a market economy, the bulk of the adjustment to reduced supplies of food grains is made by low income consumers. Thus, food aid that adds to total supplies of food grains has a major effect on incomes, consumption, and nutritional status of low income people. An important caveat is in order, however.

To illustrate, those in the top 5% of the income distribution in India spend more than two-and-a-half times as much per capita on food grains as the lowest 20%. Thus, the upper income group experiences twice as large an effect on its overall income from a change in food grain prices as does the lower income group. Whereas food grain consumption varies little in the upper income group in response to changes in food grain prices, consumption of other goods and services varies substantially. This has two important implications.

First, these changes in consumption patterns may have important indirect employment effects on the poor. Second, there may be important inflationary or foreign exchange

effects, depending on the supply elasticities for those other commodities. The first effect is a positive one. Lower prices to higher income people are in part passed on to the poor through increased employment.

Thus, there are disadvantages in market mechanisms to allocate food aid to low income persons. Prices must be reduced substantially if there is to be a favorable effect on the poor. This has a harmful effect on production because of reduced farmer incentives, as well as on public resource allocation, and the pressure on politicians to support agricultural investment. Further, while the market efficiently allocates the food to the poor, it allocates the financial benefits substantially to the rich with consequent potential for major costs in the form of other resources. These considerations lead to interest in market interventions to shift benefits more to the poor and to depress farm prices less.

Market Interventions

Market interventions must be judged by their administrative cost, the extent to which they direct resources to the targeted group efficiently, and their political support. It is because of the need for political support that interventions often cover a group larger than the more specifically defined target group.

Two questions arise when considering targeting food aid to low income, nutritionally deficient groups. First, can an intervention be defined that narrows the recipient group? Second, does making the intervention in particular forms, specific to food, for example, increase the nutritional impact?

The question of how to operate an intervention to narrow the target group is complex. The broad food subsidy schemes of South Asia narrow the target group by using lower quality products and setting a maximum quantity (Ahmed, Gavan and Chandrasekera, George, Kumar). Further limiting of access to nonincome taxpayers is perhaps possible. Food stamps appear to be administratively and politically unwieldy for low income developing countries. Programs in India and Bangladesh are confined largely to urban areas, and these limit the target group by eliminating massive numbers of very poor rural people.

The urban bias of food subsidies is much discussed. There is strong political pressure to include the bulk of the urban population in food subsidy schemes to contain the inflationary pressures on wages of rising food prices and to abate poverty. However, the fact that food consumption of urban people is lower than that of the rural population in any given income class is important. The food subsidy program brings the urban poor up to levels of food consumption enjoyed by much lower income rural people (Ahmed). In any case, the political survival of food subsidies as well as governments seems to hinge on reaching a broad segment of the urban population.

Providing rural areas with food subsidies is a much more difficult problem. First, these areas are more difficult to reach because of poor transportation and distribution channels (Lele 1971, 1980). Second, they have a much greater total number of poor. Third, there is less political pressure to reach middle income rural people. Thus, some means of restricting entry more effectively than for the urban areas is needed and may be politically acceptable. The various types of rural employment schemes, including food-for-work, are logical approaches. The nature of the physical work will tend to restrict entry much more than does the food quality factor in urban areas, although the precise impact requires additional study. Narrow targeting, fashionable in principle, seems inefficient because of large administrative costs, considerable diversion of benefits, and failure to reach many of the poor (Desai and Gaikwad).

On the second question of improved nutrition, the research of Kumar is clear. She has calculated actual nutritional status of children by anthropometric measures and compared the effect of income from various sources on those measures. Income received in the form of subsidies on food has the largest effect on nutritional status of three income sources: food subsidies, income from own farm production, and cash income, in that order.

The effect of the source of income on consumption patterns and nutrition is derived from complex causes which probably include differences in who receives income from various sources and in consumption preferences among those recipients. Kumar's research is being pursued further to include various types of food-for-work programs and the more narrowly targeted nutrition programs. But in any case, the special efficacy of broad food subsidy programs is clear.

Despite the implementation problem, the objective of market intervention is clear. An intervention is preferred that reduces prices or

raises incomes substantially for a subset of poor people with highly elastic demand. As the policy succeeds, more food aid should reach the poor, which will reduce the inflationary pressure of food aid on other commodity prices. In addition, there will be less foreign exchange drain for other commodities, and a less depressing effect on farm producer prices.

Effects on Exporters

It is clear that like food grain producers in importing countries, food grain exporters have an interest in a set of interventions that maximizes the increase in the size of the market. In effect, the exporters also benefit from market differentiation into markets of differing elasticities and subsidization of the more elastic market. One may note that exporters have been poorly served by food aid programs of the past, which have primarily shifted imports among suppliers rather than enlarging markets (Hall; Rogers, Srivastava, Heady).

Effects on Domestic Production

The evidence clearly indicates that aggregate supply elasticities in agriculture are low—on the order of 0.1 to 0.2 (Herdt, Bapna). However, a large nutritional impact through food subsidies requires a large price decline. Thus, even with inelastic supply one must be concerned with the production effect of depressed prices. Further, the very factors that shift supply schedules may themselves be responsive to prices. Food aid may reduce the sense of urgency to increase food production in the domestic political system for recipient countries.

Thus, an important aspect of a price subsidy policy is the effect it has on the range between producer and consumer prices. A number of authors have noted that food aid provides financial resources that allow a subsidized consumer price and a considerably higher producer price (Hall; Rogers, Srivastava, Heady; George; Gavan and Chandrasekera). The result is a producer price higher than would otherwise be the case and perhaps higher than world prices, even when adjusting for exchange rate distortion. This may be the most important contribution of food aid because it allows an immediate reduction of consumer prices and hence improvement in nutrition by supplying enlarged real food supplies while it generates financial resources to support farm prices and thus contributes to th long-run solution to food and nutrition prob lems (Lele and Agrawal).

Fluctuations in Supply

If food aid is to contribute to improved nutri tional status, not only must it be reliable, but i must counter domestic supply fluctuations. I is the poor who provide the economic adjust ment to fluctuating food supplies, and yet th poor have the least physical capacity to bea such fluctuations in consumption. Also, opti mal intervention programs are politically sen sitive and cannot be easily turned on and of according to the vagaries of food aid dono objectives. Note that under great financial an international political pressure, Sri Lanka re cently cut back its food subsidies and experi enced rising death rates (Gavan and Chan drasekera). Food aid for improved nutritio must be stable; if it is not, recipient countrie should use the supply to displace more expen sive imports or to build their own stocks.

However, the food aid role can be muc more positive. Because holding stocks is ex tremely expensive, it is clear that trade is much more cost-effective means of dealin with fluctuation in production than large na tional or international stocks (Reutlinger an Bigman, McIntire). Unfortunately, the worl lacks an effective means of financing move ment of grain to meet production fluctuation in low income developing countries. Food ai could at least partially fill this gap, thereb encouraging intervention programs which fa cilitate a nutritional impact.

Conclusions

Food aid can play a substantial role in improv ing nutrition of low income people in low in come countries. It can do so because calori deficiencies are large and widespread, becaus the poor spend a high proportion of their in come on food and have high marginal propen sities to spend on food, and because tota quantities of food aid have been significan (particularly in the 1960s period of large con tributions by the United States) relative t nutritional gaps in low income countries.

Market interventions, for example, throug quality specification, modified ration schemes and employment programs, can increase th

proportion of food aid reaching the poor, thereby reducing the price-depressing effects on food producers and the price-inflating effects on nonfood commodities, as well as focus total benefits more on the poor. The minimizing of price-depressing effects, through market differentiation and the financial contribution to recipient governments of foreign food aid, allows for higher farm prices and hence greater incentive to future production than otherwise would be the case.

In practice, however, food aid has been inefficient in reaching nutrition-based objectives. First, the allocations by the United States, the dominant donor, have not been noticeably related to nutritional needs or per capita income. This is particularly true in recent years. Second, to be effective in dealing with nutritional problems, food aid must be stable or counter-cyclical to domestic production of recipient countries. That has tended not to be the case.

The Contribution of Food Aid to Nutrition

Sylvia Lane

I interpreted the topic to mean the contribution of food aid to improved nutritional status. There is an extensive literature on this topic but the reported findings are often contradictory. I shall, therefore, attempt only to summarize some of the important highlights and viewpoints and indicate where they point to some tentative conclusions.

Food aid can contribute to improved nutritional status only if it reaches those who are undernourished or malnourished, i.e., whose nutritional status is below "satisfactory" levels however defined. The malnourished are, almost without exception, the poor whether they be the unemployed, refugees, landless, the indebted, or the women and children in low income households. Characteristically, food aid reaches the malnourished only if there are properly designed government policies. Even in the case of disaster relief, food ordinarily does not reach the hungry without government permission (Cambodia, for example).

To understand the contribution of food aid to improved nutritional status, it is necessary to understand the motivations of its suppliers, who will determine what will be available and what it will cost; the influence of the suppliers and their policies on the disposition of the food aid; the intent of international agencies promulgating nutrition programs; the motivations, nutritional policies, and programs of the demanders of food aid, i.e., the governments and government agencies of the receiving nations; and, finally, how the programs operate to improve nutritional status of those who ultimately eat the food.

Suppliers

Suppliers of food aid have, for the most part, been the countries with surpluses of agricultural products, i.e., the United States, Canada, Australia, West Germany, and others, and their motivations have been economic and political as well as humanitarian.[1] The economic motivations have been reduced in recent years as nonmarketable surpluses have in many cases decreased (particularly for grains), but they still play a part in determining the character of the commodities offered, e.g., skim milk powder from the European Economic Community (European Economic Community 1980, p. 78). Political motivations may involve strengthening the economic (and military) viability of friendly governments. Humanitarian considerations have been dominant in the case of disaster relief and relevant in many cases. Suppliers' policies and preferences have particularly influenced the type of nutritional programs adopted (the feeding of mothers and small children). These also have been influenced by such agencies as UNESCO, UNICEF, WHO, FAO, the World Bank, and international donor groups such as CARE.

It has been argued that programs aided by supplying countries and international agencies, even though they have resulted in an improvement in the nutritional status, may have acted so as to encourage dependence of recipients upon continued supplies from donor nations. This argument applies particularly to the introduction of foods unfamiliar, or less familiar, to the recipients (wheat instead of rice, reconstituted milk, corn-soymeal) and, despite the good intentions of sponsoring agencies, there may be some validity to this charge. Effects on nutritional status of food recipients may be favorable in the short run but perhaps not in the long run, unless the food aid continues indefinitely or unless being better nourished enables food recipients to increase their incomes. There have been cases where food aid commodities replaced commodities formerly bought in local markets (a free good competing with a market product)

Sylvia Lane is a professor in the Department of Agricultural Economics, University of California, Davis.

Giannini Foundation Publication No. 596.

[1] Not that less developed countries do not help each other . . . Mexico and El Salvador helped Guatemala after their disastrous earthquake in 1976.

and local suppliers have been left without sufficient sales revenues to survive. Moreover, where specific food aid commodities have increased supply at a particular point in time in uncontrolled markets, prices have been depressed. This has caused shifting to more remunerative crops (FAO, p. 11), which may not be unfavorable to improving nutritional status in the long run.

The lower prices also may help the poor in the short run. Where markets are controlled, food and commodities can be distributed through separate channels, farm prices can be supported, and the funds from government sale of the commodities can be used to build needed agricultural sector infrastructure or to support agricultural extension services, resulting in increased agricultural income. Where the additional income accrues to poor rural households in need of food, it can contribute to improved nutritional status. Singer, the author of "The World Food Programme's Study on Food Aid Policies and Programs," contends "theoretical analysis gives no proof that food aid, *if properly handled*, has serious disincentive effects on food production in recipient countries" in the long run (FAO, p. 2).

Demanders

Demanders, in the first instance, are food-deficit countries and generally those with large low income populations that are predominantly rural (e.g., Indonesia, Central American countries, Colombia). But countries like India, Pakistan, Bangladesh, and Egypt with large urban centers also have large low-income rural populations. Where the recipients' development policies are focused on urban industrialization (Egypt), the food aid may help make "cheap" food in the cities possible. This serves to improve nutrition among low income city dwellers as opposed to low income rural residents and such food aid has been accused of having an urban bias. To quote Singer "Some critics have also pointed out that food aid usually arrives at the main port; differentiated distribution is easier to organize in the urban areas. Even projects such as the feeding of vulnerable groups are easier to set up in urban areas . . . . In addition, it may pre-empt the best storage and milling facilities" (FAO, p. 3).

Governments of recipient nations vary in their stages of development, their commitments to develop, and their attitudes toward the agricultural sector. However, there now appears to be a far greater appreciation of the role of agriculture in development (Todaro, p. 209). But this is not enough. Compulsory food sales for state purchase at below market prices, limiting or banning private sector sales, and imposed cropping patterns are still widespread and limit farmers' incomes and incentives to produce (Egypt). To quote Singer again, "The risk of disincentives does not seem to exist where the food aid is given in the form of agricultural inputs, as, for example, feed grains . . ." (FAO, p. 3).

Another problem is infrastructure (which only government will provide) and efficient market technology and institutions not being available or facilitated, resulting in farmers being paid less and consumers paying more for food with deleterious results on nutrition for low income households (Zaire; *Wall Street Journal*, p. 1). Therefore, one of the most important contributions of food aid can be making possible, through "Food for Work" projects, the infrastructure required to increase agricultural output and the movement of that output to market at lower prices. Food aid can make a long-range contribution to nutrition wherever government invests the funds from its sale in projects that improve productivity and income of low income people. If the beneficiaries are farmers, this is indeed a long-term investment.

Direct Distribution Programs

Direct distribution programs have had a measurable and positive effect on food consumption (Gavan, George). From his analysis of the effects of the program in Kerala, where food grains are distributed to low income consumers through ration shops, George concluded, "the short-term solution for areas such as Kerala is an effective public distribution system." Kumar, also studying the Kerala system, found "subsidized rice to have a positive impact on the household diet and child nutritional status greater than a cash subsidy (equivalent to the amount saved by purchasing the ration rather than open-market rice)." Kumar also found "increasing income from own-food production could result in significant improvements in child nutrition, where aggregate wages could not" and "where woman participated in the labor force,

increments in wage income (of both parents, but particularly of the mother) were associated with improved child nutritional status" (p. 41).

Thus, the evidence, although limited to specific areas, points to the effectiveness of direct distribution systems in increasing food consumption and, to some extent, nutrition. This is confirmed by the Sri Lanka study (Gavan and Chandrasekera). The use of food aid to strengthen direct distribution programs and the smallholder portion of the agricultural sector seemingly results in improvement in nutritional status (this is confirmed by Benito for Mexico) and providing work for mothers seemingly results in improvements in child nutritional status.

Supplementary Feeding Programs

Singer in his excellent summary of the literature on food aid and supplementary feeding programs (providing food directly to recipients without retail-type intermediaries) points out that in the case of expectant and nursing mothers and preschool infants, prime target groups for these programs, total coverage from all of the food aid sources put together is of the order of 5% of the potential target population (FAO, p. 44). Supplementary feeding programs "are a feasible way of raising food intake" (FAO, p. 44). But raising food intake will not, in itself, eliminate malnutrition (Scrimshaw, Taylor, Gordon). Health factors (infectious diseases, parasites), nutritional beliefs and prejudices (e.g., hot and cold foods—no hot foods for post-partem mothers), and nutritional imbalance in local diets (too many starchy staples) may lead to malnutrition. Environmental and social conditions (poor crops, inadequate incomes) and family food priorities in some cultures (lower priorities for girls and infants) also may lead to inadequate quantities of food intake and thereby to malnutrition.

Singer reviewed eleven studies dealing with effects of supplementary feeding and found eight reporting a significant short-term impact. In three, in which an attempt was made to assess the long-term effects, the results were not consistent. He concludes "the overall impact has been mixed" (FAO, p. 50). Apparently some programs, and particularly programs directed toward women and small children, have had a significant impact, and he justified the use of food aid for both supplementary feeding programs for these groups and for school age children (FAO, p. 51). Parenthetically, research (in-depth case studies) with inputs from economists and anthropologists appears to be particularly needed in this area to identify the key variables subject to control that will make these programs more effective (cost-effective) in the long run. We need household studies understanding the household as both a production and a consumption unit. If nutritional status for all household members is to improve over the long term, it may be that customs based on values and beliefs of household members will have to be changed (such as, pregnant women do not eat certain foods, men receive a more-than-proportionate or, perhaps, a required share of nutritious foods).

Johnston contends increasing employment and improving productivity, so as to increase food availability and food intake, is an effective way of improving nutritional status of older children and adults; but, he adds, there is still a need for supplementary feeding programs for women and young children. Gavan has concluded that because of the high cost of food subsidy schemes and inadequate resources of the low income countries where they are needed, "foreign assistance must meet a major part of the burden."

Conclusions

Food aid can and has been used in programs that have had a positive effect on the nutritional status of the malnourished, especially women and children, in the short run and possibly in the long run. But it can only make a long-run contribution if it is properly targeted—government policies are economically sophisticated and supportive of more rapid and improved patterns of agricultural development. The handling of the food aid must be such as to prevent or mitigate impacts on local food production and local markets. Food aid programs should be integrated with health, population, and education programs and lead to increases in real income for the malnourished poor.

Public Law 480: The Critical Choices

Brady J. Deaton

P.L. 480 represents 30% of total U.S. development assistance, yet it is only a minor part of total private and public investments in recipient countries. While the U.S. share of total world food assistance declined from 94% in 1965 to 68% by 1976 (Maxwell and Singer, p. 266), P. L. 480 was still valued at roughly $1.6 billion in fiscal year 1980.[1] Moreover, P.L. 480 is viewed by both the United States and recipient nations as serving important objectives, such as meeting emergency food and nutrition needs, providing balance of payments support, and promoting economic development. Additional P.L. 480 objectives include assisting in domestic supply management, expanding markets for U.S. products, and achieving foreign policy objectives.

Among these objectives, the USDA Special Task Force on P.L. 480 gave priority to the humanitarian and developmental objectives which it felt were consistent with long-term U.S. foreign policy. In view of growing world food needs, the developmental use of food aid could be an important way of promoting employment in recipient countries and supporting their participation in world markets, particularly if the United States follows the recommendation of the Presidential Commission on World Hunger "to make the elimination of hunger the primary focus of its relationship with the developing countries." Accordingly, this paper will propose and discuss three selected conditions underlying a serious commitment to shape P.L. 480 into an effective tool for economic development. Resolution of the following three issues will require that (*a*) a politically strategic and creative international role for P. L. 480 must be firmly established and protected; (*b*) the alternative investment streams created by P. L. 480 must be identified, measured, and integrated into an investment program that fits the conditions of the recipient country; and (*c*) production disincentives in the recipient country must be minimized or avoided entirely.

A Strategic and Creative Political Role

Congress elevated the developmental role of P.L. 480 among the program's multiple goals in the 1977 amendments to P.L. 480, the so-called "New Directions" mandate. Title III was revised to encourage countries to use funds accumulated from the local sale of Title I commodities to finance mutually agreeable programs of agricultural and rural development, nutrition, health services, and population planning. To promote these developmental goals, multiyear agreements can be negotiated on the conditions and levels of future food aid shipments, and repayment obligations can be forgiven on a prorated basis as the objectives are pursued.

An effective developmental role for P.L. 480 must recognize the potential contribution of food aid: (*a*) for creating employment, particularly for the "poorest of the poor"; (*b*) for increasing domestic savings and investment; and (*c*) for enhancing more desirable spatial distributions of people and jobs. Clearly, these developmental objectives require that longer-term desirable consequences of program effects in the recipient country take priority in program planning over shorter-term political hegemony being sought by the United States. Such a commitment places P. L. 480 squarely within what Montgomery defined as a "strategic" framework for U.S. foreign policy, wherein program aims are designed to improve long-term economic and political sta-

Brady J. Deaton is an associate professor, Department of Agricultural of Agricultural Economics, Virginia Polytechnic Institute and State University.

The author wants to especially thank Tom Lederer OICD/USDA for his stimulating discussion of this topic and helpful comments on the manuscript. Fred Sanderson, Brookings Institution; Howard Williams, ASCS; Merv Yetley, ESCS/USDA; and Dave Culver and Dave Kunkel, FAS/USDA, also provided useful information. My colleague, Steve Buccola, read an earlier draft and made several useful suggestions. Mesfin Bezuneh, a graduate student at Virginia Tech, assisted with library research and provided lively discussion of this topic.

[1] Analysis completed for ths USDA Special Task Force on P.L. 480 (on which I served as staff coordinator) indicated that this dollar value may represent essentially no net budget outlays for the United States because P. L. 480 costs offset expenditures on domestic support programs.

bility and increase recipient countries' self-sufficiency (p. 321).

This policy stance is consistent with Liska's view of the "creative" as distinct from the "acquisitive" use of foreign aid (Liska, pp. 96–101). Creative uses are designed to achieve longer-term political and economic objectives, to recognize the evolutionary nature of political and economic change, and to shape policy consistent with long-term, sustained goals. In contrast, "acquisitive" uses of food aid would be oriented toward short-term goals and political advantages.[2]

"Acquisitive" and "creative" aid are not necessarily mutually exclusive. Acquisitive goals may have important economc consequences for creative policy, as in the case of supply stabilization and balance-of-payments support, and ultimately may lead to high priority developmental goals. In this context, acquisitive uses of food aid would receive their justification only within the purview of creative policy. This has not always been the case with the political uses of P.L. 480, as political aims have had little or no bearing on the development programs of the recipient (USDA, pp. 82–83).

A creative orientation of food aid brings economic development goals and strategic political goals into a common conceptual framework wherein their interdependence can be recognized more clearly. From the standpoint of foreign policy, a creative role places more emphasis on the second and third round consequences of policy initiatives than on short-term gains. For example, this perspective enables the market development goals of P. L. 480 to be seen more clearly as dependent on effective programs of economic development rather than on changing eating habits or inducing unnecessary economic dependency. Evidence of expanded markets for U.S. commercial exports suggests that the P.L. 480 role cannot be divorced from sustained economic progress in recipient countries.[3]

The conscious adoption of a strategic, creative aid orientation calls attention to other program modifications such as the need for a food reserve system to sustain multiyear commitments. Such a modification could help avoid the detrimental consequences, for example, of the severe food aid reductions in the early 70s.[4] The tradeoff of that period between U.S. foreign exchange benefits and the costs of losing political legitimacy in third world countries thwarted well-laid economic development programs. Schertz observed that most rich countries, including the United States, are unwilling to sacrifice foreign exchange earnings to feed the poor (p. 534). The political and economic costs of this earlier position will have to be reassessed at the highest levels of policy formation as the transition to a new international economic and agricultural order is pursued (Rothschild, p. 307).

Food Aid Investment Streams

Food aid provides a direct resource flow into the recipient country by way of concessional sales (Title I) and grants (Titles II and III). The resale of food aid in the recipient country and food-for-work provide, respectively, finances and manpower support for programs of agricultural research, extension, credit, transportation networks, and other components of rural infrastructure.

Additional resources accumulate indirectly to the recipient through wage and income effects as lower food prices result from the greater quantities of food placed on local markets and/or made available directly to consumers. Food assistance also helps minimize the threat of inflation fed by spiraling food prices, helps maintain relatively low wages, and holds the terms of trade in favor of the nonfood producing sector of the economy stimulating, in the process, profits and capital formation in the nonfood sector. Concurrently, food aid runs the risk of creating disincentives for agricultural producers unless ameliorative policy offsets the potential disincentives.

The history of most developed countries suggests that economic and particularly agricultural development occurs simultaneously with, and partly as a result of, relatively de-

[2] Strictly humanitarian and emergency uses of food aid should be placed outside this classification to avoid the irresolvable debate over U.S. motives.

[3] The most popular examples are Brazil, Taiwan, South Korea, and Spain. For further discussion of this point see USDA, *Report of the Special Task Force on P.L. 480*.

[4] Emma Rothschild pointed out that the poorest countries received in 1973 and 1974 less than one-fifth of the food aid levels received in the mid-60s, and not enough to prevent suffering from famine in Asia and Africa (p. 289). P.L. 480 wheat exports dropped from 4 million metric tons (MMT) in 1972 to 1.4 MMT in 1973 (USDA, Appendix C).

clining prices for agricultural commodities. The treadmill effect created by cost-reducing and output-expanding effects of technological change, works in favor of some farmers and against others. Even under the most labor-intensive agricultural production systems, a dynamic economy will require investments in nonfarm production to meet expanding aggregate demand and to provide employment for displaced agricultural workers. Assessing the impacts of food assistance within this dynamic framework calls attention to the alternative investment streams stimulated by injections of food aid and enables the internal rate of return to be used as one criterion in comparing the developmental consequences of each investment stream.

The initial investment stream (I_1) is generated by foreign exchange savings resulting from food aid shipments which displace other commercial imports. Even though P.L. 480 agreements require that food aid not displace commercial imports from other "friendly" nations, the Usual Marketing Requirements (UMRs), most evidence suggests that some displacement occurs.

Stevens' case studies of Tunisia, Upper Volta, Botswana, and Lesotho found that much of food aid concessional sales substituted for commercial imports, and "represented a transfer of free foreign exchange to the recipient." Hall estimated that Brazil's P. L. 480 imports displaced 89% of their tonnage in commercial imports in spite of UMR requirements. Fisher's analysis weakened the argument for UMRs by showing that the effects of "free gifts of surplus food or sales at specially [sic] low prices to underdeveloped countries are less damaging to normal export markets than simple dumping of the surpluses on the world market . . ." irrespective of the maintenance of normal food imports (p. 867). The principal justification for UMRs is to protect commercial relationships between the recipient and other "friendly" nations. Yet, Fisher's analysis demonstrates that commercial traders may benefit more from the greater total demand and stronger world prices resulting from removal of the food aid quantity from commercial markets.

The UMR can be calculated mechanically on the basis of past experience, but it may be an unreliable measure of import potential for a country experiencing rapid population growth, significant technological change in agriculture, and increases in domestic food production. Variations in these and other factors, such as the income effect of food aid, will cause the potential level of commercial imports for any given year to vary markedly from past experience.

The UMR reduces recipient country foreign exchange flexibility and, consequently, may impede economic development plans. Also, it runs the risk of biasing P. L. 480 toward more well-to-do countries which can afford the additional commercial imports. The potential balance of payments advantage of food aid is reduced in the process. Given the difficulty of enforcing UMRs and their theoretically weak justification, a reevaluation seems in order. Eliminating UMRs would turn program attention and analytical skills toward insuring an effective contribution to development of the foreign exchange freed up by food aid. Even if the UMR is strictly adhered to, the low down payment and long maturity period of Title I concessional sales enable the recipient to ration more effectively its foreign exchange, to import complementary capital goods for development purposes.

A second investment stream (I_2) created by P.L. 480 (principally public works programs and Title II) is in the form of capital produced through "food-for-work" and "self-help" programs to build roads and irrigation systems using laborers paid entirely or in part by food donations. These projects could be an important means of providing part-time, off-farm employment opportunities in rural communities.

Through innovative programming, self-help projects could be designed to promote asset ownership among low income, rural residents by creating productive capital that is owned by the laborers, or in other ways strengthening their control over income streams generated by productive assets. These steps may result in more productive uses of local savings, reduce uncertainty for peasant farmers, and stimulate entrepreneurship (Deaton). By promoting such project designs, this P.L. 480 investment stream could be an important tool for achieving optimal settlement patterns and promoting rural-urban population balance.

A third investment stream (I_3) stems from the savings generated by the income effects of relatively cheaper food and has been largely ignored in the literature. The common Engel's curve analysis provides the theoretical basis for the income effect. Isenman and Singer reviewed the intersectoral implications of the

ncome effect for inflation and induced in-
vestment, but not for the effects that may be
lerived from the investment resulting from
dditional household savings. The income ef-
ect is reallocated over the consumer budget
pased on income and price elasticities and the
narginal propensity to save (MPS). Savings
lue to the income effect are conceptually dis-
inct from savings that accrue from income
arned as wage payments under food-for-work
programs as presented in the analysis of
Srivastava et al.

The macroeconomic implications of I_3 for
lomestic savings and national investment
ould be significant. Estimates of MPS in
LDCs generally fall in the range of 10–20% for
normal income and significantly higher for
ransitory income based on consumer budget
nalysis (Hyun, Adams, Hushak; Kelley and
Williamson; Williamson). Where food aid is a
ignificant proportion of total food supply, the
potential investment effect from increased
ousehold savings should increase both the
eal quantity of savings (and investment) and
he rate of savings, assuming that the marginal
propensity to save is positively associated
with increasing income.

Schuh recently called attention to the
uman capital investment potential of food aid
which can be viewed as a fourth distinct form
I_4). This emphasis is consistent with Schultz's
Nobel lecture, which argues that improvement
n population quality is the decisive factor in
mproving the welfare of poor people (pp. 11–
4). Similar improvements may be possible
hrough institutional changes induced by food
id, such as food stamp programs (Schuh).

The Disincentive Question Revisited

The developmental role of P.L. 480 labors
nder the shadow of disincentives. The
Bellmon amendment to P.L. 480 requires that
ach country's agreement be predicated upon
he explicit determination that disincentives
or farmers in recipient countries will not re-
ult. In addition to price disincentives, policy
lisincentives may arise if recipient govern-
nents neglect their agricultural sectors be-
ause of an overdependence on U.S. food aid.

The persistence of concern about potential
price disincentives of food assistance pro-
grams attests to the power of Schultz's (1960)
eminal contribution, wherein the disincentive
ssue was raised as a theoretical possibility.
While this fear continues to haunt program administrators and has become a rallying cry for critics of the program, the bulk of evidence indicates that it is an exaggerated concern.

Two decades of research on the disincentive issue were assessed recently by Maxwell and Singer, leading them to conclude that price disincentives can probably be, and mostly have been, avoided "by an appropriate mix of policy tools" (p. 231). Only six of the twenty-one studies they reviewed reported any significant disincentives, and four of the six were based on the Indian experience. Also, Isenman and Singer criticized previous econometric work in this area for ignoring "the dynamic effects of the food aid on growth in output and employment and, hence, on demand for food grains in subsequent periods" (p. 211).

Blandford and Von Plocki respecified and evaluated earlier econometric models of food aid impacts and found that both the value and the sign of elasticity measures were sensitive to the time period studied, resulting in contrary conclusions about the price responsiveness of farmers and highly variable estimates of production declines in India. Their results call attention to the need for sensitive measurement of data for particular time periods for particlular countries and warn against generalizing beyond these particulars.

Hall's recent analysis of the effects of Title I wheat imports on Brazil's grain sector lends further support to the position that disincentives must be carefully analyzed on a country-specific basis. Hall discovered that government revenues gained by selling wheat to mills at prices above the import price were used to subsidize higher domestic price supports for producers. This effect was captured in a wheat support price equation and led to the conclusion that a sustained increase of 1,000 metric tons of P. L. 480 wheat would result in a 108% increase in Brazil's domestic grain production (p. 27).

These findings are consistent with Schuh's recent emphasis on the importance of implicit taxation schemes, common in many LDCs, to the potential incentive effect that could be created by P.L. 480. Government pricing policies generally are geared to provide low-cost food to urban populations. P.L. 480 may, in some cases, provide the leverage and resources to strengthen recipient governments' resolve to maintain sufficiently high incentive prices to rural producers.

Conclusions

Public support for a more significant developmental role for P.L. 480 is evident in recent legislative changes in the program, particularly Title III. A series of supportive and interrelated decisions of a political and economic nature will be essential if these intentions are to be realized. The purpose of this paper was to stress the interrelationships between a creative, strategic political role and a commitment to fundamental economic development programs wherein P.L. 480 serves as a productive tool for development. Although P.L. 480 is a minor proportion of total international resource flows, its developmental contribution may be significantly enhanced if the rates of return and dynamic implications of food aid investment streams are analyzed. Future research should be oriented toward meeting this objective. Simultaneously, such research should determine the complementarity between food and nonfood aid, and conditions under which incentive price structures can be created by P.L. 480. These tasks represent a formidable research and educational challenge worthy of our immediate attention, and promise high payoff for public policy.

Critical Choices in World Food Aid and Nutrition: Discussion

Benjamin Sexauer

This discussion will be broken into three segments. First, the primary objectives of food aid from the recipient and donor perspectives are enumerated for later reference. Second, a brief critique of the major points in each paper and their relationships to one another are presented. Third, a few additional thoughts on the subject, not covered by the three major papers, are provided.

Isenman and Singer provide an excellent outline of the potential benefits of food aid to a recipient country. Food assistance can (*a*) help feed the needy, either directly through subsidized distribution or indirectly by reducing food prices; (*b*) finance development projects, either directly in food-for-work projects or indirectly through generation of additional government revenues; (*c*) be used to build domestic buffer stocks to stabilize prices; (*d*) ease constraints on growth; (*e*) reduce domestic political pressures and instability. Each of these benefits can potentially affect nutrition either directly or indirectly by speeding the country's development. The motivations of donor countries may be divided into (*a*) altruism directed at either feeding hungry people or developing poorer countries, (*b*) disposal of excessive agricultural supplies, (*c*) development of future commercial demand, (*d*) support of foreign political initiatives.

The Mellor paper focuses on recipient benefit (*a*), stressing the price effect. He then progresses to the question, are there market interventions which increase the efficiency of the nutritional impact? A crucial point that Mellor makes is that market interventions must be weighed against their cost. Government administrative ability is a very scarce resource in most developing countries. Effective policy implementation may simply be beyond the capabilities of the government. Mellor points out that benefit (*e*), reducing political pressures, plays an important role in determining the structure of the intervention programs in South Asia.

The Lane paper, in contrast to the Mellor paper, focuses on direct distribution programs rather than indirect, through price reductions. She references studies which claim such programs have had a measurable positive impact on food consumption. Lane stresses the targeting of the food programs to the nutritionally most vulnerable, typically expectant and nursing mothers and pre-school children.

The Deaton paper emphasizes the potential development role of food aid, recipient benefits (*b*) and (*d*). He focuses on the use for development purposes of the revenues generated by way of concessional sales and loan forgiveness. Deaton also notes the formation of capital through food-for-work schemes. Food aid can also help lift growth constraints, particularly a foreign exchange limitation. Deaton sees hopeful signs that U.S. food aid will increasingly be used as a development tool rather than for other donor objectives.

In a crucial way the nutrition and development roles of food aid coincide since the most vital form of capital for many recipient nations is human capital formation. This perspective brings us to the recommendations of Lane for direct distribution programs to the nutritionally most vulnerable, which then brings us back to the administrative constraints noted by Mellor.

The major point to make about the possible disincentive effect of food aid is the crucial role of the recipient country's domestic policies. Mellor, Lane and Deaton, each make this point. An excellent example is the case of Brazil Deaton refers to, in which Hall found that revenues from P.L. 480 wheat were used to create incentives for domestic production. This case can be juxtaposed with Colombia, for which Dudley and Sandilands found that

Benjamin Sexauer is associate professor, Department of Agricultural and Applied Economics, University of Minnesota.

These comments are based on preliminary drafts of the papers, hence some inconsistencies may occur with the final versions. The works cited here can be found in the reference lists of the three main papers.

with P.L. 480 shipments, a substantial disincentive to domestic wheat production was allowed to arise, and production fell by 1971 to one-third of its peak levels in the 1950s. Recipient nations can not blame the donors, but only themselves, if disincentive effects occur.

On a general level, what is missing in this session is a perspective on what role can realistically be expected of food assistance. Not to sound too cynical, but such recommendations as those of the Presidential Commission on World Hunger, which advocate a major and purely altruistic role for U.S. food aid, are only rhetoric that may or may not have much bearing on reality. On the other hand, there are negative and hopeful signs in the long-run trends for U.S. food aid, the largest source of such assistance.

There has been tremendous growth in U.S. commercial agricultural exports from $3.3 billion in 1960/61 to $34.7 billion during calendar 1979. Some of the largest previous recipients of P.L. 480 aid are now among our largest commercial markets, such as Korea and Taiwan. At the peak of surplus disposal efforts in 1957, P.L. 480 shipments were equal to 68% of commercial exports. P.L. 480 now represents about 6% of commercial exports. Although the dollar magnitude of U.S. food aid has not declined, there has been a tremendous decline in the level of aid in relation to commercial agricultural trade, agricultural production levels, and the number of malnourished in the world. The era of relatively massive amounts of U.S. food assistance ended in the 1960s. Most countries, even the poorer ones, that wish to fill a gap between domestic production and consumption needs are now having to do so through commercial channels.

Additionally, the selection of recipients of U.S. bilateral food aid is still strongly influenced by objective (*d*), support of foreign policy. In 1978, Egypt and Israel received over 40% of all U.S. food exports shipped under government-financed programs.

On a more hopeful note, an increased international commitment to food assistance has developed, embodied in international agreements. Under the new Food Aid Convention of March 1980, the members of the Food Aid Committee will donate 7.6 million metric tons of cereals annually for use in developing countries. This compares with 4.2 million tons under the 1971 agreement. This new agreement is in line with trying to reach the 10 million tons of food aid annually set as a target by the World Food Conference. The United States is the largest donor, with a commitment of 4.47 million metric tons.

Even 10 million metric tons, though, amounts to less than 1% of the world production of the three major cereals, wheat, rice, and corn, based on 1978 production levels. The nutritional role food aid can be expected to play in the world is minor. The major answers to malnutrition must be found within the poor countries through expanded production, more equitable distribution, and increased employment and income. The best use to which the limited amount of international food aid available can be put is for disaster relief and in an international buffer stock role. By being available as a kind of "safety net" for countries with significant crop shortages, food aid could reduce the levels of domestic stocks required, which are expensive to maintain, and thereby have the most crucial impact on nutrition.

Estimating the Relationship between Pest Management and Energy Prices, and the Implications for Environmental Damage

ohn A. Miranowski

practicing pest management consultant re-
ntly suggested that we need to broaden our
search emphasis beyond integrated pest
anagement and consider the total crop sys-
m. Instead of our more narrow focus, a more
ppropriate area of investigation would be the
onomics of integrated crop and pest man-
gement (ICPM) systems. Components of pri-
ate crop management services may include
est, fertility, water, and soil management, as
ell as other input decisions. Yet, the key
put is improved information to assist in deci-
ion making. We need to integrate the crop
roduction and pest management decisions to
etermine the most efficient (profitable) way
produce output.

Unfortunately, a major difficulty in the eco-
omic assessment of ICPM is the lack of ap-
ropriate biological data. Many of the linkages
crop production systems are not well under-
ood or, if understood, reliable parameter es-
mates are not available. Thus, one of the
emerging issues" of the 1980s should be the
evelopment of better ICPM systems through
oth basic and applied research.

This paper considers alternative pest man-
gement systems for corn production with ris-
g energy prices. First, pest control practices
e discussed. Second, historical data are used
estimate derived demand equations for in-
cticide and herbicide treatment. Third, the
npact of rising energy prices on the future
emand and supply of pest management sys-
ms and on the implied use of insecticides is
onsidered.

onomics, Iowa State University.

Journal Paper No. J-9970 of the Iowa Agriculture and Home
onomics Experiment Station, Ames. Project No. 2368.
Without implicating them, helpful comments on an earlier draft
this paper were received from Otto Doering, Wallace Huffman,
d Katherine Reichelderfer.

Pest Control Practices in Corn Production

To better understand the potential for adjustment to rising energy prices, knowledge of current pest control practices is necessary. The number and percentage of U.S. corn acres treated with both insecticides and herbicides have increased steadily between 1966 and 1976. Insecticide treated acres increased from 33% to 38% and herbicide treated acres from 57% to 90% (U.S. Department of Agriculture [USDA] 1968, 1974, 1978). These data are important because they indicate that pest control is a vital component of the corn production system, they serve as a crude proxy for the potential environmental hazard created, and they indicate the potential for input substitution as energy prices rise.

Although the national data provide insights into current pest control practices, they provide little information on the potential for ICPM systems. Data for 1977 Iowa corn production, presented in table 1, are helpful in assessing the potential for improved management systems for corn insect control. Soil insecticides were used on 58% of all corn acres and on 91% of continuous corn acres. Although chemicals were the predominant control technique, cultural practices (crop rotations) were used widely.

The insecticide treatments in table 1 were primarily for corn rootworm (CRW) control. Of the 50%–51% of the Iowa corn acres treated in 1978 and 1979, 44%–45% were reportedly treated with a CRW insecticide (Becker and Stockdale). Entomological recommendations suggest that chemical CRW treatments are usually required only for corn following corn rotations. Yet, 25% of the corn following soybeans and 43% of the corn following other crops received insecticides in

Table 1. Acres of Crop Treated with Soil Insecticides in Iowa, 1977

	Corn Following Corn	Corn Following Soybeans	Corn Following Other Crops	Total Acre Treated
Total planted ('000 acres)	6,261	5,886	1,354	13,500
Total treated ('000 acres)	5,696	1,492	579	7,766
Percent treated	91	25	43	58

Source: Jennings and Stockdale.

1977. Additionally, Taylor cites studies that indicate that CRW insecticide use on continuous corn could be reduced over 50% with little or no loss of yield. The possible overuse of insecticides may be accounted for by lack of information to interpret indicators of potential damage and the desire to reduce variability of yield losses.

Relationship between Pest Control and Energy Prices

As relative energy prices rise, what adjustments will occur in pesticide use? Historical data are available to estimate separate derived demand equations for insecticide and herbicide treatment in corn production. Cross-sectional data for the ten USDA agricultural regions are pooled for 1966, 1971, and 1976. The empirical specification of the derived demand models for insecticide and herbicide treatment of corn acres is[1]

(1)

$$\ln ST_i = a_0 + a_1 \ln P_i + a_2 \ln P_F + a_3 \ln y + a_4 \ln SCA + a_5 \ln RE + \ln P_L + e_i,$$

where ST_i is the share of corn acres treated with insecticides or herbicides; P_i, the price of insecticides or herbicides; P_F, the price of fuel; y, the value of corn output per acre; SCA, the share of corn acres in cropland acres; RE, the lagged production-oriented research and extension expenditures; P_L, the farm wage rate; e_i, the error term; and ln denotes the natural logarithm.

The dependent variable is specified as the share of acres treated with insecticides or herbicides. The insecticide and herbicide treatment data, as well as data on share of corn acres in cropland acres, are from the USD. pesticide surveys (USDA 1968, 1974, 1978 The input price indices, P_i and P_F, are region; averages derived from data in *Agricultur Prices—Annual Summary* and P_L is fro *Farm Labor*. The values of corn output pe acre are based upon prices from *Agricultur Prices—Annual Summary* and yields from *Ag ricultural Statistics*. Prices are deflated b the index of all farm production input price from *Agricultural Statistics*. The productior oriented research and extension expenditure are the aggregate value lagged five years fro Cline. These expenditures are deflated by a index of average salaries of college and un versity teachers. Unfortunately, these est mates are not available for corn alone, so th aggregate expenditures are used.

The following relationships are hypothe sized for the insecticide and herbicide deman models. First, increasing the price of insec ticides or herbicides should reduce the shar of acres treated. Second, a positive relatior ship between fuel prices and herbicide trea ments is expected. As energy prices rise, re duced tillage systems become more profitabl relative to conventional tillage systems, whic use more mechanical (fuel) and less chemic (herbicide) weed control. Even though the ne energy saving from reducing tillage and sul stituting herbicides is not large, it is usuall significant. The relationship between fu prices and insecticide treatment is less certai but hypothesized to be positive. If herbicide and insecticides are treated as joint inputs int reduced tillage, fuel price increases that lea to tillage reductions may increase the deman for insecticide treatment. Also, as energ costs and thus total production costs rise farmers may apply more insecticides to pro tect their production cost investment, com parable to a "wealth effect." Third, increasin the value of the crop per acre should increas the demand for treatment. Fourth, ln SCA re flects the intensity of the monocultural env

[1] As Katherine Reichelderfer suggests in her comments, the levels of pest infestation should be included as independent variables in the production function and in the derived demand equations. Generally, historical data on pest infestation in corn production are unavailable.

ronment. A greater share of corn acres in a region will result in more serious insect, especially *CRW*, and weed problems and thus a greater demand for pest control. Fifth, research and extension expenditures serve as a proxy for the availability of improved information and the efforts to develop alternative pest control techniques. In the case of insecticides, a negative relationship between insecticide treatment and ln *RE* is hypothesized, given the possible overuse of chemical control and the potential of alternative insect management strategies. The relationship to herbicide treatment is uncertain. Finally, a positive relationship between herbicide treatment and the wage rate is expected. As the price of labor increases, herbicides are substituted for labor in the production process.

Separate, weighted, least squares regression models for insecticide and herbicide treatment are reported in table 2. The regressions are weighted by corn acres in the region. Two herbicide demand models are reported, one with and one without the price of labor. The results are generally consistent with the hypothesized relationships and contain interesting implications about the magnitude of pest control response to rising energy prices. Given the log specification of the models, the estimated coefficients are also elasticities.

Table 2. Estimates of the Demand Equations for Insecticide and Herbicide Treatment of Corn Acres

Observations	30	30	30

[a] *t*-statistics in parentheses.

The empirical results contain the following price effects. First, rising fuel prices increase the demand for both corn insect and weed control treatments. As fuel prices rise, farmers substitute the relatively cheaper chemical cultivation for fuel and mechanical cultivation. Possibly because of the joint nature of pesticide inputs or to a "wealth effect," a similar relationship occurs in insect control. Second, when the wage rate is not held constant, increasing insecticide and herbicide prices decrease the demand for insecticide and herbicide treatment, respectively. However, the coefficient on insecticide price is not significantly different from zero. Likewise, the herbicide price coefficient is not statistically different from zero if the wage rate is held constant. Third, when the wage rate is included in the herbicide model, it has a positive impact on the demand for chemical weed control, implying a labor-herbicide substitution.

Increasing the value of the crop per acre increases the demand for both insecticide and herbicide treatment. The elasticity is greater for insecticides and reflects, not unexpectedly, the increased demand for crop protection as crop value increases. Increasing the concentration of corn production in a region has a positive and significant impact on weed control problems. Although the coefficient on the share of corn acres has a positive sign in the insecticide demand model, surprisingly, it is not statistically significant.

Finally, lagged research and extension expenditures have a negative impact on the demand for insecticide and herbicide use. This variable reflects the impacts of both improved alternatives for pest control and improved knowledge of pest control needs. Although it does not allow us to determine the substitution possibilities between information and energy in corn production systems, it does indicate that information and alternative pest control strategies are potentially substitutable for chemical control in corn production. This result is more significant in corn insect control, where evidence of potential overuse exists.

The results in table 2 may be a better indicator of what has happened than of what is going to happen as improved ICPM systems evolve for corn production. Such management systems likely will substitute information for chemicals, especially in insect control. To illustrate future corn pest management choices as energy prices rise, the tradeoffs between alternative systems for corn rootworm control

will be evaluated, including the impact of rising fuel prices on the cost of supplying pest-monitoring services, and on the demand for alternative pest control techniques.

Impact of Energy Prices on Pest-Monitoring Costs

Although many pest information services initially are funded by public or private grants, eventually the services must switch to a more permanent funding source (e.g., Extension Service) or become a self-sustaining private enterprise. Given the limited pest-monitoring activities currently occurring in corn production, actual monitoring cost data are not available. Also, few studies of the cost of producing pest management information in other crops are available (Grube and Carlson; Hall, Willey, and Norgaard).

To assess the cost of supplying pest-monitoring services and to estimate the impact of rising fuel prices, the following pest-monitoring cost model is employed:

$$(2)\quad M = \{[ng + (n + 1)(1 - g)][m(v + f + .05\,w) + wt] + OC\}/a,$$

where M is pest-monitoring costs per acre; n, trips to fields that exceed the threshold infestation level; g, probability of a field exceeding the threshold level; v, vehicle cost per mile; f, fuel cost per mile; m, average distance to participating fields (miles); w, wage rate paid to scouts; t, $1.6 + .0067\,(a - 40)$ = sampling time per field of 40 acres or more (Steffe, 1979); OC, overhead cost of monitoring service per field; and a, acres per field. In constructing this model, it is assumed that the probability of fields exceeding the threshold infestation can be determined and that nonthreshold fields require an additional sampling.

To derive estimates of the impacts of rising fuel prices on the per acre cost of supplying pest monitoring services, the following parameter values are specified: $n = 3$, $g = .5$, $v = \$.21$, $w = \$5.00$, $OC = \$15$, $m = 15$, and $a = 40$. At fuel costs of \$1.00, \$2.00, and \$3.00 per gallon, the costs of supplying monitoring services equal \$1.81, \$1.94, and \$2.07 per acre, respectively.

Fuel costs do not significantly affect the costs of supplying monitoring services to corn producers. More profound cost impacts will result from comparable relative changes in other cost components including program participation (i.e., reducing average distance to fields), wage rates paid to scouts, and trips to fields. Likewise, the rise in monitoring costs due to energy price rises will be overshadowed by the increase in insecticide costs due to rising energy costs. A doubling of fuel costs will increase scouting costs approximately 5%–10%, but the expected rise in insecticide prices would be more significant (Pidgeon).

Pest Management Choices with Rising Energy Prices

To evaluate the impact of fuel costs on the choice of CRW management in corn production, the cost of supplying monitoring services, M, is included in the profit function specification,

$$(3)\quad y_j = \frac{\sum_{i=1}^{n} [p_i(1 - s_j)\,Y_i - C_i - M_{ij} - I_{ij} - F_i - N_i]}{n},$$

where y_j is profit per acre for ICPM strategy j; p_i, price per unit for crop i; s_j, expected corn yield loss due to CRW damage for ICPM strategy j; Y_i, expected yield per acre for crop i assuming no CRW damage; C_i, costs of production per acre for crop i excluding fuel, fertilizer, pest control, and land charge; M_{ij}, pest monitoring costs per acre for crop i with ICPM strategy j; I_{ij}, insecticide costs per acre for crop i with ICPM strategy j; F_i, fuel costs per acre for crop i; N_i, fertilizer costs per acre for crop i; and n, number of crops in rotation. This specification of the profit (net returns) function is used to simulate the impact of changing fuel prices on the ICPM choice at the farm level. The model is designed to incorporate the impact of rising fuel prices on insecticide, fertilizer, and pest monitoring costs as well. For simplicity, we consider only a limited range of pest control alternatives—soil insecticide, crop rotation, and monitoring with treatment-as-needed. Although other biological, cultural, and adult control techniques are possible alternatives, the cases considered provide an informative illustration of the impacts of rising energy prices on ICPM choices.

The empirical data used in the model are from unpublished sources. The enterprise budget data are from Extension Service circulars of Iowa State University and from U.S.

Department of Agriculture (1976). Additionally, the following assumptions are utilized: (*a*) corn price—$2.50 per bushel; (*b*) soybean price—$6.25/bu.; (*c*) corn yield—120 bu./acre; (*d*) soybean yield—36 bu./acre. The yield loss assumptions are based upon insecticide field evaluation studies from the Corn Belt states. The impact of energy price rises on fertilizer and pesticide prices are based on Pidgeon.

Seven crop and pest management systems are considered in the analysis. Table 3 lists the strategies and reports the results of the model runs for 1.0, 1.5, 2.0, and 2.5 times current energy prices. Under current fuel prices, CC-M is the most profitable crop and pest management alternative, but only slightly more profitable than the CC-I (prophylactic control) alternative. But as energy prices rise, some interesting adjustments occur in the profitability of control alternatives. First, monitoring becomes more profitable relative to prophylactic soil insecticide treatment on the CC and CCS rotations. Second, the cultural control systems (CS) become more profitable than CC-I and CC-M as energy prices continue to rise.

Two caveats are in order. First, we have assumed constant relative prices for corn and soybeans. If the relative price of corn increases with rising energy costs, the CC rotation may remain more profitable. Yet this will encourage the substitution of pest monitoring and chemicals-as-needed for cultural practices. Even though the environmental implications of CC-M may not be as positive as the crop rotation alternatives, it will encourage a substitution away from prophylactic soil insecticide treatments and reduce chemical use. Second, the model is based upon a number of assumptions concerning monitoring costs, yields, yield losses, input costs, and output prices. If these assumptions are inaccurate for particular situations, or if certain coefficients change over time, shifts in the profitability of alternative ICPM systems may result. Third, we have ignored the impact of a farmer's risk preference on the choice of pest control technology. If a producer exhibits risk-averse behavior, the prophylactic soil insecticide treatment may be preferred even if profits are lower (Miranowski; Miranowski, Ernst, Cummings).

Conclusions

Based upon this analysis, it is reasonable to conclude that as energy prices rise: (*a*) weed and insect control will be substituted for fuel inputs in corn production; (*b*) information (monitoring) services will be substituted for insecticide inputs in corn production; (*c*) systems analysis provides a useful framework for assessing the impacts of rising fuel costs on the choice of management strategies for CRW control; and (*d*) environmental quality impacts are ambiguous because we cannot ascertain if the pesticide for energy substitution will be offset by the information for pesticide sub-

Table 3. Net Returns under Alternative Crop and Pest Management Strategies for Corn with Rising Energy Costs

Economic and Biological Variables Affecting Demand for Publicly and Privately Provided Pest Information

Gerald A. Carlson

Several recent national reports have directed attention to policy changes in pest information programs. An Office of Technology Assessment report gives as a major conclusion, that there is a lack of an adequate delivery system which impedes the dissemination of data necessary to support effective pest management decisions. A lack of practical, demonstrated interdisciplinary programs has resulted in grower skepticism and uncertainty regarding the economic benefits of integrated pest management (IPM). To remove the obstacles to IPM, the OTA report gives congressional options that include among others:

(*a*) federal support for IPM training including establishing regional pest management study centers;

(*b*) creation of a federally coordinated pest and weather monitoring program, support of public information delivery systems, incentives for the formation of private information delivery systems, and increased support for state plant health clinics;

(*c*) and an attempt to overcome grower conservatism of IPM through grower education, direct grower incentives, or regulation of growers.

The Council of Environmental Quality also has a report with many of the same findings and recommendations as the OTA report. In addition it calls for a feasibility study of an "early warning system" to identify problems in controlling significant pests with chemical pesticides. It recommends development of model certification requirements for independent IPM consultants and investigation of insurance schemes for farmers participating in IPM programs.

These policy recommendations require evaluation before adoption. There are serious questions about how the extension service should assist growers and consultants. In what form, if any, do private consulting firms need assistance? Licensing, liability and crop insurance, specializied training, and loan subsidies have been proposed. In addition, the role of more conventional grower training and crop decision making may be changing.

This paper will survey past attempts of economists and biologists to model pest control "delivery systems." I will assume that delivery of pest control information includes the functions of (*a*) private consultants, laboratories, and scouts; (*b*) individual growers and grower organizations; (*c*) chemical industry salesmen and fieldmen; and (*d*) various public organizations. To simplify, let me ignore IPM research and the role of fieldmen and concentrate on the interaction between public and private sector IPM information.

Previous IPM Consulting–Scouting Studies

There has been steady progress in the use of rigorous techniques and instruments for monitoring pests. Light traps have been used for at least eighty years for sampling agricultural pests (Sterling). Classical and sequential sampling techniques have given precision to estimates of pest populations and crop damage (Sterling). Bayesian decision procedures have allowed current observations to be combined with subjective probabilities of pest infestation for improved pest control decisions for risk-averse farmers. In recent years discoveries of pest phermones and assay methods have

---

Helpful comments from Jim Seagraves and Loren Ihnen are acknowledged.

helped lower the cost of monitoring and identifying many pest species. Computers, satellites, and other communication instruments probably will further the possibilities for monitoring in pest management (Rabb and Kennedy).

Economic analysis of professional scouts is not a new topic. Paid specialists in insect scouting were operating in Arkansas as early as the 1930s, but they did not rapidly expand in number until the 1950s (Lincoln, Boyer, Miner). Willey provided the first analysis of California consultants. He found that farmers who were more risk-averse and had more contact with extension were more likely to hire consultants. The farmer's confidence in the quality of the information of the consultants as measured by their length of time in business was found to be another important feature in the adoption of consultant services. Hall continued the evaluation of California consultants over a longer period. His major focus was on showing that consultant-using farmers expended less for pesticides per acre. Grube found evidence of both complementary and substitute relationships between scouting and pesticide use. His production function showed a statistically significant yield increase from more insect scouting per season.

Other economic studies have directed attention to the interaction between farmer and hired pest monitoring. Pridgen analyzed cotton insect monitoring across the cotton belt. She found that farm size, extension subsidies and farmers' off-farm opportunity costs increased the probability of farmers hiring IPM services. She also found that higher consultant fees and farmer education decreased the use of these services. Grube showed that there were more total (hired and self) field inspections per season when expected pest damage and farmer managerial ability were higher.

None of the above studies have investigated the spatial aspects of IPM services. The question of the effect of extension activities on the profitability of similar private IPM practices has not received adequate analysis. Also, there seems to be a need for a model which can evaluate future changes in state licensing of consultants and the regional training center proposal.

Delivered IPM Advice

To facilitate the discussion, let us divide the production and dissemination of IPM advice into three components: transportation-communication, monitoring activities, and diagnosis and recommendations. The components have primarily the same focus regardless of whether the main labor source is farmers, scouts, consultants, or extension (public information). Consider momentarily this to be a model of supply of private consulting service.

The transportation-communication function is more important for pest management inputs than other agricultural inputs because of the frequent need for timely service, specific to a particular field. Production of the transportation-communication component (t) is dependent upon capital (cars, two-way radios, telephone, computers) (K), professional consultant time used in travel (T), lay labor travel time (L), farmer travel time (F) and the particular configuration of roads and crop density in the area (d):

$$t = t(K,T,L,F,d). \tag{1}$$

The field-monitoring function has had considerable long-run input from research on sampling under various crop, environmental, and pest conditions. At the operational stage it usually involves monitoring crop growth status and beneficial insects, as well as pest status at the field level. Regional public pest monitoring, weather conditions, and crop status changes can serve as indicators for sequential sampling schemes. Also, machines and traps do not have the human monitoring bias of erroring on the high pest count side to prevent unexpected large crop losses. The production of monitoring (m) can be written as

$$(m) = m(K,T,L,F,I,f), \tag{2}$$

where the first four monitoring inputs (K,T,L,F) have the same identification as in equation (1), I is public monitoring information (extension news letters, radio reports, or weather bulletins), and f refers to the particular field sizes that are in a region.

The final component of delivered IPM advice is that of diagnosis and recommendations. In some cases this component can also include IPM decision making such as when a farmer asks his consultant to contract for pesticide applications, or other actions. Alternatively, it can be entirely a grower function when he receives only monitoring reports and not recommendations from scouts. This function depends much more on stocks of knowledge on the part of growers, consultants and extension

specialists. The recommendation (r) function is

$$(3) \qquad r = r(T,F,I,N,s),$$

where T is professional consultant time in giving recommendations, F is farmer time in consultation, I is extension input in providing specific actions given specific pest conditions, N is the stock of knowledge of the consultants and the farmers, and s is farm size. Farm size is important since uniform recommendations for all acreage of a given crop on a farm can be given in a single farmer-consultant session. Each session may have considerable set-up costs.

Total production of IPM advice includes each of the three components. If one omits capital and lay labor, since they are fairly constant across all regions, then the final IPM advice (A) production function is

$$(4) \qquad A = A(T,F,N,I,d,s,f).$$

By assuming that IPM consulting firms are profit-maximizing firms whose services are divisible and excludable between customers, then one can derive a supply curve for professional consultant advice (A^s):

$$(5) \qquad A^s = A^s(F,N,I,T,d,s,f,A_p).$$

A_p is the contract price per acre-year for the consultant firm advice, and A^s is advisory services measured in acres. Advice supply is not easily observed, but numbers of consultants is. Professional consultant time is an input in IPM advisory service. Given that there is some constant labor-leisure choice by consultants, then the demand for consultants has the same arguments as equation (5) plus consultant wages (T_p):

$$(6) \qquad T^D = T^D(F,N,I,d,s,f,T_p).$$

The stock of knowledge (N), public information (I), and farmer time (F) are considered to be substitutes for consultant time in (6). More consultants will be demanded where regional crop density (d), large field (f), and farm size (s) favor lower cost provision of services per acre.

Grower Demand for IPM Advice

Grube and Hall have shown that scouting and consultant advice can enter the agricultural production function. Consider a simple single-crop production function:

$$(7) \qquad V = V(P,A',O),$$

where V is yield of crop output, P is expected pest density, A' is the level of all types of advice on pest management, and O represents all other imputs. The derived demand for the advice input is

$$(8) \qquad A'^D = A'^D(P,A'_p,O_p,V_p),$$

where the p subscript denotes the purchase price for the advice and other inputs, and V_p denotes crop value. However, this is not the demand for consultant advice, since A' is composed of advice from extensionists, the farmer himself, and consultants. Including the selection between type of advice leads to

$$(9) \qquad A^D = A^D(I_p,F_p,V_p,A_p,O_p,P).$$

In this demand for a farm input equation, the cost of using extension information (I_p) and farmer advice price (opportunity cost of farmer time) (F_p) are expected to increase the demand for consultants.

With no barriers to entry into consulting, then market-clearing prices for advice should determine the equilibrium number of consultants. If there was state certification of consultants, then consultant wages need not be equal across location. The reduced form of equations (6) and (9) can be written as

$$(10) \quad T = T(P,I,V_p,N,s,F,f,d,A_p,F_p,I_p,O_p).$$

This model could be used to evaluate each of the major sources of IPM advice. A model similar to this one has been used by Taylor to estimate the regional distribution of veterinarians. He found that having a school of veterinarian medicine in a state does not increase veterinarian density. This model should enable one to evaluate the geographical effects of the proposed IPM training centers and the regional specificity of other IPM training.

For a test of this model for private consultants, consider a simplification of equation (10) in which crop density, consultant fees, farmer opportunity cost and time, extension information cost, and all other input prices are assumed constant across regions. Field and farm size (s) will be measured by acres per farm, expected pest level (P) will be measured by pesticide expenditures per crop acre in an earlier period (Blake and Andrilenas), and public information (I) is measured by the number of extension and state IPM specialists. The stock of knowledge of farmers and consultants in a region (N) is measured by regional

cotton production. Cotton has a long history of IPM consultation, and IPM experience has been accumulated by consultants and farmers in those regions growing cotton. Crop value is crop value per acre of crop produced. The final model to be estimated is

$$(11) \qquad T = (P, I, V_p, N, s).$$

One of the most difficult problems is finding a good measure of private IPM consultants. There are many crop consultants who are not IPM specialists. Also there is no association to which all IPM specialists belong. The Intersociety Consortium for Plant Protection (ICPP) performed a survey of land-grant university department heads in 1978 (ICPP). They obtained estimates of numbers of IPM consultants (M.S. and Ph.D.), scouts (B.S.), IPM extension specialists, and departments of agriculture IPM specialists by states. Table 1 shows a regional tabulation of their results. The scout category undoubtedly includes individuals who only work at IPM about three to four months per year. The number of independent consultants shows a high degree of variability by region.

Analysis of Regional IPM Consulting

The effect of extension and other public IPM specialists is not unambiguous in the above IPM advice model. More extension effort in monitoring and recommendations will lower the supply price of consultant time and increase the supply of consultants in a region for a given consultant advice demand. On the other hand, lowering the price of extension specialist information (I_p) can lead to its substitution and reduced consultant demand. For example, it would be difficult to sell nematode assays if extension provides the same information at a lower cost.

A final estimation problem is present in the model of equation (11). The crop value (V_p), the level of pesticide expenditures (P), and public employees (I) may not be exogenously determined. However, on a regional basis, expected crop value may not be determined by numbers of consultants even though it may be at the farm level. Using the lagged, regional, pesticide expenditure level to indicate expected pest level should also help with the simultaneity problem. Only pesticide data other than herbicides was used because of the lack of variability in herbicide practices, and the general absence of IPM consultants for weed problems. For the public employee variable one may be able to argue that the public employees preceded the private ones in time.

The regional estimate of the reduced form equation for consultants was estimated by least-squares using the data of table 1. The estimated regional model of consultants per million crop acres with t-values in parentheses is

$$\begin{aligned}(12) \quad T = -.53 &+ \underset{(2.00)}{.47P} + \underset{(2.26)}{.07V_p} + \underset{(.93)}{1.49s} \\ &+ \underset{(11.46)}{.03N} - \underset{(-1.92)}{.37I} \quad R^2 = .98.\end{aligned}$$

Each of the variables has the expected effect. The demand side substitution effect of the public IPM service (I) outweighs the supply effect to give a negative influence on number of consultants.

Table 1. Number of Public and Private IPM Specialists, 1978

Region[a]	Scouts (B.S.)	Independent Consultants (M.S., Ph.D)	IPM Extension Specialists	State Department of Agriculture
Northeast	40	9	24	17
Lake States	117	15	16	14
Corn Belt	126	31	33	20
Northern Plains	94	41	20	10

Southern Plains	137	118	48	7
Mountain	112	30	29	35
Pacific	317	113	20	29
U.S. Total	1,350	486	286	185

Note: Estimates were made by department heads in crop protection disciplines at land-grant universities (Intersociety Consortium for Plant Protection).
[a] See USDA pesticide use surveys (Blake and Andrilenas) for regional delineations.

The elasticities computed directly from equation (12) are .34, .52, .11, .7 and −.4 for expected pests, crop value, farm size, knowledge stocks, and public employees, respectively. The relatively large impact of cotton production probably measures season length and pest complexity, as well as accumulated experience. A data set which had direct measures of experience could separate these effects. The highly significant effect of cotton production on consulting needs further analysis. These preliminary results suggest that further analysis should be undertaken.

There is no analysis of the substitution possibilities between consulting and pesticide use n the model above. To see what type of information is being collected on concurrent use of pesticides, nonpesticide controls and consulting, let us turn to recent USDA pesticide use surveys.

USDA Pesticide Use Surveys

The nonpesticide information gathered in the latest USDA pesticide-use surveys is extensive. In recent years, there is a distinct trend toward asking farmers more about their nonpesticide pest control practices at the same time that pesticide use is measured. There are fourteen separate surveys completed or in process. Beginning with the 1977 cotton survey, questions on target pests, scouting, and farmer management practices were first collected. Target pest tabulations give which common pest species farmers believe they are controlling with particular pesticide applications (in eight surveys). Infestation levels referring to farmer estimates of the relative level of pest attack are given in six surveys. The physiological stage of the crop when pesticides were applied was compiled for six surveys.[1]

The scouting data collection is limited in scope, but three surveys have collected fees charged, and seven will have some tabulation of type of scout employed or source of scouting information. Some questionnaires merely ask "sources of information." There does not seem to be a consistent way of tabulating farmer scouting in the survey, and often it is omitted. The studies by Willey and Grube point to the need for complete information on amount and quality of self- and hired scouting.

[1] The author can provide a table summarizing major items in each survey and the sample size for each survey.

For the USDA pesticide use surveys to be most effective for evaluation of IPM information services, there need to be some modifications. First, minimal farmer demographic data is necessary to estimate farmers' opportunity costs of time. Consultant and farmer IPM experience also should be tabulated. Average field and crop acreage sizes per farm will also be helpful in evaluating transportation. Use of traps, IPM computer links, and other capital items also could be easily tabulated.

This study separates the IPM advice process into three components and provides a supply and demand model which can be estimated. With a limited, regional set of data encouraging results were obtained. More complete data from USDA pesticide use surveys may permit better specification of such models. Policy questions on IPM information certainly require more attention by economists and biologists.

The Nature of Benefits and Costs of Use of Pest Control Methods

C. Robert Taylor

Integrated pest management (IPM) strategies are often strongly advocated as a means of increasing farm income while at the same time decreasing pesticide use and thus the external costs associated with pesticides. These impacts, though they may be true for some individual producers, are not necessarily the final outcome of widespread adoption of IPM. Emphasis of this paper is on the nature of such paradoxes and the conditions under which they can occur. Although the focus of the paper is on effects that are manifested in the marketplace, other effects such as external costs of pesticides and nonproducer costs for developing and/or implementing IPM are included for completeness.

A mathematical treatment of the paradoxes is given to add concreteness to the paper. But before proceeding with a mathematical treatment, it may be useful to take a superficial, graphical look at the paradox that while individual producers may gain from adopting IPM, income to producers as a group will not necessarily increase with widespread adoption. The classical explanation of this paradox is that with inelastic demand, total revenue, and thus profit, would decrease with an increase in production attributed to adoption of IPM. Of course, early adopters would reap windfall gains, but as more and more producers adopt IPM, aggregate income would decline. Although this classical argument is valid for a perfectly inelastic supply curve, it is not usually appropriate to the analysis of IPM because it does not account for impacts on production cost. That is, to measure farm income effects, one must take an a priori view of the supply curve rather than viewing supply a posteriori. When this view is taken, it can be seen that inelastic demand is not necessarily a condition for aggregate farm income to decrease with widespread adoption of IPM. Figures 1 and 2 illustrate these points. In figure 1, it can be seen that a shift in supply resulting from adoption of IPM will increase producers' surplus which, for purposes of this paper, is equated with farm income including the rent to fixed factors of production. Note, however, that figure 2 illustrates a case where aggregate income will decrease, even with elastic demand. In this case, supply shifts more at high prices than at low prices, which is typically the case with pest control methods since low cost producers tend to be those without serious pest problems.

Social Welfare Impacts

Complete mathematical treatment of benefits and costs that are manifested in markets, and the distribution of these values, requires specification of a Walrasian system of multiple horizontally and vertically related markets. However, for expository convenience, consider only two horizontal market levels, specifically the markets for raw agricultural products and the markets for inputs to agricultural production. Also for expository convenience, only five groups of economic actors are considered: (*a*) producers of agricultural products, (*b*) consumers of raw agricultural products, (*c*) input suppliers, (*d*) people who bear external costs or derive external benefits from production and/or input usage, and (*e*) those who pay the social overhead costs of IPM. While these groups are usually not mutually exclusive, the surplus doctrine in conjunction with the compensation criterion implies that social welfare can be measured by

$$(1) \quad W = \Pi_Q + CS_Q + PS_x + E - G,$$

where W is net social benefits; Π_Q is the profit or rent accruing to producers; CS_Q is consumers surplus measured in general equilibrium in the raw agricultural product markets, which is surplus for final consumers plus all forward

C. Robert Taylor is a professor of agricultural economics and economics, Montana State University.

The author wishes to thank Glenn S. Collins, Jean-Paul Chavas, and Oscar Burt for their constructive comments.

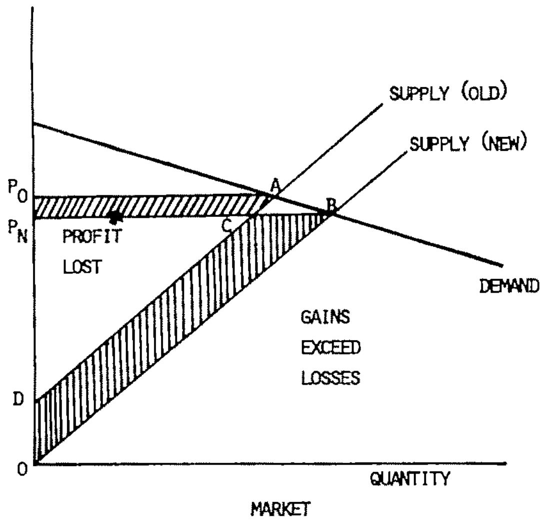

Figure 1. Situation where aggregate profits increase

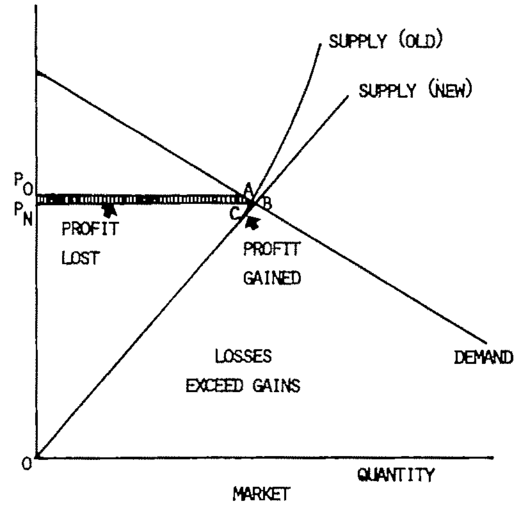

Figure 2. Situation where aggregate profits decrease

rents; PS_x is producers surplus in the input markets, which is rent in input markets plus all backward rents plus surplus for raw material suppliers (Collins; Chavas and Collins; Just and Hueth); E is external benefits (costs); and G is the social overhead cost for IPM programs.[1]

Most IPM strategies represent a distinct and discrete change from conventional pest control. However, before turning to discrete changes, it is perhaps instructive to consider an infinitesimally small change in the mix of pest control technologies and information systems. Letting M be a proxy variable denoting the technology-information mix, the change in net social benefits for an infinitesimally small change in M will be

$$(2)\quad \frac{\partial W}{\partial M} = \frac{\partial \Pi_Q}{\partial M} + \frac{\partial CS_Q}{\partial M} + \frac{\partial PS_x}{\partial M} + \frac{\partial E}{\partial M} - \frac{\partial G}{\partial M}.$$

Let us now examine each of the terms on the right-hand side of equation (2) for a multiproduct, multi-input case. Mathematical treatment of profit effects of changes in a factor such as M commonly begins with an assumption about optimizing behavior on the part of producers. Here, however, it is not essential to make any restrictive assumptions about optimizing behavior; rather, the analysis can be based on an assumed behavioral relationship. Then the analysis can focus on the profit incentive to adopt and the aggregate impacts of adoption. Consequently, consider a behavioral relationship for a multiproduct producer, postulating that acreage of the jth crop depends on per acre net returns of that crop and competing crops:[2]

$$(3)\quad A_{ij} = \bar{A}_{ij}\,(R_{i1}, \ldots, R_{iJ}),$$

where A_{ij} is acreage of the jth crop for the ith producer; and R_{ij} is per acre net returns, defined to be

$$(4)\quad R_{ij} = P_j\, Y_{ij} - \Sigma_k\, r_k\, X_{ijk},$$

where P is the per unit price of the jth product; Y_{ij} is per acre yield; r_k is price of the kth input; and X_{ijk} is per acre input usage. The set of X's can be defined to include application rates for each pesticide used or which can be used, different methods of scouting for insects, and all nonpest control inputs. An implicit production function relates Y_{ij} to X_{ijk}. Production of the jth crop by the ith producer will be $Q_{ij} = A_{ij}\, Y_{ij}$, and total production of the jth crop will be $Q_{\cdot j} = \Sigma_i\, A_{ij}\, Y_{ij}$.

Profit Impacts

Profit to the ith producer can be represented by the profit function,

[1] The result that PS_x measures backward rents and CS_Q measures forward rents is, however, derived from profit maximization assumptions in other markets.

[2] Equation (3) can be derived from profit maximization for some production relationships and constraints. A more general case would have $\bar{A}(P, Y, r, X)$. Results based on this more general case are similar to results based on (3), but (3) is used for notational convenience.

(5) $\Pi_i = \Sigma_j A_{ij} R_{ij} = \Sigma_j \tilde{A}_{ij} R_{ij}$,

which can also be expressed as

(6) $\tilde{\Pi}_i = \Sigma_j (P_j Y_{ij} - \Sigma_k r_k X_{ijk}) \tilde{A}_{ij}$.

Since individuals view product demand and factor supply as perfectly elastic, the incentive for an individual to adjust the IPM technology-information mix, M_i is[3]

$$(7)\quad \frac{\partial \tilde{\Pi}_i}{\partial M_i} = \Sigma_j (P_j Y_{ij} - \Sigma_k r_k X_{ijk}) \frac{\partial \tilde{A}_{ij}}{\partial M_i} + \Sigma_j \left(P_j \frac{\partial Y_{ij}}{\partial M_i} - \Sigma_k r_k \frac{\partial X_{ijk}}{\partial M_i} \right) \tilde{A}_{ij}.$$

Equation (7) will be positive, zero, or negative, depending on whether the producer is underutilizing M_i, using the profit-maximizing M_i, or overutilizing M_i. The remaining analysis in this paper will focus on the case where (7) is positive, since this is the case commonly encountered in pest control.

Consider now the impacts of increased adoption of IPM, or increased use of M_i, on industry profits. Summing over producers, industry profits can be represented by

$$(8)\quad \tilde{\Pi}_Q = \Sigma_i \tilde{\Pi}_i = \Sigma_i \Sigma_j (P_j Y_{ij} - \Sigma_k r_k X_{ijk}) \tilde{A}_{ij}.$$

Because it is usually not appropriate to assume perfectly elastic product demand and factor supply at the industry level, the change in industry profits will be:[4]

$$(9)\quad \frac{\partial \tilde{\Pi}_Q}{\partial M} = \Sigma_i \frac{\partial \tilde{\Pi}_i}{\partial M_i} = \Sigma_i \Sigma_j (P_j Y_{ij} - \Sigma_k r_k X_{ijk}) \frac{\partial \tilde{A}_{ij}}{\partial M_i} + \Sigma_i \Sigma_j \left(P_j \frac{\partial Y_{ij}}{\partial M_i} + Y_{ij} \frac{\partial P_j}{\partial M_i} - \Sigma_k r_k \frac{\partial X_{ijk}}{\partial M_i} - \Sigma_k X_{ijk} \frac{\partial r_k}{\partial M_i} \right) \tilde{A}_{ij}.$$

Rearranging terms, equation (9) can be expressed as

$$(10)\quad \frac{\partial \tilde{\Pi}_Q}{\partial M} = \Sigma_i \left[\Sigma_j (P_j Y_{ij} - \Sigma_k r_k X_{ijk}) \frac{\partial \tilde{A}_{ij}}{M_i} + \Sigma_j \left(P_j \frac{\partial Y_{ij}}{\partial M_i} - \Sigma_k r_k \frac{\partial X_{ijk}}{\partial M_i} \right) \tilde{A}_{ij} \right] + \Sigma_i \Sigma_j \left(\tilde{A}_{ij} Y_{ij} \frac{\partial P_j}{\partial M_i} \right) - \Sigma_i \Sigma_j \Sigma_k \left(X_{ijk} \frac{\partial r_k}{\partial M_i} \right).$$

The first term in brackets on the right-hand side of (10) can be related to equation (7) which shows the individual incentive to adopt M. As noted previously, we are interested in the case where individuals are underutilizing M_i; hence, the first term in brackets in (10) will be positive. Note, however, that the last two terms in (10) can have any sign, depending on industry adjustments as translated into price changes. The direction of impact is easier to see in the case of a single product. If adoption of IPM results in an acreage and output increase and thus a product price decrease, the second term on the right-hand side of (10) will be negative. The final term can be either positive or negative, depending on whether the weighted value impact on input usage increases or decreases. Hence, equation (10) can be either positive or negative, depending on changes in production, input usage, and the slopes of general equilibrium product demand and factor supply curves.

Effects on Input Use

Industry use of the kth input will be

$$(11)\quad X_{\cdot\cdot k} = \Sigma_i \Sigma_j X_{ijk} \tilde{A}_{ij}.$$

The change in total use of the kth inputs used in agricultural production, resulting from adoption of IPM, will be

$$(12)\quad \frac{\partial X_{\cdot\cdot k}}{\partial M} = \Sigma_i \Sigma_j X_{ijk} \frac{\partial \tilde{A}_{ij}}{\partial M_i} + \Sigma_i \Sigma_j \tilde{A}_{ij} \frac{\partial X_{ijk}}{\partial M_i}.$$

An interesting paradox relating to total pesticide use can be examined with equation (12). If an increase in M involves reduced per acre use of pesticides, the last term in (12) for a pesticide input will be negative. However, the first term on the right-hand side of (12) will be positive if acreage expands as a result of adoption of M. Thus, total pesticide use can increase, even though the intensity of pesticide use decreases.

Impacts on Surpluses and Net Social Welfare

Consider now the impacts on net social welfare, equation (2), of a change in M. Close inspection of equation (10), which shows the

[3] A product subscript, j, was not included for M because pest control on different crops may be interrelated. The variables X_{ijk} and Y_{ij} are implicit functions of M_i; thus R_{ij} and $\tilde{A}_{ij}$ are also implicit functions of M_i.

[4] Due to the connection between individual firms' decisions and market price, the price P_j is an implicit function of M_i, for all i. Similarly, r_k is an implicit function of M_i, for all i.

impacts on industry profits, will reveal that the next to last term is the negative of the change in consumer surplus:

$$(13)\quad \frac{\partial CS_Q}{\partial M} = -\Sigma_i\Sigma_j\left(\tilde{A}_{ij}\, Y_{ij}\frac{\partial P_j}{\partial M_i}\right)$$

$$= -\Sigma_i\Sigma_j\, Q_{ij}\frac{\partial P_j}{\partial M_i}.$$

Similarly, the last term in (10) is the negative of the change in surplus for producers of X:

$$(14)\quad \frac{\partial PS_X}{\partial M} = \Sigma_i\Sigma_j\Sigma_k\left(X_{ijk}\frac{\partial r_k}{\partial M_i}\right).$$

Substitution of (10), (13), and (14) into (2) gives:

$$(15)\quad \frac{\partial W}{\partial M} = \Sigma_i\Big[\Sigma_j(P_j Y_{ij} - \Sigma_k r_k X_{ijk})\frac{\partial \tilde{A}_{ij}}{\partial M_i} + \Sigma_j\Big(P_j\frac{\partial Y_{ij}}{\partial M_i} - \Sigma_k r_k\frac{\partial X_{ijk}}{\partial M_i}\Big)\tilde{A}_{ij}\Big] + \frac{\partial E}{\partial M} - \frac{\partial G}{\partial M}.$$

In the absence of externalities, E, and social overhead costs, G, equation (15) will be nonnegative for any adjustment in the set M_i, which moves individual producers closer to the individual profit-maximizing level of M_i. Thus, we have the familiar result that if one or more producers are not using the profit-maximizing level of M, social welfare can be increased by an adjustment in the set M_i that moves it to, or closer to, the privately optimal level. However, whether these benefits accrue to producers, consumers, or both depends on the specific case considered.

With externalities and social overhead costs, equation (15) can be of either sign. In one case, the social overhead cost changes, $\frac{\partial G}{\partial M}$, could outweigh any benefits manifested in the marketplace. In another case, the change in external costs could be negative because total pesticide use would increase with adoption of IPM, as was illustrated with equation (12).

Lumpy Changes in IPM

For lumpy changes in M, impacts on industry profits can be obtained by integrating (10) from the initial M to the final M. Similarly, impacts on total use of pesticides, consumer surplus, surplus for input suppliers, and net social welfare can be obtained by integratior of (12), (13), (14), and (15), respectively. Although space does not allow for mathematica specification of these integrals, it is very important for empirical work to note that integration must be from one general equilibriun point to a new general equilibrium point. Fo example, in estimating impacts on consume surplus, which is the integral of (13), integration must be along a set of general equilibriun demand functions where all other prices in th economy are allowed to adjust. Thus, for em pirical work it is imperative to have a mode that either explicitly or implicitly accounts fo general equilibrium adjustments. Worded an other way, empirical estimates based on par tial equilibrium curves, which are typically es timated in econometric models and are im plicit in many other aggregate models, wi give biased results, with the magnitude of bia depending on how strong markets are interre lated.

Another word of empirical caution is that t compute the effects of IPM on aggregat profit, we are usually better off using a direc profit function rather than the area above product supply curve and below price. Th only case where the two measures are equiva lent is if the supply curve is also a margina cost curve. In practice, we seldom kno whether supply is marginal cost, so use of th area above supply and below price may i clude factors such as risk premium and expec tations that are never realized.[5]

Mathematical derivations given above we for the adoption of an IPM technolog information mix, under the assumption that M $= M_i$ for all i. The derivations also hold f other changes, such as a technology chan (Chavas and Collins) or a pesticide ban. C course, for a lumpy change, one must use th appropriate integration points, which will di fer from the case discussed above.

Concluding Remarks

This paper has attempted to provide a co crete explanation of some of the paradox

[5] If the supply curves shown in figures 1 and 2 are gene equilibrium marginal cost curves and the demand curves are ge eral equilibrium relationships, it can be shown that integration (15), excluding E and G, for a lumpy change in M will give t measure of welfare change that is shown in these figures. Ho ever, if the supply curve does not reflect marginal cost, then o must use a profit function to measure the impacts of widespre adoption of IPM on industry profits.

The case of unrealized expectations can be seen by setting

associated with widespread adoption of integrated pest management. IPM is often "sold" on the basis that it increases farm income and decreases pesticide use. Neither of these claims can be taken as a foregone conclusion. Generally, consumers will benefit from IPM through relatively lower food prices, and the component of social welfare that is manifested in the marketplace also will increase. But whether aggregate farm income will increase or decrease and whether net social benefits will increase is a moot point that can only be answered by empirical studies.

Empirical analysis of the aggregate economic impacts of widespread adoption of IPM is challenging indeed. Even more challenging is educating lay people on the paradoxes associated with widespread adoption of IPM, or for that matter any technology.

a profit maximization model, but assuming that the producer consistently over- or under-estimates the marginal physical productivity of pesticides. Then the area above the derived supply curve and below price will measure expected profit, which will never be realized. This seems to be a plausible case in regard to pesticides.

Economics of Integrated Pest Management: Discussion

Katherine H. Reichelderfer

Pest managment offers numerous opportunities for challenging economics research. Investigation of the economic aspects of agricultural pest control is in high demand. This area of research, however, is fraught with potential problems. I will use the three papers presented in this session to illustrate some common problem areas.

Good interdisciplinary communication is essential to the success of empirical investigations of pest management and other agricultural issues. Economists and plant protection scientists are dependent upon one another for data, methodology, and research results. As Swanson has aptly pointed out, economists must take care to be sure that they understand the biological system with which they are working and also must transmit a good understanding of economic systems to the biological science community. Taylor's paper is an attempt to avoid some of the problems that can arise from a lack of such mutual understanding. His careful explanation of the range of possible outcomes of a change in pest control technology is a vital exercise in transdisciplinary communication.

Data problems abound in pest management economics and are evident in Carlson's and Miranowski's papers, and in almost every other empirical work in this area. There are a variety of ways of coping with these problems, but often "solutions" create new problems. For example, Carlson follows a questionable practice in using pesticide expenditures as a proxy for expected pest level. This implicitly assumes that farmers have good knowledge of pest level expectations (in which case they need no advice) and base pesticide purchase and use decisions on that knowledge. The proxy also distorts any effects of the differences in pesticide materials and prices among regions. The use of proxies, or omission of variables necessitated by lack of data, may be unavoidable. But following such practices requires strong qualification of research results.

Economists typically express production as a function only of variable and fixed inputs, as Miranowski has done in his paper. The use of input quantities rather than a measure of pest infestation level to represent the impact of pest control on yield is a common practice but not a preferred approach. Pest control affects pests. It is the pests, rather than direct productive inputs, that affect yield. The productivity of a unit of pest control is completely dependent upon target pest numbers. There exists, in essence, a family of production functions for a given pest control input, each showing the effect of varying rates of control on a single pest level and the subsequent effect of reduced pest numbers on yield. Production functions for pest control are unrealistic if they do not express yield as a function of pest levels. This problem should be kept in mind by anyone estimating pest control productivity or substitutability with other inputs.

Another common, but often necessary, assumption that may create problems in empirical studies of pest control options is that of the profit incentive. Previous studies (Farnsworth; Miranowski, Ernst and Cummings) indicate that risk perception or risk aversion are more compelling bases for pest control decisions than is profit maximization. Evidence also is available to suggest that the real value of many pest management practices is reflected in a change in yield or income variability rather than a change in average expected yield or profit (Hall). Conclusions such as Taylor's that are based on studies that assume the profit incentive should be carefully interpreted.

Much of the popular demand for a change in pest control technology is related to social costs of pesticide use. However, little empirical work on the net social welfare aspects of agricultural pest control has been conducted.

Katherine H. Reichelderfer is an agricultural economist in the Natural Resource Economics Division; Economics, Statistics, and Cooperatives Service; U.S. Department of Agriculture.

This probably is related to the difficulty in estimating the external effects of pest control actions (see LeBaron). Taylor uses an "*E*" to represent a variable that, for lack of data and/or appropriate valuation techniques, is often ignored or discounted.

Generalization and oversimplification are enticing, but dangerous courses to follow in examining the complex issues of pest management economics. Taylor has been careful, in one sense, to warn us of this problem. However, he, like others, makes some assumptions that may have created an error similar to the one he sincerely warns against. His assumption that "supply shifts more at high prices . . ., which is typically the case . . . since low cost producers tend to be those without serious pest problems" may be true for cotton production, but is it valid across the board? Our familiarity with one cropping system, region, or pest problem must not be allowed to affect our overall perspective or approach to empirical work on integrated pest management (IPM).

A last potential problem is one not relevant to the papers presented in this session, but that deserves attention nonetheless. The intertemporal aspects of pest-control decision making and productivity are sometimes disregarded in empirical works that otherwise would benefit by their inclusion. Changes in input productivity depend upon the stage of crop development, rate and age structure of the pest population, and a range of other dynamic variables. The economic implications of such variables can be significant and should, when they are relevant, be considered.

Some of the problems discussed above are avoidable and should be addressed whenever possible. Others, like lack of data, may be relatively unavoidable in the short term. It is, in part, the need to address these problems and derive approaches for their resolution that makes the economic study of IPM so challenging.

Economics of Integrated Pest Management: Discussion—An Entomologist's View of IPM Research Needs

William G. Ruesink

Ten years ago it would have been difficult to find four economists with working experience in integrated pest management (IPM). Today we have four on the program and they probably represent only 5% to 10% of the world's investment into the economics of IPM. Thus, while the number is still small, it is growing rapidly. As an entomologist, I am delighted to see this increase and to hear the presentations today. I must say I find little to criticize and much to be optimistic about. In view of this and because an entomologist rarely has the opportunity to address an audience of so many economists, I will use my time to present one entomologist's views on the needs for future research in IPM. In doing so, I will indicate which of those needs I see as best fulfilled by economists and biologists working together and which can best be fulfilled by each of the two groups working separately.

First, consider the research which should be a joint effort. Foremost on this list is to join with systems scientists to develop a holistic overview of pest management. Such an overview would include defining the goals of IPM, identifying the component parts of an IPM system and the boundaries of that system, discovering the inputs and outputs of the system, and so on. This probably should be done for several specific crop production systems, for example, the corn-soybean cash-crop system of this part of the country. As part of this effort, we should develop several lists of criteria for "good" pest management. I say several lists because I propose we need one for the growers' point of view, another for the local community, a third for the region, a fourth for the entire country, and perhaps one for the world. These lists can serve as points of reference whenever we evaluate a particular IPM program.

Another joint effort is the development of proposals for alternative IPM programs. The biologists possess technical information about agronomic and environmental relationships, while the economists work with the social and economic aspects. Ideas leading to these proposals will be generated in part by the first joint effort and in part by the several separate efforts which follow.

There are three efforts which should be largely the responsibility of the biologists. One is to develop an understanding of the relationship between crop yield and pest population level. At its simplest, this relationship is expressed as a univariate equation with population level measured at a single point in the life cycle of the pest. More generally the relationship includes temporal dynamics to account for the variation in crop yield that results from variation in pest population over time. Another task for the biologists is to quantify the impact of PM actions on pest populations. For example, what does crop rotation do to next year's corn rootworm population? A third task is to develop models for change in pest populations. Given a set of environmental and management conditions, and an initial pest population, a method is required that forecasts changes in population level over time. And of course, the biologists must design experiments and sample surveys to obtain the data needed for these three tasks.

There are also three tasks which are largely the responsibility of economists. One is to develop farm level budgets for each alternative PM program. These probably must be disaggregated enough so differential effects can be detected by region and by grower classification. Another task is to evaluate each alternative against the several lists of criteria, that is for the grower, the community, the nation

William G. Ruesink is an associate professor of agricultural entomology, University of Illinois, and associate entomologist, Illinois Natural History Survey.

etc. The third task is more of a request: Please tell the biologists what you need and how important each need is. Do you need the models I have assigned to the biologists? Are deterministic models adequate or should we invest a significant part of our resources into quantifying risk? Or, does the biologist even know what an economist means by risk? Finally, just as the biologist must gather data, so also must the economist. Do not complain to me that you cannot find data on how much corn is grown under rotation versus under continuous culture. You must design and execute sample surveys or use whatever other means you have available to acquire the information needed to accomplish the above tasks.

In closing, I appeal to biologists, economists, and everyone interested in IPM to remember the word "pest" has no biological or ecological significance. Pest management is only important when it benefits mankind. Our job is to develop IPM programs that are, over the long term, socially and economically best for the largest possible number of people.

The Political Economy of Rural Development
(Sidney Evans, North Carolina A&T State University, Presiding)

A New Approach to Nonmetropolitan Development: National Sectoral Policies

Pat Choate

The stimulation of economic development in nonmetropolitan areas lies as much in efforts to strengthen the overall economy and the vitality of specific industries and groups of linked industries, called "sectors," as in traditional area development policies.

Revitalizing the overall economy, its parts, and that of specific places—metropolitan and nonmetropolitan—will involve three interdependent courses of action: (*a*) improving capital formation and productive investment, (*b*) accelerating the development and application of new technologies, and (*c*) improving labor quality. Although these principal elements of a national economic revitalization effort are relatively clear and the potential benefits to nonmetropolitan areas relatively obvious, there is less clarity both on how to proceed and on the capacities of nonmetropolitan areas to participate fully in such an effort.

The purpose of this paper is threefold: (*a*) explore present economic and institutional circumstances that are key to national economic and economic revitalization, (*b*) describe how national sectoral policies can be used to guide national economic revitalization, and (*c*) assess the development capacities of nonmetropolitan areas to participate in a process of national economic revitalization.

A Changing Economy

During the past two decades, there has been a major shift of investment and employment from metropolitan to nonmetropolitan areas. This shift has made these nonmetropolitan areas sensitive to those international and domestic economic changes that affect specific firms, industries, or groups of linked industries—sectors. For example, as the fortunes of the domestic automobile assembly firms have declined, dozens of linked supply firms, such as tires, batteries, plastics, and steel, also have been adversely affected. Because many of these assembly and supply firms are located in nonmetropolitan areas, the effects of change have rippled through specific places and affected specific employment groups.

The creation of targeted national, state, and local economic strategies in the future will require increased reliance on microapproaches, approaches targeted to specific industries and sectors. The creation of such approaches requires a critical evaluation of national economic weaknesses and strengths that eventually must be addressed. Specifically, a number of indicators are cause for concern, including:

The United States' rate of productivity growth has fallen for almost a decade and a half. In 1979 and in the first quarter of 1980, actual productivity levels fell. This key economic indicator suggests that the United States is losing its competitive edge with international competitors whose productivity has declined but at not nearly the rate experienced in the United States.

Structural unemployment and high inflation have become a seemingly permanent feature of the U.S. economy. The present administration in its *1980 Economic Report of the President* predicted that unemployment would not reach 4% levels until 1985, and inflation would not be reduced to 3% levels until 1988.

Firms of other nations are capturing an increasing share of both domestic and international markets formerly serviced by U.S. companies. The difficulties in steel, automobiles, textiles, apparel, and shoes are merely the most obvious. Even seemingly thriving industries such as semi-conductors and computers are now potentially at risk.

Although these signs of economic decline are cause for alarm and action, economic and

Pat Choate is a visiting fellow with the Academy for Contemporary Problems, Columbus, Ohio.

political panic must be avoided. The U.S. economy is strong and has all the key elements necessary for a restored economic vitality and growth. For example:

Although other nations have closed overall productivity levels, the United States remains the most productive among major industrial powers.

The size of the domestic economy is a major asset. Specifically, the $2.4 trillion-U.S. economy remains the largest single market in the world. The combined value of the gross national product (GNP) of the nineteen members of the European Organization for Economic Cooperation (OECD) is only slightly larger than that of the United States.

During the decade of the 1970s, the U.S. economy was able to absorb over 20 million additional workers, an increase roughly equal to the entire work force of either Italy or France.

Although other nations are increasing their competitive position in technology, the overall U.S. technological base is still the most advanced in the world.

The Changing Role of Government

A contemporary economic and political reality is that virtually all decisions by business and entrepreneurs are now shared with government. This expanded role of government in the economy is a consequence of the growth of public interventions through a diverse and interdependent array of fiscal, monetary, trade, area development, and regulatory activities.

The multiple economic interventions of the public sector are distinguished by their size, scope, directive influence, and their policy and administrative disarray. The disorder in public economic interventions is producing a number of unwanted, even unanticipated, side effects that in aggregate seem to retard overall productivity. In large measure, this disorder reflects the use of antiquated techniques of public administration, such as large-scale patronage, even though disguised under civil service labels. This disarray also reflects the absence of either macro- or micro-national development objectives.

At present, national development policy essentially consists of a number of discrete individual programs and regulatory activities. The responsibility and authorities for the policies and administration of these multiple interventions is fragmented among and between the many agencies of the federal government, the fifty state governments, and the more than 79,000 units of local government.

The inefficiencies and adverse consequences contained in public economic interventions have not gone unnoticed. For at least three decades, a diverse number of efforts have been initiated to bring rationality to these economic interventions. The principle of these efforts have been reorganization efforts, creation of a variety of intergovernmental planning requisites, coordination approaches, and the use of numerous "advanced" management techniques such as planning, programming and budget control, and zero-based budgeting. These approaches have produced some results, but on the whole they have failed. For example, since 1948, there have been twenty-eight major attempts to reorganize the economic policy machinery of the federal government now located in thirty-three separate departments and agencies outside the Executive Office of the President. Yet, the policy disarray continues as does the structural fragmentation.

Pluralism, both structural and issue, is a strong force in the U.S. political and economic system, which must be recognized if improved public administration of the nation's economic interventions is to be achieved.

A New Approach to Nonmetropolitan Development

The most promising and efficient approach for bringing coherence to government's many economic interventions and to public, nonmetropolitan development policies/programs is the creation of economic strategies targeted to specific industries and groups of linked industries (sectors).

Industrial and sectoral policies essentially would be a process by which government, business, and labor would openly and cooperatively devise a set of common economic objectives (long- and short-term) and identify the respective roles and responsibilities each party would have. This common framework would provide a needed source of logic and discipline for government's many economic interventions and at the same time increase needed conditions of certainty for business and labor.

National sectoral policies would have a

number of basic characteristics, including: they would be more inclusive than the current, limited concepts of reindustrialization. Rather, sectoral policies would recognize the role and interdependence between manufacturing, agriculture, finance, services, resources, and other parts of a total economy. Such policies would be formulated in the context of general economic goals (macro-objectives) of reducing inflation and unemployment and of increasing per capita GNP. Such policies would harmonize the objectives of balanced growth between regions and between metropolitan and nonmetropolitan areas. And, they would assist in bringing better balance between the nation's efficiency, equity, and quality-of-life objectives.

In creating national sectoral policies, the initial focus would be on three categories of economic activities: (*a*) those having high growth potential; (*b*) those basic, mature, but essential economic activities such as steel production; and (*c*) those distressed economic activities such as apparel which eventually will drift to a lower level of production and employment because of strong international competition. Strategies for each of these three categories of economic activities would vary according to specific needs and opportunities that would be identified through cooperative business, government, and labor production committees, committees that would in many ways borrow from the experiences of the agricultural sector.

Creation of national sectoral policies would differ significantly from traditional concepts of a planned economy. By the use of formal working groups from all affected parties—business, government, and labor—the focus of policy creation would be the creation of compacts that will provide guidance to actions that already would be taken, but that otherwise would be unfocused. Because of the size and complexity of the U.S. economy, creation of national sectoral policies by necessity would not directly involve every industry or economic activity. Rather, if business, labor, and government in a number of key economic activities such as housing, automobiles, biochemicals, apparel, and primary metals can cooperatively devise effective economic strategies, then the hundreds of other linked industries and economic activities will also benefit. Such a limited, but highly targeted, approach to bringing rationality to government's economic interventions and public/private cooperation is within the present management capacities of business, government, and labor.

There are a number of requisites for the creation of effective national sectoral policies including: an improved analytical capacity that will permit collection and analysis of better economic information; creation of a mechanism in the executive branch of the federal government (preferably in the Executive Office of the President) that would be responsible for initiating and evaluating national sectoral policies and coordinating them with fiscal, area development, monetary, trade, and regulatory policies; creation of improved consultative systems among and between the many federal agencies, the Congress, and the state and local governments; and creation of an effective consultative system with the private sector, both business and labor. Each industry has its own potential and its own problems that must be addressed systematically by those most intimately involved. The success of the agricultural sector in the United States illustrates the many benefits to be gained from focused cooperation between business, workers, and government.

Nonmetropolitan Development Capacities

The sweep and power of the changes underway in both the international and domestic economy are often beyond the development and remedial capacities of individual communities and individual nonmetropolitan communities. For example, there is little that Youngstown, Ohio, or even U.S. Steel, can do under present circumstances to alter the worldwide shifts underway in steel production. Too many factors are concerned and too many participants are involved.

Nonmetropolitan areas would be major beneficiaries of sectoral development approaches. Partially, these benefits would be derived from an improved national economy. Also, such benefits would accrue to nonmetropolitan areas because of the weak development capacities they now possess. Thus, targeting of public or private actions could minimize weaknesses and build on what strengths that do exist. For purposes of analysis of the capacities of nonmetropolitan areas to participate in national economic revitalization, a typology will be used as follows: (*a*) nonmetropolitan institutional and leadership capacity; (*b*) nonmetropolitan financial capacity; (*c*) nonmetro-

politan human resource capacity; and (*d*) nonmetropolitan physical capacity.

Institutional and Leadership Capacity

Nonmetropolitan areas are burdened with too many units of government. Although nonmetropolitan areas possess less than one-third of the nation's population, they have 85% of the 3,042 county governments, 70% of the 18,000 municipalities, 80% of the 16,000 townships and towns, 67% of the 26,000 local special districts and authorities, and 45% of the 2,000 sub-state multijurisdictional districts. This excessive number of governmental units creates complexities and administrative costs that are beyond nonmetropolitan capacities. Institutional consolidation seems unlikely in the foreseeable future.

Leadership for public sector development activities comes primarily through federal-sponsored programs such as the Farmers Home Administration, the Small Cities Program of the Department of Housing and Urban Development, and the Economic Development Administration. These programs provide funds for institutional building and direct technical assistance. However, these program activities possess only limited coordination at either the policy or program level. The funds provided through these programs for staff are limited—less than $100 thousand per program for a seven- or eight-county area. Planning activities are focused more toward the delivery of agency funds than overall development needs. Staff are given limited training. For example, the staff charged by the Department of Agriculture to conduct its nonmetropolitan development through more than 1,000 county offices is trained in agriculture as opposed to economic and community development.

Financial Capacity

Nonmetropolitan areas have inadequate access to public and private capital. Theoretically, capital markets are efficient. In reality they rarely are. These areas have limited financial resources for private sector investments, particularly for small business, reflecting the small size of nonmetropolitan financial institutions, and their lack of experience making nonagricultural business loans.

The diversity of size, numbers, and financial capacities of nonmetropolitan units of government, coupled with the generally lower per capita incomes, restricts the financial abilities of these areas to undertake many essential public activities, such as construction of community facilities.

Human Resource Capacities

Publicly sponsored training and vocational education programs are a major tool for improving the productivity of firms and the per capita incomes of individuals. Although substantial progress has been made in the construction of vocational facilities in nonmetropolitan areas, there is substantial evidence that these programs are little related to the economic development needs of the places they serve. Although some states, such as South Carolina and Oklahoma, have used vocational education as a means to increase nonmetropolitan investment and increase placement rates of the trainees, these programs are still the exception rather than the rule.

Physical Capacities

Nonmetropolitan areas traditionally have had limited public infrastructure. This has limited nonmetropolitan development. In response to this perceived need, a wide array of public programs has been created, such as the Rural Electric Administration, Farmers Home Administration Community Facilities Program, Economic Development Administration, Appalachian Regional Commission, Title V Commissions, and a variety of special purpose programs. In aggregate, these programs have substantially enhanced the physical development capacities on nonmetropolitan areas over their previous condition.

Yet, as the nation enters the 1980s, there is growing evidence that even with these prior investments increases in population and the expansion of public regulatory requirements have created conditions whereby the physical plants of nonmetropolitan areas are increasingly inadequate for either community development or economic development needs. The Department of Commerce, in *A Study of the Public Works Investment in the United States,* has documented that in terms of real purchasing power the United States is now investing less in public works than in the 1960s, approximately 30% less. Although this can be explained in part by completion of the original

interstate highway system and declining demands in education, the declining levels of investments are prevalent in real terms even when these two items are excluded. If there is a relationship between private investment and public works, this decline in public infrastructure investments may have long-term negative consequences.

A series of studies by the Economic Development Administration also have documented how many of those public works investments made for development purposes are unused. Specifically, EDA has found that less than 25% of its industrial park investments are being utilized. This represents a substantial diversion of limited public infrastructure investments to nonproductive uses. The EDA example is a paradigm for other programs found through the federal, state, and local levels of government.

Strengthening Nonmetropolitan Development through Sectoral Policies

Sectoral policies would permit the focusing of the limited area development assistance that is available to nonmetropolitan areas. Specifically:

The creation of a common logic for economic revitalization will permit the many units of local, state, and federal government to focus their policies and programs on key actions. Such targeting can do much to limit the present chaos found in economic interventions by multiple agencies.

The creation of sectoral policies will permit better identification of capital gaps existing in nonmetropolitan areas. Such identification would in turn permit existing federal financial programs, such as the FmHA Business and Industrial Loan Program, Small Business Administration, and EDA Title II Business Loan Program to better assess aggregate needs and better allocate the credit they do control.

The creation of sectoral policies will assist nonmetropolitan areas to identify and implement training programs that can improve placement of trainees and attract private investment. Such policies can provide a conceptual framework for a number of needed reforms in the nation's nonmetropolitan training and vocational education programs. (*a*) There should be an improvement of data and information systems to identify specific training demands/supplies by geographic area, skills, and time frames. (*b*) Improvement of polic and administrative structures that administe training and vocational education programs including improved local involvement, i needed. (For example, metropolitan area now are given autonomy in the administratio of CETA funds, while nonmetropolitan are programs are closely controlled by state gov ernments.) Finally, (*c*) there should be im provement in the links between training an vocational education and potential employers

The creation of sectoral policies can serv to better target public works investments. I an era of increasingly scarce public resource and declining real levels of public work funds, nonproductive investments must b avoided. National, state, and local sector policies will permit the targeting of publi works to those activities that have a highe probability of enhancing the community itse as well as its economic development.

Conclusion

For the foreseeable future, America face many changes—some will be disruptive an some will be opportunities for growth. Th success of business, labor, and government i minimizing the negative consequences change and in seizing new opportunities wi largely determine the economic and comm nity development fate of the nation and i nonmetropolitan areas.

Social Science Contributions to Rural Development Policy in the 1980s

Kenneth L. Deavers

Because it will help to frame the subsequent discussion in this paper, let me begin by defining rural development policy. As I see it, rural development policy involves deliberate action by federal, state, and local governments and private institutions and individuals to achieve three goals: (*a*) improved rural income levels and employment opportunities; (*b*) improved access by rural residents to adequate housing and essential community facilities and services; and (*c*) responsible use of rural resources and the rural environment to preserve the quality of rural life.

In attempting to achieve these rural development goals, federal policy needs to be guided by some set of implementation principles. As enunciated by the current administration, these principles include: (*a*) recognizing the diversity of rural areas and providing continuing opportunities for individuals to choose among a wide range of rural lifestyles; (*b*) achieving an equitable distribution of opportunities, primarily through targeting action on distressed rural areas, communities, and people; (*c*) increasing the planning, management, and decision-making capacity among public (and private) institutions concerned with economic opportunity and quality of life in rural America; (*d*) implementing federal actions in a way that recognizes local priorities and coordinates federal, state, and local rural development spending; and (*e*) providing delivery mechanisms that make programs more accessible to rural governments, community-based organizations, and citizens. Rural policies and programs undertaken in this context provide the funds for and mechanisms of rural development.

National Issues and Rural Development Policy

One key to shaping federal rural development policy in the 1980s will be an improved understanding of the linkages between national issues and trends, and rural economic and social conditions. The social sciences can contribute to this understanding through research and analysis focused on significant national issues and their rural policy consequences. Obviously, there will be a somewhat different list of significant issues relevant to different policy spheres. For rural development policy, the test of relevance is that there be differential effects on rural areas and/or that public policies to deal with problems be different for rural areas. One example is energy.

Energy

Rapidly rising relative prices of energy and efforts to develop domestic energy resources are the two characteristics of the energy situation likely to be significant to rural areas in the 1980s. (Absent a major U.S. foreign policy failure, or government mismanagement of energy pricing, I do not believe that "shortages" will be important.) How will rising energy prices affect rural development?

I do not think we really know very much about the role of energy prices in shaping the overall spatial distribution of economic activity and population, other than to observe that the current situation occurred during a period of stable or falling relative prices of energy. Improvements in the highway transportation system clearly played a role in facilitating the decentralization of manufacturing activity, in the growth of the rural recreation industry, and in the deconcentration of population—and rising energy prices have contributed to a rapid increase in the relative price of transportation (especially for freight). But, are transportation costs a pivotal factor in any of these trends?

I think it is likely that the effect of rising energy prices will be significant for only a few rural industries, and that the major adjustments will be confined to a relatively small

Kenneth L. Deavers is director of the Economic Development Division; Economics, Statistics, and Cooperatives Service; U.S. Department of Agriculture.

number of rural areas—leaving the general distribution of economic activity and people largely unchanged. Whether that overall assessment is correct or not, we can, I believe, identify some kinds of rural areas that are particularly vulnerable and begin to address the public policy issues involved in their adjustment to higher energy prices.

For example, throughout the High Plains of Nebraska, Colorado, Kansas, New Mexico, Texas, and Oklahoma where irrigated agriculture is prevalent, concern has been expressed about the long-term viability of that kind of agriculture. Falling groundwater levels have contributed to a gradual rise in irrigation costs (and potential absolute shortage of water), but rising energy prices have compounded the problem by greatly increasing the rate of increase of irrigation costs. It seems likely, in the absence of public policy intervention to subsidize continued production of current crops, that these areas will return to dryland farming—much more rapidly than availability and cost of water alone would have dictated. What kinds of adjustments does this imply for the farm owners directly affected, and for the region's rural communities? What are the costs and benefits of various policies to prevent or facilitate such adjustments, and how are these costs and benefits distributed among individuals, communities, and over time? It seems to me that answers to such questions are well within the state-of-the-art of the social sciences, that they require the skills not just of economists, but demographers, and rural sociologists as well, and that they would contribute to better public policy.

Research on the social and economic impacts of energy development in rural areas, especially in the Northern Great Plains, has identified a number of policy issues likely to grow in importance during the 1980s. Among the most significant of these issues is that of "mitigation strategies;" that is, the set of public policies aimed at avoiding socially disruptive and wasteful boom and bust cycles in energy-impacted communities. It seems reasonably clear from current research (and growing experience) that the construction phase of new mines, thermo-generators, and synthetic fuel plants stimulates considerably larger population, employment, and income growth locally than are sustainable in the long run. To accommodate this growth requires significant additions to the stock of local public capital. One question is how to provide for this peak demand without providing excess capacity which rural communities will not need in a few years and which locally generated public revenue may be unable to support. A second question is how various community relationships respond to growth stresses and how adverse distributional effects can be avoided in our quest for domestic energy.

Renewed Rural Growth and Changing Settlement Patterns

Perhaps the most important national trend for rural areas in the 1970s has been the rural population turnaround. From 1960–70, 3 million more people left nonmetropolitan areas than moved into them. By 1978, the net movement between metropolitan and nonmetropolitan areas was again nearly 3 million, but in the opposite direction. Reduced outmovement from farms, increased rural mining, manufacturing, and service employment, increased rural retirement, longer-distance job commuting, and a strong residential preference for rural/small town living have all contributed to this trend. The speed, persistence, and widespread nature of the trend have surprised nearly everyone.

As the map of nonmetropolitan population change since 1970 (fig. 1) shows clearly, rural population growth has not been uniform. In fact, nearly 350 nonmetro counties have grown at three times the rate of the United States as a whole. At the same time, there are more than 500 nonmetropolitan counties declining in population. For many of these places, the adjustment to decline is a continuation of a decades-long process. For more than twenty years we have thought about rural development policy primarily as a response to population decline and economic stagnation. But, it is becoming clear that rapid unanticipated growth also can create problems for rural areas. In both cases, local institutions are called upon to adapt to the changing size and composition of the community's population and economic base. In some ways, adjustment to growth may be more difficult because traditional community values and individual lifestyles may experience the most significant strains.

Thus, rural growth is a possible new focus for rural policy in the 80s. In my judgment, social science research and analysis can play an important role in determining whether such

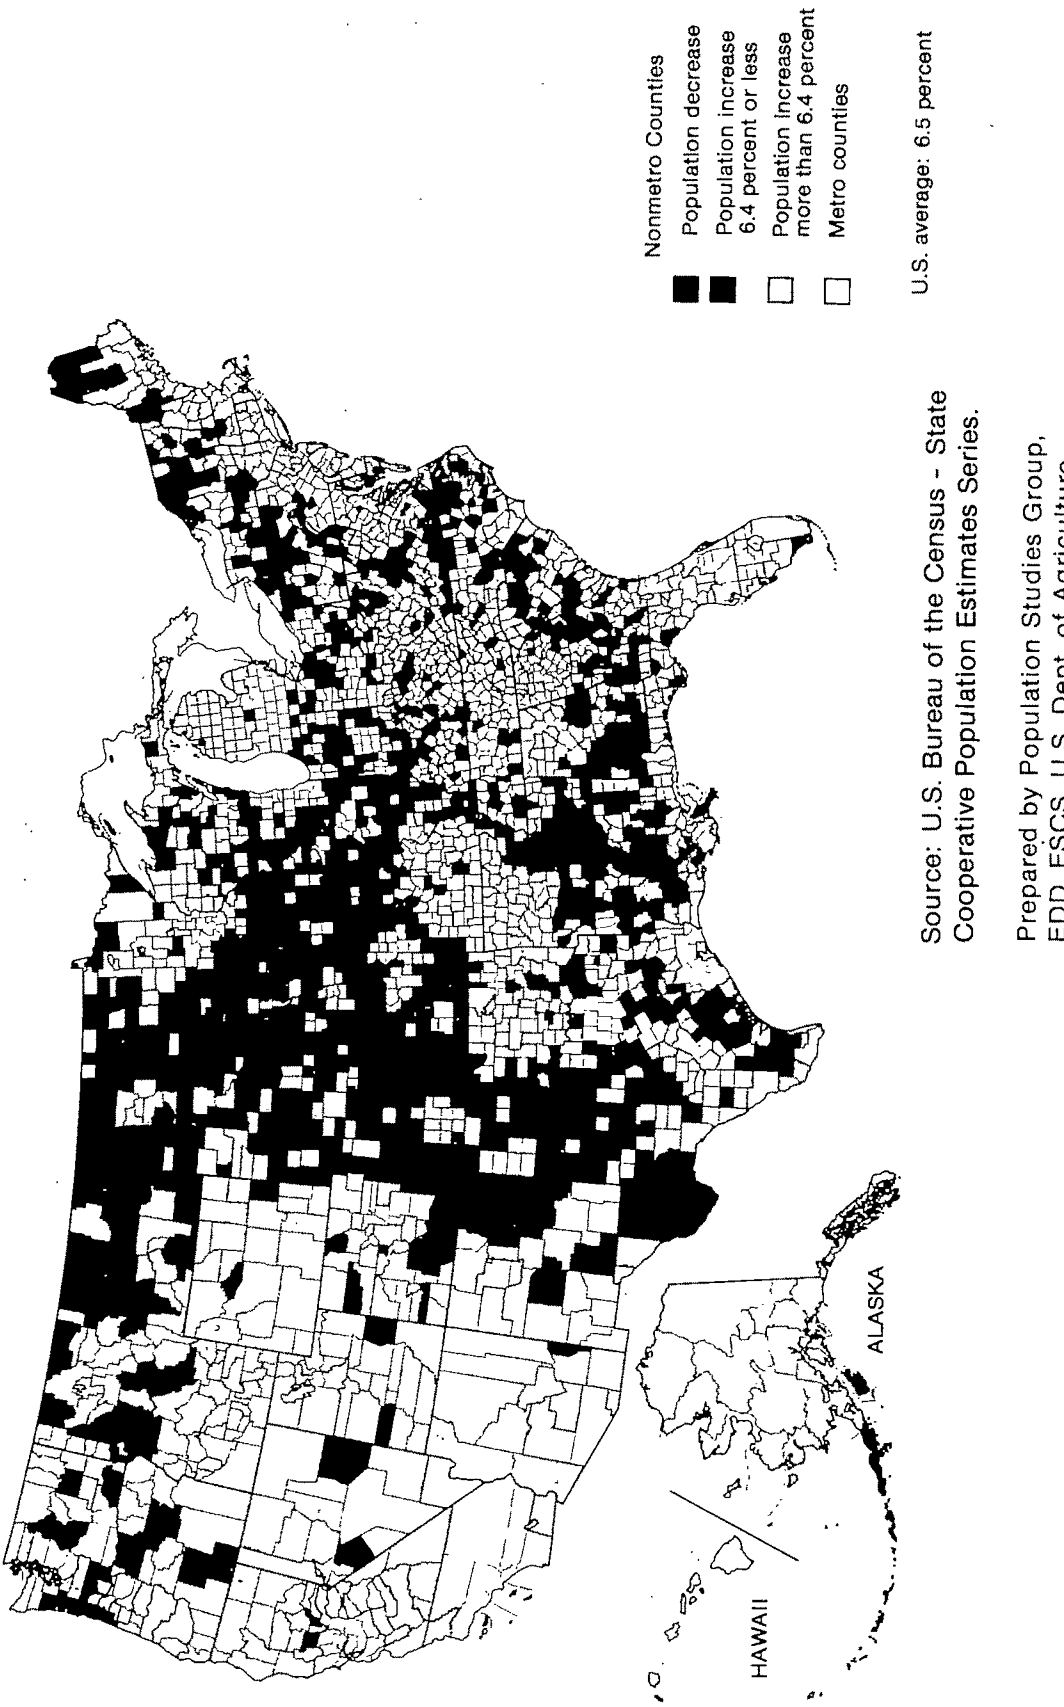

Figure 1. Population change for nonmetro counties, 1970–77

a focus for policy develops. In order for that to happen, I believe that considerably more attention needs to be given to analysis of the causes and consequences of rural population turnaround than to its description. This task should be among the highest priority research tasks once the 1980 census of population and housing becomes available.

Associated with that task, of course, is more social science research aimed at increasing our understanding of the causes and consequences of renewed rural growth and some assessment of the likelihood that it will continue in the 1980s—if so, where, and on what scale? Rural development policy appropriate to the 1980s will be difficult to formulate in the absence of such research knowledge.

Targeting Assistance on Unique Rural Problems

In the past two decades, rural lifestyles have changed—so much so, that the uniqueness of rural communities for policy purposes may have weakened significantly. Considerable fragmentary evidence for this assertion is available. For example, per capita personal income levels in rural areas have risen to 80% of those in urban; adjusting for cost-of-living differences probably would eliminate much of this remaining discrepancy. Rural residents also work at a wide-ranging set of activities similar to those of urban Americans. In March of 1975, manufacturing, wholesale and retail trade, and services, each had roughly 20% of rural employment, while agriculture had less than 10%. There is no longer any significant difference in infant mortality rates between urban and rural areas, and substandard rural housing has declined from 59% only twenty-five years ago to less than 7% today. But these comparisons of aggregate or average conditions in rural and urban areas obscure important differences. Two of these differences seem to me to be of particular policy significance. In each case, I believe that the social sciences have failed to marshall evidence effective to shape rural policy (although, perhaps, the failures have been for different reasons).

Rural Poverty

Poverty continues to be a serious problem for many rural Americans. However, because rural poverty is often scattered and hard to se (and may even appear "picturesque" to casual observer), the public perceives povert in 1980 as a largely urban phenomenon. Nevertheless, the roughly 9 million rural poor con stitute 34% of the nation's total poor.

Poverty is not uniformly distributed in rura America. Because of the residence patterns o rural minorities, and historic U.S. economi development patterns, rural poverty is heavil concentrated in the South. Nearly two-third of the rural poor live in that region, where ove 20% of the rural population failed to earn in comes above the poverty level in 1975. Th incidence of Southern rural poverty is like tha in many large Northern cities; e.g., Detroit Chicago, Boston, and Baltimore. As evidenc of the chronic and persistent nature of Southern rural poverty, 237 of the 255 counties tha have fallen into the lowest 20% of rural coun ties by income rank in each decade since 195 are located in that region.

Rural poverty differs from that in urba areas in some fairly fundamental and impor tant ways. At the community level, where lo personal and family income are so endemic a to be reflected in area-wide data, the ru poor often are located in environments whic lack adequate human and community fa cilities, which are isolated from other area with such facilities, which lack a wide range o employment opportunities, and where institu tional capacity—particularly governmental— is unable or unwilling to provide support. Fo individuals and families, rural poverty is ofte not the result of unemployment. Rather, it re sults from the types of jobs available in rur labor markets, a lack of appropriate skills an training for better jobs, a lack of transporta tion access to take advantage of opportunitie and chronically poor health.

For many of the rural poor, especially chronically disadvantaged areas of the Sout welfare reform is a key element of federal rur policy. Welfare reform proposals considere in recent years would have established na tional minimum payment standards, mad numerous changes in asset qualification re quirements, and changed participation re quirements related to family status and lab market status that would have benefited rur residents. While not strictly a developme policy, no expansion of traditional econom development programs would have as imme diate and obvious consequences for the we being of the rural poor—in terms of their ab

ity to obtain the food and services essential to a decent level-of-living—as welfare reform.

Rural Isolation

There is good reason to believe that Americans view rural communities as providing a lifestyle worth preserving. Residential preference research has shown consistently that a significant segment of the population would prefer to live in smaller cities, towns, or rural areas. The changed geographic distribution of economic activity favoring more rural locations, combined with a preference for living in such places, makes it likely that the 1980s will provide opportunities for many people to realize their lifestyle preference and an acceptable standard of living. But rural life is increasingly complex and diverse, and for some rural areas distance and scale are a significant impediment to improved conditions.

The basic character of dispersed rural populations is that they do not have as wide a range or high a level of facilities and services as city people. The extent to which this is true varies widely. There is a class of counties that have no town of 10,000 population and that are not readily and inexpensively convenient to either the larger nonmetro cities or to metropolitan centers. These mostly rural and remote counties are largely in the West (but not the Pacific Coast). However, smaller groups of them are found in the Ozarks, the Southern Appalachians, and the Upper Great Lakes. About 600 counties with a population of approximately 6 million are in this group. At the extreme are a number of settled areas in the Plains, the Great Basin Country, and Alaska that lie more than 100 miles from the nearest place of 10,000 people.

Overcoming the disadvantages of physical isolation and low population density are a major and unique part of rural development policy. The application of new forms of organization and technology—transportation, communication, and telecommunication—can contribute to alleviating conditions of isolation. Furthermore, federal assistance may help to make available the skills, experience, and fiscal resources necessary to deliver services to a low density population. What seems likely to happen, in the absence of effective social science contributions to research on this topic, is the application of (or even federal requirements for) urban-based, capital-intensive technologies. In the process we may end up destroying rural forms of settlement and their capacity to provide unique kinds of lifestyles.

Public Policy and Social Science Research

Public policy responses to a social issue can take several forms ranging from no action, relatively simple change in the rules and procedures of current programs, to legislative initiatives creating new agencies and programs. One can argue that the level of policy response will (and should) be related to the perceived political and substantive importance of the issue. In addition, there is an essential time dimension. For example, one reason public policy has not yet responded to the rural population turnaround with new legislation and programs is its relative newness. This newness affects both the perceived political salience of the turnaround and understanding of the substantive issues it raises.

There is, of course, no guarantee that the results of social science research will be influential in shaping policy. The relationship between research and policy is tenuous. Policy makers do not always understand how to use the results of research, in part because research fails to indicate what policy choices are available, and who will benefit or lose from particular choices. For example, most research monitoring rural population trends in the 1970s has paid only passing interest to the potential implications of these trends. Thus, it is difficult for policy makers to judge the costs and benefits of the turnaround, or to anticipate its impact in different areas and for different population groups. Moreover, very little research has focused on the process through which population change impacts on community structure—which institutions are involved, what is the timing of impacts vis-à-vis the initial population growth, how are the impacts distributed throughout the community? Yet, these are the issues which can give population turnaround political salience as an issue, and which can shape the public policy response.

Researchers need to know how, where, and when one gains entry to the policy process. They need to understand that many groups are involved—the White House, executive branch agencies, Congress, governors, mayors, and private interest groups. As a consequence,

there are many options—local, regional, state, and national—for building bridges between their work and the policy making process. In addition, research results need to be disseminated to policy makers in a useful and understandable way. Without more effective communication, there is little chance that the knowledge gained from social science research will contribute to rural policy in the 1980s.

Prospects for Rural Development Delivery Strategies and Programs in the 1980s

John M. Cornman

Obviously, predicting the future of any endeavor involving politics is risky, particularly when the assignment is to look a decade ahead. However, the assignment is not unattractive. There is little need for copious foothoting, and the chances are slim that anyone will check these predictions in ten years. Even so, it would seem prudent to establish several definitions.

Development encompasses economic de-/elopment, access to services and public 'acilities, stewardship of natural resources, ınd the enhancement of the environment. It ılso includes the process of increasing the ca-)acities of rural people and the institutions which serve them to identify problems, establish goals, set priorities, and devise, select, ınd carry out strategies to attain those goals.

Economic development encompasses the ıvailability of jobs, the closing of gaps in in-;ome and wealth, and the creation of diverse, esilient local economies. Thus, extraction of nineral ore, which creates a boom and bust ycle, may represent economic growth in the arly stages; but it may not achieve stable,)ng-term economic development. Rural de-'elopment also concerns agriculture and other ital efforts.

A development policy consists of goals, ac-on or funding programs, and the process or elivery strategies which join the two.

Finally, development goals for jobs, inbme, services, facilities, health, and others re, for the most part, the same for both rural nd urban areas. Different delivery strategies nd variations in program designs are re-uired, however, to achieve goals within those vo areas.

The prospects addressed in this paper re-ect the view that what is needed is not an rban versus rural development policy, but ıther a national development policy with de-very strategies and programs appropriate to urban or rural areas. Such a policy would allow one to muse about prospects for the whole policy as well as the rural elements of that policy. The prospects of both will be affected, if not determined, by international, national, and rural issues, the resolutions of which I am no better prepared to predict than I am to predict the future of strategies and programs, themselves. I do not pretend this list of issues is complete or that I have included all the implications of these issues and their ramifications for development in rural areas.

International Issues

The overriding international concern is peace, or, perhaps more accurately, the degree of peace present over the next decade. A convincing case can be made that the demand for food and nonfarm manpower needs of World War II were major factors in speeding the mechanization of farm operations, a decline in farm jobs and a rural-to-urban migration. Similarly, international confrontations consume resources, and agendas that involve long-term commitments, such as development, do not receive high priority. And, of course, if the confrontation were nuclear, all issues other than survival become moot.

How the United States uses its agricultural capacity and expertise in international affairs will be another major factor in the coming decade. Will we choose to export food to balance our oil deficit or our expertise to help nations meet their own needs—or, more accurately, what blend of those choices will we pursue? Equally important will be the method chosen to implement the selected strategies. If, for example, a chosen strategy demands greatly increased production of certain commodities, implementation of the strategy could emphasize research, resources, and/or policies that ignore broader concerns of rural development.

Another international issue which will affect

ɦn M. Cornman is president of the National Rural Center, ashington, D.C.

rural development is trade agreements. There is evidence that trade agreements that encourage low-wage industries abroad may succeed at the expense of low-wage industries in domestic rural areas, a traditional way of bringing industries to our rural communities. To offset this, however, the next decade may provide new export opportunities for rural enterprises.

Paramount among international trade issues are those affecting oil. These will affect not only our domestic policies but also our foreign policies and world peace.

National Issues

The list of national issues affecting prospects for rural development begins (or ends, depending at what part of the cycle you begin) with the extent of the nation's commitment to national development goals. Little progress will be made concerning employment, housing, or health problems in rural areas unless there is a commitment to address these issues nationally. Even if such a commitment exists, efforts will continue to be focused on urban areas unless there is broader understanding and acceptance that the nation has a stake in rural development. That stake includes meeting society's responsibility to the poor, ten million of whom live in rural areas; meeting national goals such as those concerning employment, housing, health, and energy; creating the jobs and markets needed for a viable national economy; and providing job and residential options necessary to the well-being of a free society.

The degree of commitment will be influenced by the degree of inflation and the degree of faith (well placed or not) in the impact of a balanced national budget.

The ability to deliver on the commitment will be affected by the impacts of energy policies (including cost and availability) and new technology on rural development opportunities, and our willingness and ability to relate macrolevel policies and microlevel programs more effectively in the future than in the past.

Will the energy crisis work for or against location of manufacturing and service jobs in rural areas? Will it help or hinder dispersion of food-processing facilities? Will it help or hinder rural residents commuting long distances to jobs? Will new technology encourage dispersion or concentration of jobs and facilities and will it serve smaller-scale enterprises and communities as well as larger ones? Will we learn how to transfer the benefits of this technology to meet rural needs? Will we remember the importance of smaller-scale enterprises as we debate the reindustrialization of the nation?

Obviously, the migrations caused by all of the above will affect prospects for rural programs in the decade ahead. Will "reverse" migration continue? Who will be moving? How well will we understand what is happening and who is benefiting?

Prospects on the national level also will be influenced by the outcome of presidential and congressional elections. A president committed to rural development can help make up for the lack of an organized constituency, and members of Congress who look beyond special interests can provide needed leadership.

Rural Issues

Certain rural issues are critical to prospects for rural development policies. A better understanding of the diversity of rural areas; an adequate data base; increasing the capacities of rural people and the institutions which serve them; organizing to influence governments, and public and private sector investment decisions; selecting leaders committed to development—all will be vital to rural development in the decade coming.

Rural areas differ geographically, ethnically, and by virtue of population size, level of development, and degree of poverty. Rural people and those working on their behalf must understand the need for flexible development strategies that can respond to that diversity. Too often, rural advocates as well as national-level policy makers are insensitive to this diversity.

The inadequacy of an adequate rural data base is both a serious barrier and a convenient excuse. Too little is known about the extent of poverty, unemployment, and underemployment in rural areas; about who is moving where for what reasons; about the impact of fewer farms on the quality of life in rural communities; about the costs of delivering services in rural areas; about the quality of education in rural schools. There is a need to identify data gaps and improve current data

collection efforts in rural areas. New data collection efforts should include program documentation and evaluation as well as the gathering of statistics.

A growing recognition of the need for such data is an encouraging sign. So is the acknowledgement that development requires the support of permanent institutions to deliver services and assist with capacity building (increasing the capacity of rural people and their institutions to identify problems and set and attain goals). This represents an important departure from the recent past.

For most of the past two decades efforts to nclude those omitted from the development process focused on guaranteeing certain rights and securing more equitable distribution of public resources. I think history will show hat, as an initial effort, the focus was correct. We will be hard pressed to come up with a ural development act for the South as effecive as the 1964 Voting Rights Act. That act lealt with a permanent (I trust) institution: the ormal procedure through which citizens elect leaders and influence policy. However, nany other efforts concentrated on establishng new organizations to deliver services and nfluence various levels of government. As a esult, we have a plethora of citizen-based organizations, coordinating committees, reional commissions, lobby groups, and cauuses, concerned with aspects of developnent. Many of these entities have been establshed to compete with existing, but nonreponsive, institutions. Whatever the merits of uch a strategy, it has yet to deal with two rucial elements—permanency and intellecual base. Forced to live on grants, many of hese organizations have had to trim sail or hange course in response to the grantsmanhip process. Many of the grant makers have ad no coherent or consistent development rategy to guide their decisions. Neither has hought been given to providing these organiations with the information required to roaden their perspectives.

What is involved is a fundamental change om a confrontation strategy to a developental strategy. With a shrinking, or at best atic, public grants budget, people interested development find these organizations serely limited in funds and expertise to make e change. At the same time, many of the ermanent institutions which could be importnt to development in rural areas—the land ant universities, community colleges, planning districts, and traditional citizen groups—have not grown to fill the gaps.

Recognizing that development takes time, patience, and commitment, it is becoming clear that the absence of permanent, responsive institutions with long-term commitments to rural development is a serious barrier.

And finally, to complete this list of factors affecting prospects for rural development in the 1980s is the ability of rural people, with all their diversity, to organize effectively and make themselves heard. Rural people, dispersed, diffuse and relatively few in numbers, frequently are ill-equipped to compete in the national arena for attention and resources, a cause of many of the barriers discussed above.

Given the historic inability of rural people to organize effectively around development issues on a national basis, and given the array of imponderables which could adversely affect rural development, it would be prudent to predict that there are no prospects for any new major, federal rural development programs or delivery strategies in the 1980s.

However, being something of an optimist, I do not believe the picture need be entirely bleak, if rural development advocates are willing to settle for a limited number of important advances and if the research community is willing to address rural development issues in ways useful to policy makers. Given a degree of cooperation between those two worlds, important advances could be made in the quality and quantity of data collected and disseminated; in understanding what is meant by capacity building and how to deliver what, to whom and when; in learning how to link various development programs for maximum impact; in encouraging the use of small business development as a tool to create new jobs; and perhaps in creating a broader development constituency around these issues.

These advances can be justified in ways consistent with what appears to be the political mood of the decade. Improved information could help program managers make better use of resources under their control. If the data collected involved the private as well as public sectors, the data could be used as a basis for improved private-public sector cooperation. Further, if encouragement of small businesses turns out to be a useful way to create new jobs, efforts in the area could attract the support of a wide range of interests—starting with small business and full employment constituencies, but extending to constituencies

concerned with development in general, civil rights, tax reform, small farms, conservation, and economic concentration.

Finally, I can predict that if progress is made along these limited fronts in the 1980s, then prospects for rural policies in the 1990s will be greatly enhanced, depending of course on war, peace, energy, agriculture. . . .

Rural Development: A Critique

Barbara J. Redman

The philosopher George Santayana once said that "those who cannot remember the past are condemned to repeat it." In order to know the present and future of rural development, one must know its past. In particular, it is necessary to know what has been wrong in the past if one is to know how to improve in the future.

All the other papers in this session are very similar. All identified broad goals of rural development, issues which in the coming decade should affect rural development, and suggestions for the future in policies and areas of research. None paused to reflect on the past, whether of institutional programs or academic research. None identified correctible errors or appraised the system's overall worth and effectiveness, in spite of widespread opinion (for example, Schaller 1978) that the history of rural development programs has been something less than an unqualified success story. It has thus been left to this paper to undertake the critical analysis, which given page constraints will focus on the academic literature.

What Has Gone Wrong?

Practicing economists will no doubt accept on faith the proposition that economic theory is an appropriate tool to use, although this assumption can be questioned. (Berry, for example, believes that ecology rather than economics is the most relevant discipline.) Given this assumption, economic analysis must always specify first, the arguments in the objective function, and second, some means of measuring or quantifying those arguments. This paper contends that researchers in rural development analysis have erred in each of these basic specifications.

Arguments in the Objective Function

As Deavers states, the goal of rural development should be to improve rural well-being and quality of life. However, in defining these terms, economists have almost always emphasized traditional economic concepts, such as level of per capita income, economic growth, and technical efficiency of operation, and ignored the subjective, noneconomic elements.

As a fairly representative example, consider the 1976 AAEA invited papers session on rural development. Edwards cited five bases for regional growth: increasing resource availabilities, advancing technology, expanding markets, conquering space, and building institutions. The only mention of human involvement is of population as a factor of production. Jansma and Goode merely assumed an upward sloping labor supply curve and then made it operational. Morgan emphasized the necessity of studying community decision-making processes, citing as proof the frequently impassible gap between researchers and community leaders, but one is left with the impression that he would like to be able to manipulate community decisions to agree with the researchers' policy proposals. Sorensen and Hartman, from a philosophical and sociological perspective, lamented the loss of sense of community in rural America which they believe is a result of centralized organizational structures. They criticized economic research for its emphasis on control of variables and faulted the social system and the disciplinary training of researchers for the fact that "no longer is primary attention given to determining the needs of people or to measuring the effectiveness in meeting those needs" (p. 935). A few years earlier Bawden's invited address on "The Neglected Human Factor" had merely pointed out the need to consider who will benefit from a program and the fact that average measures of income do not reflect inequalities; he acknowledged neither human involvement nor the possibility of goals other than income and employment.

These papers implicitly assume that income is a suitable proxy for quality of life. However, quality of life is not equivalent to income, much less to aggregate income without regard

Barbara J. Redman is an assistant professor in the Department of Agricultural Economics, University of Gerogia.

to its distribution. Poverty programs which dictate how government aid should be used have frequently "failed" in their objectives because the social worker's utility function is not the same as the welfare recipient's utility function. Government planners should have paid more attention to the indifference-curve analysis of matching versus unconditional grants.

The psychological and social needs and values of a community should be considered, especially the needs the community, not the planner, feels are important. (There are, to be sure, problems of establishing a community utility function.) Not all communities have the same values; studies show not only that rural values differ from urban values, but that farm values differ from rural nonfarm values (Larson). In addition to pointing out the need for individual community analysis, this demonstrates that as the rural nonfarm sector becomes more important (Beale), the equation of rural development policy with farm policy which has often been made in the past becomes more and more tenuous.

The importance of human values becomes especially evident when economically feasible new programs are introduced. For example, a county whose citizens voted to go legally dry may not welcome the advent of a distillery. One need not go to such an extreme example; cases frequently arise where a value for a quiet small-town existence is strong enough to veto industrial development. In his discussion of the implications of the rural population turnaround, Deavers mentioned that traditional community values and individual lifestyles can pose problems for adjustment to economic growth. In the development of its farm policies and programs, Congress has often been confronted with the conflict between values associated with small family farms and the greater efficiency thought to be associated with large-scale commercial operations. Given such values, researchers should realize that pursuit of the objective of rural development by economic measures need not maximize community satisfaction and may even decrease it. For example, the majority of rural white male suicides are those who have urban-oriented occupations and attitudes (Segal). Neither should researchers disparage the community if it rejects their advice (Sorensen and Hartman).

Harman, Eidman, Hatch, and Claypool, in a positive step, attempted to determine which among eight possible goals had highest and lowest priority for farmers, by the method of paired comparisons. This type of investigation, both in its purpose and in its methodology borrowed from psychology, should be encouraged as a check on whether economic research is seeking to maximize the proper objectives.

The importance of community attitudes to the success of a program has been demonstrated in the rural programs of the National Institute of Mental Health (Segal). Mental health is a particularly touchy area, because of age-old prejudice against the mentally ill and the stigma that is often attached to those utilizing mental health services. The success of these services is thus directly related to the attitude of the rural population toward mental illness and mental health services. Fortunately for its programs, the NIMH received encouraging responses in its preliminary surveys of attitudes. These attitudes also have become more positive in recent years.

Another area in which values affect economic performance is that of religious outlook. For example, Weller found that the people of Eastern Kentucky carry strong values for traditionalism, individualism, fatalism, immediate as opposed to long-term action, stoicism, and personal as opposed to object relationships. These values, but especially those of traditionalism and fatalism, impede implementation of many rural development programs. Redman has demonstrated (1979, 1980) that the area's religious history not only implies these personal characteristics which, according to Weller, then affect regional development, but that conservative versus liberal religious outlook affects the time and money an individual devotes to religious relative to secular market activities. The effort devoted to secular market activities is directly related to effort devoted to economic improvement.

In addition to having preferences among two or more goals, the community will perceive costs to each. These costs need not be identical with monetary costs. Morgan and Deaton investigated the psychic costs to workers of employment in a particular city, and concluded that migration did not always respond to monetary wage differentials. The psychic costs were significantly related to family earned income and satisfaction with social relationships. Satisfaction with new social and physical surroundings was more impor-

nt than satisfaction with work in the city for e successful adjustment of rural-to-urban igrants (Deaton, Morgan, and Anschel), hich again indicates the need to consider oneconomic factors. Schaller (1972) recogized that a tradeoff often exists in practice etween the possibilities of improving ecoomic versus noneconomic well-being. The ommunity must then choose between them, ased on its preferences. The rural population urnaround and the increased congruence of ocation with original preference of lifestyle, in pite of the general belief that urban areas ffer greater economic well-being (Dillman), uggests that noneconomic well-being carries ncreasing weight in locational decisions. eavers is concerned with maintaining the pportunity for choice among a variety of ural lifestyles. This is a refreshing and valuble focus in research and policy formulation, nd should be continued.

One further point concerns an input into the conomic development program, the develpment of people. Traditionally, economists ave dealt with the use and augmentation of hysical resources. In rural development especially, human resources must have at least qual importance. Economists have in recent ears begun to estimate the effects of education and physical and mental health on human apital and therefore on income and productivy (for example, Fein, Levine and Levine). s Cornman suggests, health and education re national policy goals which for rural areas ay need particular delivery strategies. Some fforts in this direction have been made, such s Daberkow and King's study of emergency edical service; these efforts should be connued.

uantification of Arguments

conomists have also often used biased estiates of even the traditional economic varibles. Consider as examples the frequently sed concepts of efficiency in farming and rofitability as an indicator of efficiency. Agcultural economists have often pointed to the crease in farm output per labor hour emloyed in farming as an indicator of increased rm efficiency. Even if one accepts this as an ppropriate concept (and Perelman questions because it is a measure of an average rather an marginal product), it is misleading in that does not include the nonfarm agribusiness sector which has greatly expanded in recent years. "Although only 4.5% of the U.S. population works on farms, another 5% is engaged in producing supplies, and another 10% is employed in processing the food and bringing it to the consumer" (Perelman, p. 66). The 4.5% presently employed on farms represents a steady decline from 30.1% in 1920 and 24.9% in 1930 (Perelman), but the inclusion of the expanding farm supply, processing, and distribution sectors considerably lessens the impact of these figures. If the total percentage of U.S. population in agriculture has declined, it has not declined by startling proportions. The real question is whether society has benefited by the replacement of farm labor by capital equipment. While mechanization has been the major emphasis of research, it also consumes much energy, with which society is only now beginning to be concerned. The question of effects of energy prices on factor combinations in farming and manufacturing industries can be added to Cornman's question of effects on industry location in rural versus urban areas. Both carry implications for rural employment and income.

Profitability, too, can be deceptive; it often is used as an indication of efficiency. However, measures of profitability usually have not excluded the effects of government legislation. Tax shelters and loopholes and farm subsidies (as proportionate to farm sales) favor large farmers; pecuniary economies of scale exist in acquiring inputs and financial capital. Further, Hightower's by-now-famous critique of the land-grant university system indicates that agricultural research is designed to aid large farmers and agribusiness, not small farmers. Schaller (1978) holds that national farm policies overwhelmingly tend to be commercial-farm policies. The built-in advantages which large farms face in the American economic systems should lessen the conviction that profitability is necessarily proportionate to inherent technical efficiency.

While these criticisms refer primarily to rural farm development research, rural nonfarm development research also suffers from errors in quantification. A particular vulnerability of this type of research is selection of appropriate proxy variables. Unfamiliarity with the local culture as well as data limitations can result in inadequate or inappropriate proxies for the social and psychological benefits received from a program; for example, in one study the number of movies and

ballgames attended served as a measure of Southern Appalachian mountain recreation, human resource development, and cultural isolation (Smith, Wilkinson, Anschel).

What Has the Past Trend Implied for Human Satisfaction?

As the present system favors big farms, so does the trend. The number of farms has steadily decreased since 1930, and average farm acreage has steadily increased. Rural industry only recently has begun to have prominence. What effect does this trend have on rural development and human satisfaction?

The major observable effect, at least until recently, has been labor migration away from the farms and rural communities, motivated by employment opportunities. This trend has been mitigated by some recent government and industry efforts to locate more industry in rural areas, which raises the problem of possible clashes of values discussed above but which at the same time makes it easier for a person to choose a preferred rural lifestyle. Out-migration creates adjustment problems for ex-farm workers, who traditionally have received little or no help in retraining or relocation. Migration to the cities due merely to economic inability to stay on the farm or in the rural community generally does little to maximize the individual's utility function (Deaton, Morgan, Anschel).

Problems also may arise for those who remain, whether on the larger mechanized farms or in new industry. The Marxian analysis of alienation (Elliott) may provide some insight here. Marx's basic premise is that creative, purposeful work is an important differentiating quality of the human from the animal species, and a person thus finds self-fulfillment in productive activity. However, a person tends to objectify what he or she produces and in time comes to see the product as something not only alien but also as taking on an existence of its own and controlling the producer's life. A contemporary analogy would be a successful businessperson's complaint that he or she is on a treadmill and unable to get off. The more specialization and mechanization, the less fulfillment and the more alienation, because the worker is more distant from the product of labor and cannot take particular pride in its production. Because labor is part of the essence of being human, the individual also feels alienated from himself or herself an from the rest of humanity. Current findings o the lack of job satisfaction in assembly-lin types of jobs suggest that Marx's analysis o alienation has some relevance to job satisfac tion, which in turn relates to the individual' perception of own well-being and quality o life. This, however, may be classified as a addition to Cornman's list of national issue with implications for rural communities rathe than as a particularly rural issue.

Alienation and the counter-struggle to retai one's humanity have been recurrent themes i American culture in the last two decades. I addition to Marx's view, psychologists hav suggested other theories on what is distinc tively human about humans as a species. Fc Freud, it is the prolonged period of childhoo dependence and narcissism which is then ab ruptly attacked by the outside world; fc Fromm, it is the search for love; for Frank the search for meaning in life; for existen tialists, the anxiety created by the polarity c freedom and the finitude of choices which ca be made. Maslow's hierarchy of needs, whic has a highest need of self-actualization (sel fulfillment), bears some resemblance t Marx's analysis. While theories and te minologies vary, most psychologists agre that nonacknowledgement of any major part c a person's psyche is unhealthy for the persor Freud and Jung particularly emphasize this All this seems to suggest that the increasin specialization associated with increased siz of operation and increased mechanizatior with the resulting depersonalization of th work and the emphasis on only a few particu lar needs and skills, may not be best fo the humans involved in targeted developmer areas even if technical efficiency is best serve by it. Although a certain degree of alienatio cannot be avoided, it could perhaps be re duced by careful planning.

This returns to the earlier question of argu ments in the development objective functior The first part of this paper pointed out th need to respect the community's wishes an values if community satisfaction (and not th developer's satisfaction) is to be maximized psychology, which should be added to Dea vers' list of social sciences, has much to cor tribute in determination of preferences. Th second part of this paper called into questio the reliability of the conventional measurin concepts of the conventional arguments. Bu finally, even if one initially ignores the com

nunity utility function, one is forced by the onsequences of industrialization and expanion to acknowledge negative consequences to he humans involved. While in Marxian analyis this is inevitable in all capitalist society, ne could perhaps mitigate some of the effects f one made appropriate provision for human alues at the outset. This reinforces the first ontention that rural developers should place nore emphasis on the noneconomic values of heir clientele.

s Correction of Past Errors Worth the Effort?

'he above analysis has omitted one important uestion: Is the whole effort worthwhile? Schaler (1978) suggests that it is not at all clear how nuch of the improvement in the well-being of ural people over time is due to rural development policy and how much is due to national conomic conditions. For example, he proposes that the rural population turnaround has nly been enhanced by development programs nstead of caused by them. Other factors acilitating rural in-migration include social ecurity retirement payments, increasing rural wareness of urban problems, and more limed urban employment opportunities. If in ict it is largely coincidental that programs to ncourage industry location in rural areas apeared at the same time as the population turnround, why spend the taxpayers' money on iese programs?

Cornman's paper approaches this viewpoint recommending a national development poly with location-specific delivery programs ther than an urban versus rural development olicy. Either alternative would keep domes- development economists gainfully emoyed. No profession would advocate curilment of its own sphere of employment, and e certainly should not expect this of econoists, in spite of the economic arguments for locative efficiency. However, one can safely lvocate research to determine the most efctive focus of research activity. If national onomic conditions are indeed the critical ctors in rural well-being, one may still ask s did Smith, Wilkinson, and Anschel) hether alterations in the rural infrastructure ould enhance or retard transmission (and so, considering the current state of the econny, whether improved transmission is desirle). One also may extend the suggestions ade in the earlier part of this paper to naonal development policy.

It is, admittedly, more difficult to correct deficiencies than to continue as is. The methodological suggestions are particularly difficult to implement because they require much primary data and, for many researchers, a reorientation in thinking. If specific development programs are to be continued, however, these deficiencies must be remedied. Still open for research is the broader question of allocation of economists' and taxpayers' resources; that is, are rural development programs per se worth their expense?

The Role of Economic Analysis in Futures Market Regulation

Anne E. Peck

The history of regulation of commodity futures markets manifests persistent concern over "excessive speculation." The phrase is found repeatedly in the hearings leading to the earliest federal statute—the Grain Futures Act of 1922—and it reappears in each subsequent revision of the statute, including the two major ones, the Commodity Exchange Act of 1936 and the Commodity Futures Trading Act of 1974 (Cowing, Rainbolt). A substantial revision in the Commodity Exchange Act in 1968 was also largely an outgrowth of the notorious vegetable oil swindle of 1963. The phrase "excessive speculation" has not been defined, much less quantified, in the statutes, even though the phrase is used specifically to justify the creation of limits on speculative positions. The economic literature has recognized the need for and importance of speculation and even has provided evidence of speculative inadequacy as a chronic affliction of some futures markets (Gray 1960, 1967). A major effort to fill the definitional void was Working's construction of a speculative index (1960). Whereas the term "excessive" is employed in the pejorative sense in the congressional deliberations, Working simply undertook to use market statistics to describe the relationship between hedging and speculation. His research led to a measure, the speculative index, which reflects the extent by which the level of speculation exceeds the minimum necessary to absorb long and short hedging, recognizing that long and short hedging positions could not always be expected to offset each other even in markets where these positions were of comparable magnitudes. Speculation above the minimum defined by the index was not defined simultaneously as excessive. Indeed, in some markets whose performance is demonstrably hampered by speculative inadequacy, the level of speculation exceeds that minimum.

It is important in any effort to arrive at a definition of "excessive speculation" to keep market performance criteria in mind, and to distinguish between characteristic levels of speculation in different markets over time and episodic flurries of speculation in a particular market which may reflect underlying fundamentals but which may otherwise suggest price distortion or price manipulation. Market regulation, whether at the exchange or government level, is concerned with preventing abuses and has its focus upon particular episodes or crises. The economist, while remaining cognizant of the potential for abuse, needs to try to understand why levels of speculation vary so widely across markets as a continuing phenomenon, and how market performance may be related to such variation. As but one example, data presented in this paper will confirm that the pork belly futures market is much more speculative than the wheat futures market, yet speculative abuse (or the threat of abuse) has been charged several times in recent years in wheat futures and not in pork belly futures.

This paper does not directly address the questions of episodic market distortion or manipulation, although economic research has its bearing on these problems too. Rather, what is undertaken here is an assessment of the speculative character of selected markets with particular reference to the impact of changed hedging requirements upon the speculative component in recent years. The overall market performance issue will then be revisited in the context of the three wheat futures markets, and the caveat will be reiterated that less speculation does not make for better markets.

The author is an associate professor, Food Research Institute, Stanford University.

Comments by Tom Hieronymus on an earlier paper stimulated the research reported here and comments by Roger Gray on an earlier version of this paper clarified these arguments. Their assistance is gratefully acknowledged.

Measures of Speculation on Eight Futures Markets

Estimates of speculation and hedging participation in most futures markets are available monthly from the Commodity Futures Trading Commission (CFTC) *Commitments of Traders* reports. There, participants are categorized, first, as large or small (reporting or nonreporting) traders, and then the positions of the large traders are identified as speculative, spreading, or hedging. The small traders are not further classified; hence, depending upon the relative size of this group, descriptions of the market based upon these data vary in accuracy. The data do reveal basic trends in market composition. In the major agricultural markets, reported hedging has grown much more rapidly than the growth in the total market activity. In the two decades prior to 1972, long hedging in the wheat markets accounted for 23% of the open interest, and short hedging accounted for 45%. Since 1972, short hedging averaged 61% of the open interest and long hedging was 65%. Similar growth in hedging use of futures market is apparent in the corn and soybean markets, and some evidence of the extent of changes in the composition of the open interest on these markets is provided by the data on reported hedging ("long" and "short") in table 1. An earlier paper describes the changes in market use evidenced by the numbers reported here in more detail and examines the relationship between hedging use and total market use (Peck).

Not only has the hedging component in these markets grown, but the balance between long and short hedging has become closer. Balanced long and short hedging might suggest that speculators are not needed in a market, long hedgers would offset the positions of short hedgers. One measure of the speculative character of a market uses this notion, being the speculation exceeding that required to offset any unbalanced hedging. With nearly balanced hedging, this measure would be infinitely large and would imply that markets are highly speculative. The difficulty with the net hedging concept is that individual hedgers are rarely so alike as to size and timing of their positions and as to specific delivery months to be used, that only occasionally will long and short hedging positions offset each other.

Illustration of the problem is provided in the commitments data by the separation of positions into those held in "old crop" and "other" futures. On 31 January 1978 (when "old" and "other" divide the wheat crop year and the total positions roughly in half), reporting hedgers in Chicago wheat held 110.0 million bushels long and 114.8 million bushels short, for a net short futures position of 4.8 million bushels. In this situation, minimum required speculation could be defined as a 4.8 million bushel long position. However, hedgers' positions in "old" crop futures (March and May options) were net short 7.9 million bushels and were net long 3.1 million bushels in the "other" options (July, September, and December). Thus, a measure of the speculative requirement of the 31 January 1978 Chicago wheat market ought to reflect that both long and short speculation was required to offset the net short position of hedgers.

As the balance becomes closer and the hedging component grows within a market's total composition, the likelihood of direct offset increases, but it remains uncertain. Working's speculative index (T), was constructed with the differing needs of long and short hedgers in mind. It was derived from the analysis of the relationship between long relative to short hedging and long speculation relative to short hedging. In effect, the index measures shifts in the relationship between these two variables, measuring the excess speculation over that required to offset both the long and short hedging on a market.

The difficulty in calculating Working's index, or any index, is that the positions of the small traders must be assigned as either speculative or hedging. As there is no one right way to make the assignment, two alternatives are used here. A common assumption in using these data is that most small traders are speculators. It is convenient to extend this assumption here to say that all small traders are speculators. This provides an upper bound estimate of the speculative index. A second estimate results from allocating the small positions as speculative or hedging. In a variant of the procedure suggested by Larson's work and developed by Rutledge, the distribution of hedging and speculative positions from the historic full market survey reports are used to classify the monthly, nonreporting data into its appropriate category.[1] As with Rutledge's re-

[1] Rutledge's method, when applied to current data, often resulted in negative hedging of speculative positions, reflecting the significant changes in market composition which have occurred since the period when the market surveys were taken. Rutledge'

1978	1.125 (0.034)	1.494 (0.179)	n.a.	30.9	33.4	29.9	11.0

Note: Based on data from Commodity Futures Trading Commission, "Commitments of Traders," monthly (formerly available in USDA "Annual Summary of Commodity Futures Statistics").

[a] The periods for wheat, corn, soybeans, and Maine potatoes are crop years and the indicated year is the year of the harvest. All wheat is the sum of positions in Chicago, Kansas City, and Minneapolis.

[b] Working's speculative index $= 1 + \frac{SS}{HS + HL}$, when $HS \geq HL$,

$$= 1 + \frac{SL}{HS + HL}, \text{ when } HL > HS,$$

where HS and HL are total short and long hedging and SS and SL are total short and long speculation. All unmatched reported spreading was assigned as speculation. The difference between the lower and upper bound estimates is described in the text. Standard deviations appear in parentheses.

[c] See text for a discussion of the limits reported here. Figures in parentheses are limits as a percentage of the average open interest.

sults; the allocation model used here showed a positive relationship between the percentage of nonreporting positions which are hedging and the percentage of open interest which is reported hedging. When applied to current data from the major agricultural markets and their large hedging percentages, this procedure allocated the majority of the nonreporting positions to hedging. Hence, hedging is probably overstated and the speculative index calculated from these allocations generally provides lower bound estimates of the speculative character of the market. Both upper and lower

allocation model was reestimated with logs of ratios of the percentage distributions as dependent variables and the same set of independent variables. The estimated percentages are thus constrained to the (0, 1) interval.

bound estimates of the speculative index are reported in table 1.

The examined markets include wheat, corn, soybeans, pork bellies, live cattle, Maine potatoes, 90-day treasury bills, and GNMA mortgages. The commodities encompass a variety of production and marketing attributes, including storable grains, nonstorable and continuously produced products, and government-secured debts. These markets also reflect a range of speculative and hedging participation as reflected in the estimates of the speculative index and the average percentages of the open interest which are reported long and short hedging. Also included in table 1 are measures of offset hedging and balanced hedging, based on the reported hedging data only. "Offset hedging" is simply the smaller of short or long hedging, which defines the maximum amount of hedging which could be offset by other hedging. It measures the amount of hedging in a market which is mathematically balanced, ignoring the kinds of differences in long and short hedging requirements noted above. "Balanced hedging," on the other hand, takes account of the likelihood that hedging would be offsetting, given the speculative character of the market and the total amounts of long and short hedging. It is derived from Working's index. Balanced and offset hedging are calculated only for the case when all small positions are assumed to be speculative to enable direct comparisons between reported positions and the two measures of hedging balance.

The upper bound estimates of the speculative index range from 9.0 for pork bellies to 1.2 for corn and wheat in the 1972–77 period, while the lower bound estimates range from only 3.7 to 1.0. As T cannot be less than one—there must be enough speculation to offset the unbalanced hedging positions—these averages are remarkably low. Interestingly, if the results for the pork belly market are ignored, then the two financial markets represent both ends of the speculative spectrum and are not dissimilar from the agricultural markets. Under both the upper and lower bound estimates, the treasury bill futures market appears to be twice as speculative as the GNMA market. This difference is mostly illusory and reflects the difficulties of intercommodity comparisons based on the reported positions data and of the accepted procedures for apportioning small positions as hedging and speculation. Reporting requirements in the two markets are identical at twenty-five contracts. Thus, a position in treasury bill futures representing $25 million is reportable, while one of only $2.5 is reportable in GNMAs. Data from the first full market survey showed total hedging of similar proportions on both markets (Hobson). A more recent survey shows total hedging in treasury bills to have been nearly twice that on the GNMA market, a reversal of the average reported hedging results (Jaffe and Hobson). Using the allocation procedure does not alter the basic result since small trader hedging is positively correlated with reported hedging and no adjustment is made in the procedure for differences among commodities as to reporting requirements.[2]

Though the sample is quite small for these two markets (twelve observations), the results were retained to provide comparisons with the agricultural markets and to highlight the need for more careful attention to the question of reporting requirements and its effects on the description of a market provided by the positions data. Research is needed to create a better allocation scheme, one which would correct for deficiencies in the data and not exacerbate them.

Among the agricultural commodities, two distinct groups of commodities emerge, using either the upper or lower bound estimates. The wheat, corn, and soybean markets are characterized by very low relative levels of speculation. Maine potatoes, live cattle, and pork belly markets have considerably more speculation, with the belly market nearly twice as speculative as the other two. The dichotomy is especially strong if the 1972–77 indices for three major markets are used in the comparison. Speculation in contemporary wheat, corn, and soybean markets is barely adequate, while that in the cattle, pork belly, and potato markets is somewhat greater.

Coincidentally, these groups of commodities are dichotomous in the levels of speculative limits which have been established. Corn, wheat, and soybean limits, set by the CFTC, are currently at 3 million bushels. While the limits in the corn and soybean markets have been at 3 million bushels since 1971 (the entire 1972–77 period), that in wheat was increased

[2] Both Rutledge and Larson included shifter variables in their equations for the different commodities included in the full market surveys, but these were not significant and were excluded in the final estimates. Also, the financial market surveys were not included in either Rutledge's or Larson's work and were hence excluded in the estimates used here.

to 3 million only in August 1976. For the bulk of the 1972–77 period, a limit of 2 million bushels applied, and this is shown as the limit in column 3 of table 1. The limits for all these commodities averaged less than 1% of the open interest, irrespective of which limit is used for the wheat market. Limits on speculative positions in potatoes were established by the CEA in 1964, those for cattle and pork bellies are set by an exchange, and speculative positions in cattle are limited by maturity but not as an overall position. These limits are significantly greater percentages of open interest than in the three major markets, averaging more than 2% of their respective open interests.

These data call into question the adequacy of Commission review and evaluation procedures for the establishment of limits. Further, they suggest some intriguing possibilities for intercommodity, market performance research. Are there measurable differences in price behavior between markets with minimal speculation and those with larger amounts? Would these comparisons lead to an estimate of a desired level or even an adequate level of speculation? Speculation in the wheat market with an index of 1.04 (1.18 upper bound) may be inadequate and pork bellies at 3.66 (9.0 upper bound) may be more than adequate from the point of view of optimal market performance. The contrast between pork bellies and potatoes is also intriguing. The limits generally are more restrictive in bellies than in potatoes, yet the speculative index for bellies is larger, suggesting that more than the absolute size of the open interest needs to be considered in establishing limits.

The need for market performance research is emphasized by the significant historical changes within the corn, wheat, and soybean markets. In the decades of the 1950s and 1960s, these markets would hardly have been characterized as speculative. The soybean market, with the least amount of continuous government control, was the most active market and the speculative index was greatest. For all three markets, the speculative index has significantly decreased in the post-1972 period, the period in which these markets have been characterized as being speculative. In reality, speculation was barely adequate on average. A related fact, documented by Gray (1979), is that, far from causing the explosive price increases of 1973–74, speculation, which was net short over the period of the price rise, obviously helped to contain it. The general inadequacy of speculation on these markets is further suggested by the extreme daily price moves; soybean futures prices, for example, frequently touched upper and lower limits on the same day. These and other market performance issues need to be considered in conjunction with the obvious constraints on speculation in the three markets. Such research might lead to speculative limits more responsive to the needs of markets.

Speculation on the Three Wheat Markets

The speculative indices for wheat, reported in table 1, were based on aggregate positions in all three wheat markets, Kansas City, Chicago, and Minneapolis. Minneapolis and especially Kansas City are preferred hedging markets for the hard wheats. They specify delivery of spring and hard winter wheats, respectively, in locations desirable for many hedging purposes. In the 1972–77 period reported long hedging averaged 87% of the open interest and short hedging averaged 86% in Kansas City. The comparable percentages in Minneapolis were 82% and 81%. Hedging in the Chicago market, on the other hand, averaged only 45% of the long open interest and 52% on the short side. The average month-end open interests were 194.7, 87.6, and 27.1 million bushels on the Chicago, Kansas City, and Minneapolis markets, respectively. Thus, while more important in the composition of the Kansas City and Minneapolis markets, aggregate hedging positions are largest in Chicago.

Estimates of the speculative index and the extent to which hedging may be viewed as offsetting or balancing are reported in table 2 for the separate markets. In the pre-1972 period, Chicago was the most speculative of the three markets. In this period, the indices show there was some speculation at the Kansas City and Minneapolis markets above that minimally required to offset hedges. Previous research documented that a significant portion of speculation at Kansas City and Minneapolis was from traders who were willing to assume positions in those markets only when they simultaneously assumed offsetting positions in Chicago. Gray (1967) showed that the net positions of the reported spread traders showed a close correspondence to the net positions of the reported hedgers at both Kansas City and

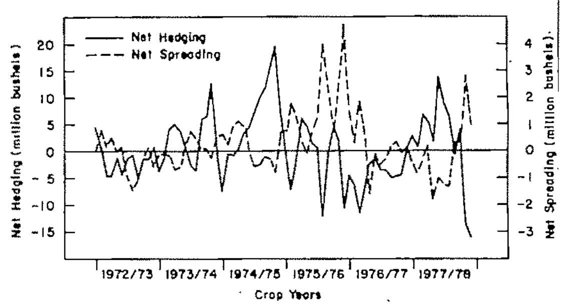
Minneapolis. This unbalanced spreading was in fact speculation from Chicago. The subsidiary markets survived only because necessary speculation could be transfused from another market.

In the post-1972 period, the speculative indices on all three markets have decreased significantly, in spite of tremendous growth in each of the markets. The indices for Kansas City and Minneapolis are negligibly greater than minimal values. Significantly, the index at Chicago also has decreased to a value close to that of the two subsidiary markets in the earlier period. The Kansas City market is of particular interest in these comparisons, and the relationship between hedging and net spreading at Kansas City in the post-1972 period is shown in figure 1. As with Gray's results, there is clearly a close inverse relationship with net spreading and net hedging. The significant difference from his earlier results is the magnitude of the response of spreaders to changes in net hedging. In the earlier period, the unbalanced spread positions were of the same order of magnitude as net hedging positions. More recently, changes in the net spread positions are approximately one-fifth those of the net hedge positions. The explanation of this change is most likely tripartite. First, Kansas City may have grown enough in the recent period to attract nearly sufficient speculation, thereby becoming less reliant upon Chicago for its needs. Second, the significant decline in speculation relative to hedging needs in Chicago suggests there is little remaining "excess" speculation in Chicago to respond to the needs of the subsidiary market. Third, the aforementioned closer balance between short and long hedging provides more offsetting hedging. Kansas City continues to suffer from a lack of speculation, though the deficit is smaller now than in the past. In fact, all three wheat markets appear to have inadequate speculation.

In light of these results, a recent statement (Stone, p. 56) by the current chairman of the CFTC, who said, "Relatively few markets fit



Note: Based on data from CFTC, "Commitments of Traders," monthly.

Figure 1. Hedging—spreading relationship in Kansas City wheat futures, monthly 1972–77

the textbook description of a futures market: one in which most of the business is commercially oriented, with just enough speculation to provide the lubrication the system needs. One that does, for example, is the Kansas City wheat market . . ." can only be termed astonishing. Speculation at Kansas City is manifestly inadequate—an inadequacy which is apparent every day is spreading to Chicago. And while the spreading manifests the inadequacy, it does not measure it—its true measure would require knowing how much more price sacrifice would be entailed in placing a trade at Kansas City absent the Chicago spread opportunity, in addition to the price sacrifice already encountered in the presence of the spread opportunity. If Chairman Stone finds so inadequate a market as that for Kansas City wheat to be so nearly ideal, why does he not exhume the markets for bran and shorts, which died there for lack of speculation?

Conclusion

The role of speculation in commodity futures markets is perhaps the least well understood economic activity. Its existence has been the source of much regulation, its abuses serve only to focus attention on our ignorance. The data assembled here attempt merely to refocus attention, providing a view of the speculative composition of a variety of markets. These data confirm the inadequacy of speculation on the tributary wheat markets and suggest its inadequacy in wheat, corn, and soybeans generally. Coincidentally, speculation was most inadequate on those markets with the most restrictive position limits.

The diversity in speculative composition among markets suggests a variety of interesting, useful research needs. Are there detectable differences in price behavior among markets with significantly different speculative components or within markets where relative speculation has changed significantly over time? Is price behavior measurably different in the Kansas City wheat market, with its still inadequate speculation, than in Chicago? Has this difference changed over time? In markets characterized by barely adequate speculation and hence low speculative indices, much hedging is required to be balancing, more than might be expected on a well-functioning, liquid market. Are the costs of hedging higher on these markets? Have higher costs altered significantly hedger's use of the markets?

Analysis of these market performance issues has not been attempted. Rather, the analysis documents pronounced differences in speculative adequacy among a variety of futures markets. That market performance research is needed is clear. Economic analysis which focused upon these questions could contribute both to our inadequate knowledge and, hopefully, to enlightened regulation.

Inventive Activity in Futures Markets: A Case Study of the Development of the First Interest Rate Futures Market

Richard L. Sandor and Howard Sosin

The GNMA Futures contract that began trading in 1975, and the one that trades today, retains much of the character of an agricultural commodity futures contract. That is, it carefully balances the diverse interests of cash and futures market participants and the diverse interests of potential longs and shorts. Alternatively stated, the key considerations in designing this contract were a desire to obtain active participation of floor traders along with the desire to encourage use by the trade. Participation by these parties ensures liquidity, helps to provide an inexpensive hedging vehicle, and guarantees convergence between cash and futures prices.

This paper traces the development of the GNMA Futures contract from first draft to final product. The evolution of the provisions of the contract is of interest as it provides insights into the art of contract design and because it provides information that may be useful in evaluating the potential of the more than forty-five proposals for futures contracts that are currently pending at the Commodity Futures Trading Commission. The provisions of the contract that are analyzed include contract size, tick size, daily limit, position limit, and deliverable trade.

In addition to carefully balancing the interests of potential participants, the GNMA contract was designed to reflect the regulatory environment of the time. This paper discusses the role of the Commodity Exchange Authority, the Federal Home Loan Bank Board, the Securities and Exchange Commission, and the Commodity Futures Trading Commission. It describes a draft of a bill that would have given the Federal Home Loan Bank regulatory authority over mortgage futures; the 1974 effort by exchanges, regulators, and individuals to define the word "commodity" to ensure an unambiguous regulatory environment; the approval of the GNMA contract by the CFTC; the effort by the SEC to block trading; and the recent court case concerning the establishment of trading months.

Richard L. Sandor is Director, ContiFinancial and Visiting Professor of Finance, Northwestern University; Howard Sosin is associate professor, Columbia Business School, and Acting Director, Center for the Study of Futures Markets, Columbia University.

Editor's Note: The authors submitted the above abstract in lieu of a paper.

Futures Markets: The Interaction of Economic Analyses and Regulation: Discussion

Gary L. Seevers

Regulatory problems which require a heavy input of economic analysis can be placed in three categories.[1]

The first is the age-old issue of speculation. What are its economic functions? What are the consequences of various amounts and types of speculative activity? Should speculation be regulated and, if so, how? The Peck paper deals with some question in this category.

The second category covers the growth of futures trading, particularly into new commodity areas. Currently, there are numerous regulatory questions that stem from the expansion of trading into "macroeconomic" commodities such as the successful new GNMA contracts discussed in the Sandor-Sosin paper. Specifically, regulators are concerned about the effects of the rapid spread of futures trading in financial futures and the proliferation of essentially identical contracts at different exchanges.

The third category includes various regulatory restrictions on market access and flexibility, such as daily price limits, setting "closing" prices, position limits, as well as controls on foreign traders and computerized trading programs. Neither paper really addresses these more technical issues.

I agree with Peck's concluding statement that "The role of speculation in commodity futures markets is perhaps the least well understood economic activity. Its existence has been the source of much regulation, its abuses serve only to focus attention on our ignorance." As she acknowledges, the paper does not add very much to alleviate our ignorance.

I have three specific comments on the Peck paper. First, using the Working index, she shows that hedging has become more important compared with speculation in the grains complex since the early 1970s. The need to hedge the expanded marketings of grains clearly has been the primary reason for greater activity in grain futures; it is significant that hedging has increased in a relative sense.

Second, the paper distinguishes between markets like pork bellies that have a continuous high level of speculative activity and speculative problems of a temporary character, such as those that have occurred in particular delivery months. Much more could be done to examine various types of speculative activity. Certainly trading activity by the professional "local" trader should be separated from that of the part-time "retail" investor and also from the large investor who may be accumulating sizable positions for long-term investment purposes.

Third, her empirical findings show that speculation is considerably more significant for some commodities than for others. She attributes the low speculation in grains to government-set position limits which have existed since the 1930s. While I agree that limits are low, there is another explanation that she should explore. The commodities with low speculative indexes are commodities that always have a physical inventory to be carried forward. Grains, soybeans, and GNMAs are inventory commodities and for these the prices in deferred delivery months are consistently related to current inventories. In contrast, commodities like livestock products and treasury bills have higher speculative indexes. For these commodities, inventories play a small or minor role, and pricing of deferred months depends mainly on anticipated production and demand rather than on current supplies. Futures markets in noninventory

---

[1] Excluded here are problems that involve the protection of individual investors and users of futures, as well as various types of trading irregularities that do not affect general market performance.

commodities may require more speculation to function, or they may just attract more speculation.

The Sandor-Sosin paper makes the point that those who were involved in designing the GNMA futures contract made good use of their knowledge about agricultural futures. Since the GNMA contract has been successful and has pioneered a new area of futures trading, this is an important by-product of our years of experience with agricultural futures.

However, this paper should have been a case study about how regulation can either deter or expedite an innovative concept. The idea of a futures market in mortgages originated, no doubt, in many places. It was advanced in 1971 when the concept was presented to the Securities and Exchange Commission (SEC), an agency often regarded as the premiere federal regulatory agency. However, the SEC reacted in a negative way and the supporters of the idea considered the prospects for SEC approval to be bleak.

A couple of years later Congress created another independent agency, the Commodity Futures Trading Commision (CFTC), to regulate futures trading and also broadened the scope and extent of regulation. In the process, the legislative history made clear that Congress wanted the CFTC to have exclusive regulatory jurisdiction over all forms of futures trading. Two months after CFTC started its work, in April 1975, the Chicago Board of Trade submitted a GNMA contract for approval; trading began only a few months later in October 1975. Subsequently, various exchanges submitted other interest-rate futures contracts, which eventually were approved by CFTC. Today a brand-new area of futures trading exists that might not exist without a major change in the regulatory structure.

As those who follow futures regulation know, this is not the end of the story. The jurisdictional dispute continues and has been intensified by problems in silver trading that erupted earlier this year. The jurisdictional dispute probably will require further congressional action in order to resolve and clarify the roles of various agencies including the CFTC, the SEC, the Federal Reserve Board, the U.S. Treasury Department, and possibly other agencies such as the Department of Agriculture.

I would say that what Congress helped create could be damaged or even destroyed if Congress were to splinter jurisdiction for the regulation of futures trading among several agencies. And, if this is done for interest-rate futures, it is quite conceivable that agricultural futures could be similarly affected at some point. Quite clearly, the regulation of futures is an unsettled area. The way it is resolved will certainly affect the rate of innovation in futures markets, which is the main point in the Sandor-Sosin paper.

These two papers, seemingly unrelated to each other, deal with aspects of the same general skepticism and misunderstanding that has plagued futures trading for decades. Due to lack of understanding particularly about speculation, as well as periodic abuses and market problems, there is a propensity to add more government regulation. Likewise, lack of understanding of the economic role of futures has kept government agencies from permitting new concepts to proceed. It seems clear that this state of affairs will continue in the foreseeable future.

Futures Markets: The Interaction of Economic Analyses and Regulation: Discussion

Reynold P. Dahl

We commend our speakers for interesting and thought-provoking papers. However, neither focuses clearly on the theme of this session. Peck comes the closest with an analysis of market composition between hedging and speculation. But, this dichotomy has proven to be of limited value in futures market regulation. I fear it also has limited value as a research tool. Sandor and Sosin present a useful historical review of the evolution of the GNMA futures contract, but its regulatory implications are unclear. Futures market regulation continues to be a ballgame in which lawyers are carrying the ball, with economists on the sidelines.

Public criticism of futures markets over the years, as Peck points out, has been heavily concentrated on speculation. Futures markets facilitate speculation and speculation is considered objectionable for two main reasons. First, to many people, speculation is synonymous with price distortion or manipulation. Second, speculation is said to contribute to frequent and unwarranted variability in futures prices as well as in spot prices. These criticisms are long-standing and reflected in the futures market regulatory legislation which mandates the close monitoring and control of speculation through a reporting system and speculative position limits.

Experience has shown, however, that fixed speculative position limits are ineffective regulatory tools. Speculators are not a greater threat to efficient market performance than hedgers whose normal operations often involve large positions in both cash and futures. Efficient futures markets require both hedgers and speculators. The economic distinction between them is more illusory than real.

The real problem, in my view, is that economists have not done a very good job in helping the general public distinguish between speculation and manipulation. The two terms are not synonymous. It is price distortion or manipulation, regardless of its source, that demands more study rather than speculation, per se. What is price distortion or manipulation? How can it be detected? Is it a problem in maturing futures in certain delivery months? What constitutes "orderly markets" and "orderly trading" in the delivery month? Unless reasonable answers to such questions are obtained, I fear we are headed for more rigid government controls on futures trading, which could have deleterious effects on market performance. Proposals to increase margin requirements and place them under government control are examples.

Increased speculative position limits also have been proposed despite their proven ineffectiveness in preventing market abuse. The Commodity Futures Trading Commission (CFTC) has recognized the inefficiency of fixed speculative position limits. The agency has been searching for alternative regulatory tools that would assist it in monitoring possible price distortions that may occur in the delivery month of certain maturing futures due to technical conditions or squeezes. Hence, it proposed the so-called "Twenty-five Percent Rule" on 13 April 1978. This proposed rule provided that no contract market would permit any trader (speculator or hedger) to have a position in excess of 25% of the open interest during the last fifteen days of the delivery month unless the market determined that the holding of such a position is not likely to result in price manipulation or market congestion (Federal Register, p. 15440). This proposal received a cool reception from the markets, who considered it unworkable for a host of reasons.

The CFTC could well have undertaken economic analysis on the possible feasibility and

Reynold P. Dahl is a professor in the Department of Agricultural and Applied Economics, University of Minnesota.

efficacy of such a rule before proposing it. The agency has an important regulatory role to play in the detection and prevention of possible distortions in futures prices. It needs more guidance from economists as to the nature of the problem, if it exists, and how best to deal with it. Heifner also has proposed prescribed limits on traders' positions during the last few weeks of trading in a maturing future. While his proposed limits are similar in intent to the proposed CFTC "Twenty-five Percent Rule," they would be a function of the deliverable supplies rather than the open interest. Such proposals merit more study in the search for workable alternatives to speculative position limits as regulatory tools.

The rules and regulations of all contract markets provide for self-regulation through business conduct committees composed of members assisted by professional staff that are charged with the responsibility of preventing price manipulation. The CFTC also has this responsibility as directed by Congress through legislation. Heifner has articulated what he views as a serious problem in sharing regulatory responsibility between the CFTC and the markets. This stems from different philosophies of regulation as to what constitutes price distortion. Cases have arisen in the past where the CFTC saw a threat of price distortion in a maturing future while the markets found no such evidence and, consequently, no need for emergency action. Similar cases are likely to arise in the future. I agree with his assessment that it is extremely important to establish equitable procedures for dealing with such situations. Again, this calls for better economic information as to what constitutes "price distortion," "orderly markets," and "orderly trading."

Futures contract terms also impinge on market performance and merit continuous economic analysis. In fact, proper contract terms may be more effective in preventing market abuse than any regulatory action after the abuse has occurred. It is in their own best interests for the markets to review continuously the terms of their contracts and alter them when needed to meet changing economic conditions and marketing patterns.

In concluding, I will make several general observations on futures market regulation from the perspective of someone who has served as a public director of a contract market for the past eight years. Congress created the CFTC in 1974 when prices were extremely volatile. To its credit, Congress considered and rejected many specific regulatory restrictions that would have had adverse effects on market performance. But, it did give broad discretionary authority to the new Commission. The implementation of the legislation to date has been disappointing to many. Of course, it takes time to develop effective regulatory policies and procedures. But, an important reason for many confrontations and open conflicts that have developed between the markets and the new Commission is that it has moved forward simultaneously on many perceived regulatory problems without clearly defined priorities. Economic analysis has played only a limited role in defining regulatory priorities.

An efficient system of futures market regulation is in the best interest of both the markets and the general public. More economic analysis is needed to help define regulatory problems and policies. Better working relationships between the markets and the CFTC also are needed for the delineation of the appropriate roles for self-regulation and government regulation of futures markets.

Inflation Effects on Financial Performance and Structure of the Farm Sector

David A. Lins and Marvin Duncan

Inflation is measured as the rate of increase in the general price level. As Samuelson and others point out, the problem with inflation is not so much price increases, but rather the inefficiencies and inequities that result from inflation-induced changes in relative prices. Relative price changes affect supply-demand relationships for both factor and product markets. Changes in these relationships in turn influence the level and distribution of income, asset values, cash flows, debt, net worth, and structural characteristics of farm firms. The objective of this paper is to provide a broad overview of inflation's impact on the financial performance and structure of the farm sector.

Relative Price Changes during Inflation

Correlations between the inflation rate (measured as the percentage change in the Consumer Price Index) and the percentage change in various prices paid and received by farmers give some indication of the relative price changes that can occur during a period of general price inflation. Obviously, factors other than inflation also affect relative prices. Changes in supply-demand relationships probably have the major impact. However, correlations calculated over the 1949–79 period by subperiods and by whether the inflation rate was above or below trend are revealing. Table 1 displays some of the more important correlations.

The percentage change in prices paid on production items is more highly correlated with the rate of inflation than is the percentage change in prices received. The disparity between these correlations has grown in more recent years. Moreover, this suggests that in the short run, a higher inflation rate may be associated with higher prices paid on production items without a corresponding adjustment in prices received. If so, this can lead to greater variability in farm income.

Substantial differences among correlations are evident. For example, during the 1965–79 period, changes in prices received on crops were more highly correlated with inflation than prices received on livestock and livestock products, a reversal from the 1949–64 period. Correlations between the percentage changes in prices received and paid and the inflation rate from the period 1965–79 tend to be lower than for the 1949–64 period. This undoubtedly reflects greater price variability in more recent years. Recent government programs that link price supports and target prices to costs of production may, however, tend to make commodity prices more responsive to inflation affecting costs of production.

An important component in the cost of production is interest expenses. The relationship between nominal interest rates and the inflation rate has an important bearing on financial performance and structure of the agricultural economy. While past evidence shows that interest rates paid by farmers did not move in tandem with national financial market rates, that circumstance is changing. As farm credit markets are more closely linked to national financial markets, interest rates to farm borrowers likely will track financial market rates more closely and exhibit greater variability than has previously existed.

Effects of Inflation on Financial Performance

Inflation has differing long-run and short-run impacts on the financial performance of the farm sector. In the short run, inflation may

David A. Lins is an agricultural economist, U.S. Department of Agriculture, and associate professor of agricultural finance, University of Illinois. Marvin Duncan is assistant vice president and economist, Federal Reserve Bank of Kansas City.

contribute to reduced farm income, increased capital gains, reduced liquidity, and greater income instability. In the long run, financial outcomes may not be substantially altered, but firms in the industry may adjust toward those who can best deal with income instability and capture growth opportunities.

While empirical quantification is beyond the scope of this paper, we hypothesize that inflation (*a*) increases the income variability associated with agricultural production activities; (*b*) affects farm income more in the short run than in the long run; (*c*) affects the nominal and real value of assets, especially farm real estate; (*d*) increases the reliance on debt financing; and (*e*) creates cash flow stress for farm firms.

Income Variability

As shown in table 1, farm production costs have been more closely linked with general inflation rates than have prices received by farmers. This circumstance reflects differences in structure between the farm input and farm production sectors of the economy. Input suppliers often operate within a framework of administered prices. Hence, higher inflation translates into higher farm production costs without a necessarily corresponding short-run response in farm prices received. Income variability for the farm firm is thus increased.

Not all segments of farm production are affected equally by inflation. For example, dairy prices, administered through a complex set of milk-marketing orders, respond quickly to inflation. Increased export demand for food grains, oil, seed crops, and cotton has caused the percentage increase in these commodity prices over the past decade to exceed that of the index of prices paid by farmers. In contrast, the prices of meat animals, feed grains, and fruit have not increased as rapidly as production costs. Rising energy costs have affected the income, wealth, and liquidity positions of heavy energy-using farming operations, especially irrigated agriculture. Consequently, inflation has been associated with intrasector variability in the incomes of producers. The use of public policy to dampen this variability has, thus far, met with mixed success. In fact, Schultz argues that adding artificial stability to one segment of the agricultural sector adds instability to other segments of the sector.

Inflation also leads to greater variability in farm income because farm input firms can pass price risks on to farmers. A recent example is in financial markets where a marked shift by lenders toward variable interest rates—either explicitly or *de facto*—has occurred. This, coupled with changes in implementing monetary policies, means that farm borrowers face increased interest rate variability. This increases farmers' financial risks and may cause changes in farm financial structure in response to higher risk.

Level of Income

Because price inflation can result from increases in only a few components of the consumer price index, it is difficult to generalize the impact of inflation on the level of farm income. For example, CPI increases that result from price increases for raw agricultural products could result in improved farm incomes. In contrast, inflation resulting from increased prices of farm inputs could adversely affect farm income.

Tweeten and Quance, however, have shown that there is not a one-to-one correspondence between input price increases and reduced farm revenue. The supply-induced response to higher prices has a tendency to dampen the adverse effects of input price increases. In

Table 1. Correlations between Changes in the Consumer Price Index and Changes in Selected Prices Paid and Received by Farmers

	Percentage Change in Consumer Price Index				
Percentage Change in Index of	1949–79	1949–64	1965–79	Inflation above Trend[a]	Inflation below Trend[a]
Prices paid on production items	.82	.80	.71	.77	.67
Prices received	.48	.77	.19	.32	.36
All crops	.42	.63	.29	.37	.16
Livestock and livestock products	.45	.78	.00	.24	.42

[a] A linear trend line was fit to determine those years in which the inflation rate was above or below trend.

evaluating increases in input prices, Eleveld found that nominal net farm income increased, but real net farm income decreased due to the concurrent rise in the consumer price index. In contrast, Tweeten and Griffin estimated that each percentage point increase in the inflation rate reduces net farm income by $.7 to $2 billion in nominal dollars. On balance, inflation in input prices can reduce net farm income in the short run. But, significantly, inflation in product prices can increase net farm income.

The long-run impact of inflation on farm income is not clear. Ruttan argues that inflation dampens productivity growth. This seems intuitively reasonable, since inflation tends to discourage research and investment with long payback periods—the kind often associated with productivity increases. Milton Friedman suggests that inflation also leads to economic inefficiency because it makes prices a less efficient system in coordinating economic activity. However, we know of no evidence to suggest that the long-run impacts of inflation are any more severe for agriculture than for other sectors of the economy.

Value of Assets

Nominal and real capital gains on farmland have been substantial over the last two decades. Lins has shown that over the 1960–79 period, nominal gains on farmland averaged 9.3% annually, while real gains averaged 4.2%. Over the same period income returns to land grew at an annual rate of 14.8% in nominal terms and 9.7% in real terms, thus exceeding the capital gains rate on land. The implications of these relationships have not been completely reflected by the popular press.

It is commonly agreed that price inflation leads to higher nominal prices for farmland. But does price inflation lead to an increase in the real price of farmland? Reviewing past growth in real prices of farmland during periods of relatively high inflation has led some analysts to answer yes. We contend that the conclusion is misdirected.

Melichar has shown that the growth in the real value of farm real estate is explained by the growth in real income returns to land. It is this growth in real income returns to land that has sparked the growth in real land values. If inflation has an adverse effect on real net cash flows, then inflation likely would lower the real value of farm real estate. The fact that real values of farm real estate increased in the face of substantial inflation does not refute this argument, unless one argues that policy makers either purposely or because of misinformation enacted farm policies which interacted with inflation in the economy to raise real returns to land. This latter explanation seems plausible.

Reliance on Debt Financing

Farm firms have relied increasingly on debt financing to finance the operating inputs and capital assets used in farm production. For example, from 1950 to 1978 the number of farm real estate transfers on which debt was incurred increased from 58% to 89%. Over the same time, debt as a percentage of purchase price increased from 57% to 76% on those debt-financed purchases. Likewise, the proportion of total capital purchases financed with debt capital increased from 17% in 1950 to 50% in 1978 (USDA 1979a).

Because many factors are involved, explicit determination of the impacts of inflation on debt financing is difficult. However, it does appear that inflation has contributed to increased reliance on borrowed funds. Past inflation has contributed to the expectations of continued inflation. In an attempt to obtain the benefits of capital gains, investors are encouraged to "buy now" before the price goes even higher. Lacking the reserves to pay cash, the investor borrows the money. Since total returns (income plus unrealized capital gains) from farm real estate investment have exceeded the cost of borrowing, debt financing of farmland has increased the investor's equity growth.

Cash Flow Stress

There is considerable evidence that the liquidity position of farm firms has decreased over time. For example, Lins has shown that the percentage of liquid assets of farm firms (financial assets and crop and livestock inventories) has decreased relative to fixed assets such as farm real estate and machinery. This may be in response to inflation's impact on relative rates of return to assets held by farmers. Likewise, the ratio of debt outstanding to net cash income has trended upward over time, implying a higher proportion of net farm income must be allocated to debt service. Thus, farmers are increasingly exposed to cash flow stress.

The cash flow stress fueled by inflation is perhaps most readily apparent in the acquisition of farm land. As expected inflation in land values and the net returns to land increase, the price paid for land becomes more a function of expected inflation rather than current returns. Investors who finance the purchase of land with borrowed funds find that the cash returns from the land in the early years are not sufficient to make the loan payments. These deficiencies must be made up from other sources such as financial reserves, nonfarm income, or income from other land. If expectations of inflation increase, this early-year cash flow deficiency in meeting loan payments likely will rise. Conversely, were inflation rates to decline—and rates of increase in returns attributable to land as well—the early-year cash deficiencies could be even more extended.

Effects of Inflation on Structure

Recently, considerable effort has been devoted to studying the structure of U.S. agriculture and the role of public policy in shaping such structure. Three major publications: *Another Revolution in U.S. Farming?*, *Structure Issues of American Agriculture*, and *Farm Structure* have resulted from these efforts. While each publication contains papers which allude to impacts of inflation on U.S. agriculture, researchers have been cautious about ascribing any cause-and-effect relationship. Because empirical testing is difficult, the following should be considered a set of tentative hypotheses about the impacts of inflation on selected elements of the structure of agriculture. We hypothesize that inflation (*a*) leads to fewer and larger farm firms; (*b*) encourages ownership of assets, but makes them more difficult to obtain; (*c*) encourages (with the aid of existing regulations) a move toward a corporate form of business organization; and (*d*) encourages vertical integration and coordination.

Fewer and Larger Farms

Inflation has encouraged the trend toward fewer and larger farms. This is most obvious in the case of farm real estate. Encouraged by past inflation, existing landholders have used their wealth to buy additional land. The purchase of land is most easily accomplished by well-established operators or people with substantial sources of off-farm income.

Both the variability in farm income and the rewards for risk bearing—in the form of higher leverage ratios—are increased by unexpected inflation. Since not all farm sector participants are willing or able to bear such risk, those less averse to risk—and able to bear it—tend to accumulate additional assets. Inflation interacts with numerous other factors in encouraging these kinds of structural change, as well.

Ownership of Assets

The ownership of farm sector assets, especially land, has been desirable because of the favorable growth in real values. Both farm and nonfarm investors have come to view land as a good hedge against inflation. However, present owners tend to retain their land for the same reason. The restricted supply coupled with strong demand has exerted strong upward pressure on land values.

The upward pressure on land values has created a selectivity in who can purchase land. Income returns to current market value of land have averaged about 5% in recent years, while unrealized capital gains have added around 12% annually to land values. The combined average return of around 17% has been favorable relative to the cost of borrowed funds and relative to other investment options. But if a significant portion of the sale price is borrowed with interest rates at 8%–12%, the land being purchased will not generate a sufficient cash flow to make the loan payments. Only those with access to funds generated outside the land being purchased can meet the cash flow requirements. Hence, concentration of land ownership among existing landowners is a logical and economically rational consequence.

Business Organization

Reimund has shown that both the number of farms and the amount of land in farms controlled by firms organized as corporations have increased over time. The move to a corporate form of business organization reflects in part the interaction of inflation with public policies such as federal income and estate taxes.

Inflation and progressive marginal tax rates have resulted in a higher tax burden, i.e., an inflation tax. In response to these higher tax rates, farmers have sought tax reduction strategies. The favorable corporate tax rates have made incorporation an attractive alternative, particularly for farm firms with large taxable

incomes. Moreover, inflation in asset values also has encouraged incorporation of farm firms to facilitate estate planning.

Integration and Coordination

The impact of inflation on integration and coordination of farm input-production-marketing activities is generated primarily through its effect on income variability. To the extent that inflation creates income instability, agricultural firms are likely to seek alternatives for alleviating or reducing such instability. Integrating production-marketing activities, use of the futures markets or cash forward contracts, and greater use of price forecasting services are all methods of reducing such instability. Diversification of farm firm enterprises and developing off-farm income are other alternatives for dealing with income variability. Although data is limited, it does appear that some of these risk-reduction strategies are gaining wider acceptance among farm firms.

Concluding Comments

Inflation influences the financial performance and structure of the farm sector by altering relative prices in factor and product markets. In the short run, income variability is increased because prices paid for production items respond more quickly to inflationary pressures than do prices received. In the long run, inflation alters income by reducing growth in productivity and the pricing efficiency of input and product markets. Yet, many questions about the effects of inflation on agriculture remain unanswered.

Research is needed to determine the inflation-induced changes in relative prices apart from supply-demand-induced changes in relative prices. There is also a need for better information on how inflation affects productivity increases in agriculture, nominal, and real net farm income, and the distribution of income and wealth. Research also is needed to determine inflation's impact on tenure patterns and other structural characteristics of agriculture.

Extension needs also are increased by increasing inflation. There is a need for information to help farmers deal with cash flow stress and other inflation-induced changes in financial conditions. There is also the need to make clear who gains and who loses from inflation. Inflation has also increased the need for extension information on acquisition and intergenerational transfers of capital assets.

Inflation has caused serious problems for the farm sector. But falling inflation rates also would create problems. For example, those who purchased assets expecting increased returns (fueled by inflation) to provide cash flows to service debt could be disappointed. In a less inflationary environment, many farm firms may be excessively leveraged. Finally, less inflation resulting in slower equity growth would leave new entrants or recently expanded businesses vulnerable to the adverse impact of nature-related risks for a longer period of time than if the expected rate of inflation had continued.

Effects of Inflation on Financial Markets and Agricultural Lending Institutions

Danny A. Klinefelter, John B. Penson, Jr., and Donald R. Fraser

Inflation, one of the most misused words in the English language, is defined here as a continuing rise in the average level of prices for real goods and services. The following price changes thus do not constitute inflation: (*a*) a price increase for an individual good or service, (*b*) a once-and-for-all increase in the average level of prices, and (*c*) a temporary increase in the average level of prices. For example, a price increase for an individual good may affect the average price level. But by itself, this price increase is not inflationary since it is self-limiting; either producers will increase their production and hence drive the price down or else consumers will substitute for other goods in response to the higher price.

Inflation of the "steady pace" variety which can be forecasted with little or no error will have one set of effects on an economy. Inflation of the "fits and starts" variety which cannot be forecasted with a reasonably low error will have another set of effects. The generalization that inflation transfers wealth from lenders to borrowers, for example, is not valid if inflation can be forecasted with little or no error and if it can be fully reflected in interest rates. As Balbach points out, however, a monetary policy characterized by frequent changes in the rate of growth of the monetary aggregates will make it harder to forecast inflation, and hence lead to greater wealth transfers from lenders to borrowers than if these aggregates exhibited a stable growth pattern over time.[1]

Inflationary pressures in an economy can occur for a number of well-known reasons. For example, excessive growth in aggregate demand relative to aggregate supply will result in excess demand inflation. The growth in aggregate demand is influenced by macroeconomic policies that affect the growth in the monetary aggregates as well as taxes and government spending. Aggregate supply, however, is influenced more by the availability of labor and capital services than government policies in the short run. Thus, it is no wonder that an examination of the causes of inflation frequently starts with an analysis of recent macroeconomic policies to see if they have been overstimulating aggregate demand. Many analysts, for example, have concluded that excessive monetary expansion in the later 1970s, which had the effect of allowing us to pay for oil imports with cheaper dollars, is one of the major causes of recent inflation.

Having defined inflation and suggested one of its major causes in recent years, our task in this paper is to trace through the effects inflation has upon financial markets and the lenders providing loan funds to agriculture.

Effects of Inflation on Financial Markets

The impact of inflation on financial markets has been enormous. In the short period since 1966, U.S. financial markets have been devastated by periodic episodes of high and unstable rates of inflation. Moreover, with inflation has come high and extremely volatile interest rates that have intensified interest rate risk for participants in financial markets. Cyclical peaks in inflation and interest rates in 1966, 1969, 1974, and 1980 and the monetary and fiscal policy responses to these developments have substantially reduced the efficiency of financial markets. Long-term sources of funds for businesses, consumers, and governments during these periods not only became more expensive, but in many cases were unavailable at a reasonable price. Reflecting the acceleration of their costs, many lenders have recently sought to modify the terms of traditiona

Technical Article No. 16195 of the Texas Agricultural Experiment Station.

[1] This is not without its costs, however. The time spent managing these balances will cause a shift in the utilization of labor away from other activities.

contracts—bonds and mortgages—to protect themselves against declines in the purchasing power of their funds. Moreover, the behavior of financial institutions—the major participants in financial markets—is altered dramatically in an inflationary environment.

The impact of inflation on financial markets stems largely from the inability of market participants to anticipate correctly the rate of inflation over the life of the financial contract. If market participants accurately forecast future rates of inflation, nominal rates would adjust rapidly to changes in expected inflation and the real rate of interest would be constant.[2] The existence of an "efficient market" for information means that changes in expected inflation would neither benefit nor harm lenders and borrowers. However, given the underestimation of inflation rates in recent years, the real rate of interest realized by lenders (the nominal rate less the realized rate of inflation) frequently has been negative, which means that lenders have been subsidizing borrowers. This has led to an intense demand for loan funds and to savers becoming less willing to postpone consumption in order to provide loanable funds to lending institutions.

Reflecting the recent high and unpredictable inflation rates are the changes we have seen in the nature of financial instruments traded in financial markets. Lenders have become increasingly reluctant to subsidize borrowers with long-term fixed-rate contracts. The maturity of bonds and other fixed-income instruments has also been shortened. Moreover, lenders have sought to structure loan contracts where possible so that borrowers share a portion of inflation-induced profits with the lender. Examples of these "equity kickers" include requirements on loans for income-producing property that allow the lender to share in any unexpected increase in rental income from the property in addition to the interest payment. Borrowers also have sought to modify the terms of the traditional contract in response to inflationary trends. For example, at least one company has sought to reduce the interest cost of its borrowing activities by allowing the lender to redeem its bonds in a fixed number of units of a precious metal.

[2] This generalization is complicated by the fact that income taxes are levied on nominal rather than real interest and that a tax deduction is allowed on nominal interest payments rather than real interest payments. Given the present structure of the tax system, an increase in expected inflation would produce an even greater increase in nominal interest rates.

Perhaps the greatest impact of inflation has been on the mortgage market. The traditional long-term fixed rate mortgage has lost its viability in this type of environment. Increasing use has been made of the variable rate loan (Melton and Heidt). The variable rate mortgage, where the rate and/or maturity of the loan is automatically adjusted during the life of the loan, has become very popular in California and is spreading nationwide. In addition, the Canadian roll-over mortgage—rechristened the renegotiable rate mortgage—has been authorized for all federally chartered savings and loan associations. Under this latter type of mortgage contract, the maturity of the loan is short—generally three to five years—and the interest rate is renegotiated when it matures. Undoubtedly, other variants will be devised if inflation and interest rate risk remains high.

These changes have important implications for both borrowers and lenders. In recent years with the traditional fixed rate contracts, lenders accepted interest rate risk and thus suffered as inflation exceeded expectations. With shorter-term variable rate loans (and it is likely that variable rate lending will also come to the bond market), however, lenders are attempting to shift this risk to borrowers. Shorter-term contracts do, of course, substantially increase the need for liquidity management by borrowers. Moreover, they make borrowers more dependent upon lenders since the terms of the financial contracts must be negotiated more often. In addition, these new financial contracts may place a greater strain upon borrowers in periods of rapidly rising interest rates by lowering the expected value and increasing the variability of their investment returns.

Another way in which lenders have responded to the greater volatility of interest rates is by hedging in the financial futures market. It is no accident that trading in futures contracts for U.S. Treasury bills, notes, and bonds as well as commercial paper and Government National Mortgage Association pass-through certificates has developed at the same time that interest rate risk has increased. Indeed, the founding of the interest rate futures market in the early 1970s and its explosive growth in the late 1970s is directly attributable to the greater uncertainty in financial markets (Arar and McCurdy).

Inflation also has had a substantial effect on the nation's equity markets. It is not surprising

that equity prices have shown little gain in nominal terms (and a substantial decline in real terms) since inflation has become more pronounced. Equity values do, of course, represent the discounted present value of expected future cash payments. With inflation and higher interest rates, the applicable rate used to discount future cash flows is higher. Moreover, along with inflation has come greater variability of earnings and dividends. This greater variability, *ceteris paribus*, results in lower share values. In addition, recent data released by major corporations using Financial Accounting Standards Board guidelines for reporting inflation-adjusted financial statements suggest that actual earnings have been well below those reported to shareholders and that many firms have paid out more than their current earnings in cash dividends.

The response of economic stabilization policies to inflation has further implications for the nation's financial markets. As inflation accelerates cyclically, stabilization policy—especially monetary policy—seeks to "lean against the wind" by restricting the availability of credit. Not only do interest rates rise in these periods, but there is also a sharply diminished availability of funds to particular sectors of the economy, like the housing sector and to small businesses in general. Moreover, it is during these periodic "credit crunches" that financial innovations such as money market funds occur that have had such a profound impact on the structure of the U.S. financial system.

Effects on Agricultural Lending Institutions

In addition to affecting financial markets, inflation also affects the lending activities of institutions providing loan funds to agriculture. In examining these effects, we shall separate those factors that affect the demand for loan funds from those factors that affect supply.

Effects on Demand for Loan Funds

The demand for loan funds in agriculture in recent periods of inflation has been affected in several different ways. First, anticipated inflation reflected in higher interest rates charged producers has increased the cost of financing annual production expenses and capital expenditures, thereby lowering nominal net farm income.

Second, the purchasing power of net farm income is lowered in an inflationary environment. And, because net farm income is taxed in nominal rather than real dollars, the current real savings of producers is further reduced.

Third, expectations about future relative prices and interest rates also influence annual investment decisions and hence the demand for loan funds (Fama; Levi and Makin). For example, a producer considering the purchase of a new piece of equipment must form expectations about future cash receipts and expenses as well as the relevant marginal income tax rate. In the case of land, the producer must also form expectations about the capital gains income on this investment and the capital gains tax rate. If relative prices can be forecasted with a reasonably low forecast error, the producer may well rationalize he is better-off going ahead with investment projects now rather than waiting and paying a higher purchase price later. However, higher forecast errors and correspondingly higher risk-adjusted required rates of return may well mean some projects are no longer acceptable.

Fourth, the expectation of future increases in land values has had the positive effect in agriculture of increasing the nominal net worths of those who own land. These unrealized capital gains often collateralize loans to finance short- and intermediate- as well as long-term uses of funds. But, rising debt levels in agriculture, coupled with lower nominal net farm incomes, underscore the increased exposure to financial risk for both borrowers and lenders and the increasing burden placed upon future income to retire debt.

Finally, inflation has brought with it uncertainty about future government policies. This greater uncertainty pertains not only to those policies that address the need for deficiency payments and economic emergency loans to producers in agriculture, but also to those monetary and fiscal policies that affect the cost and availability of loan funds as well as the level of income and social security tax payments (Balbach).

Effects on Supply of Loan Funds

Of the financial institutions providing loan funds to agriculture, commercial banks appear to be the most affected by inflation. This impact is evident in four areas: (*a*) legal lending limits, (*b*) usury ceilings, (*c*) the availability of loan funds, and (*d*) funds management.

The problem of legal lending limits per borrower has increasingly handicapped rural banks in financing producers. The problem is directly related to bank structure and is most constraining in unit banking states. Since legal lending limits are based upon the size of a bank's capital and surplus, increasing farm size and greater use of purchased inputs increasingly cause loan requests to exceed bank legal lending limits. The problem becomes acute in periods of inflation in agriculture because input costs tend to rise faster than product prices, which translates into an increased demand for loan funds and slower loan repayment.

Usury ceilings have created problems for banks in three ways. First, these ceilings tend to divert funds away from areas subject to usury ceilings, which in many states includes loans to farm proprietors. Second, bank profits are reduced, which further decreases the ability of banks to make loans by limiting the growth of their capital and their ability to attract deposits. Third, banks have experienced a loss of market share, particularly to the Farm Credit System and government lending agencies. Banks have had to restrict their loan funds in periods of high rates while their competition has been unconstrained by state usury ceilings. These competitors are also not required to hold a portion of their sources of funds in reserve.

The Monetary Control Act of 1980 overrode state usury laws for agricultural loans exceeding $25,000. However, two problems still exist. First, some farm loans are made that do not exceed this amount. While banks will consolidate a borrower's loans as the total reaches $25,000, some loans initially will be subject to usury ceilings. As a result, smaller producers requiring only operating funds may still find loan funds restricted when market interest rates are increasing. Second, this provision expires on 1 April 1983, or earlier if ceilings are reinstated by the state (American Bankers Association).

Limited availability of loanable funds at banks often reflects the fact that deposits are growing at a slower rate than the demand for loan funds. Although this problem tends to be both regional and cyclical in nature, projection of further increases in the use of debt by producers indicates this problem will persist. Moreover, because of their size and market area, rural banks are not in a position to bid for funds in the national money market. And the growth in the popularity of money market funds has accentuated the drain on deposits in many smaller banks into major money center banks.

To counteract the problem of loan fund availability, banks have been forced to increase their use of correspondent bank and PCA participations, to create agricultural credit corporations which either sell commercial paper or discount loans with Federal Intermediate Credit Banks, and to use bankers acceptances placed through city correspondents. They also have attempted to stem the outflow of deposits by offering money market certificates of deposit. The 17 April 1980 action of the Federal Reserve to make it easier for small banks to utilize the "seasonal borrowing privilege" and the provisions of the Monetary Control Act to allow access to the discount window for nonmember banks are other examples of responses to the shortage of loanable funds at rural banks.

Cyclical fluctuations in market rates on government securities in an inflationary environment also affect bank liquidity by increasing the cost of converting securities into loanable funds to meet loan demand. As interest rates rise and security prices fall, banks would suffer capital losses if they sold these securities to generate loanable funds. The problem of loan fund availability is also compounded by the fact that the higher rates on securities and other investment alternatives often make them more attractive than loans, particularly when usury ceilings and credit restraint programs exist.

Serious funds management problems have been a relatively recent phenomenon for rural banks. Although the introduction of money market certificates has allowed them to stem losses of deposits, the certificates have not produced a net inflow of funds to rural banks. Because the rates on these certificates are tied to new U.S. Treasury issues, many rural banks are for the first time experiencing the problems associated with managing purchased money and reflecting these costs in their loan-pricing and fund allocation decisions. This environment is further aggravated by the phasing out of Regulation Q, the payment of interest on transactions accounts and the fixed interest rates banks have traditionally charged on loans. Now banks find that both costs and revenues are fluctuating, which creates decision situations for a management that is often ill-equipped to handle them. It is not surprising

therefore that there has been a dramatic growth in holding company acquisitions in those states which allow multiple bank holding companies.

In contrast to commercial banks, the Farm Credit System obtains its funds from the national money market and thus far has not been faced with a reduced availability of loanable funds. The cost of these loanable funds, of course, increases as interest rates rise. But, because the Farm Credit System is exempt from state usury laws and uses a variable interest rate program, it is able to pass these increased costs on to their borrowers. Moreover, the Farm Credit System has not been limited by legal restrictions on the size of a loan to any one borrower.

While the Farm Credit System has experienced relatively low levels of delinquency, cyclically increasing inflation rates tend to increase its exposure to risk. To a large extent, farm borrowing has been collateralized by unrealized capital gains stemming from rising land values. Producers have thus been able to refinance short-term debt on a longer-term basis when farm incomes have fallen. As a result, however, the Farm Credit System is more than ever dependent upon land values continuing to appreciate rather than depreciate.

The fastest growing source of loan funds to producers in recent years has been government lending agencies like the Commodity Credit Corporation, the Farmers Home Administration, and the Small Business Administration. The Commodity Credit Corporation, which was not a market factor during the early 1970s, has again become a major source of funds because commodity prices have fallen below loan rates. The nonrecourse provision of these loans, the subsidized nature of their interest rates, and the option to extend the loan on stored commodities has made CCC lending programs increasingly attractive to producers, both from a marketing standpoint as well as a financing standpoint. The fixed rate feature of these loans is also attractive as is the downside price protection provided by the loan rate, the removal of the set-aside provision and the ability of producers to now place their entire crop under loan. Unless market conditions improve dramatically, the CCC loan program will continue to account for an increasing share of the market.

The greatest growth in agricultural loans made by the Farmers Home Administration and Small Business Administration has been in the area of emergency and disaster loans. Because an economic emergency can occur for reasons other than natural disaster (such as a general tightening of credit or unfavorable income levels), monetary policies which raise interest rates and restrain credit in the private sector cause producers to turn to government lending agencies. These emergency loan programs are also not as restrictive in terms of loan limits as are the normal operating and farm ownership loan programs. In some instances, these programs have encouraged production and further capitalization in high risk areas.

The impact of inflation has also been enormous on the other institutional sources of debt financing. Life insurance company loans and merchant-dealer credit virtually stopped during the most recent surge in inflation and interest rates. Since the mid-1960s, the life insurance company share of the farm real estate debt market has declined in each of the cyclical peaks of inflation. As sources of consumer credit shrink and interest rates rise, many policy holders borrow against the loan values of their policies, thereby cutting into life insurance company investable funds. Like commercial banks, usury limits have forced life insurance companies to divert funds to areas where earnings rates are not artificially restricted. The decline in farm incomes and the slowing in the growth rate of farm land prices have tended to make agricultural loans less attractive from a risk standpoint, particularly when better, more stable yields are available on other investments.

Merchant-dealer credit also tends to contract as inflation rates increase. The cost of acquiring loanable funds reduces the profitability of extending credit for the credit subsidiaries of manufacturing firms. Moreover, retailers are forced to tighten their credit policies as the cost of carrying customer accounts increases.

Potential Issues

If the U.S. economy continues to be plagued by periods of high and variable rates of inflation, there will be both enormous impacts on the flow of funds in agriculture and significant research opportunities. For example, what are the structural implications of continued variable inflation rates for the lenders serving ag-

riculture? What about the government lending agencies and the Farm Credit System? Will they be able to accommodate an increasingly larger share of the market? What effect would a policy change that significantly reduced the government's involvement in agricultural lending have upon borrowers and nongovernment lenders? If the Farm Credit System continues to account for larger and larger market shares, will it affect their ability to acquire funds in the nation's financial markets and the cost of these funds?

There are also some significant implications for the commercial banking industry. What are the potential effects on how agriculture is currently financed if the ownership of banks becomes more concentrated in bank holding companies which are headquartered in the major money centers? We must also consider the potential structural effects of interstate banking. Many of these trends are already underway. However, they will probably be accelerated if the instability associated with the current inflation picture continues. There are also other important issues relating to the impacts of the 1980 Monetary Control Act, including how monetary policy is transmitted. Three areas of this Act appear to have a particular impact on rural banks: (*a*) the effects of expanding Federal Reserve authority to cover nonmember state banks, (*b*) the effects of phasing out of Regulation Q and the introduction of interest-bearing transactions accounts on the already serious funds management problems confronting rural bank management, and (*c*) the potential changes in the availability of loan funds due to the override of state usury ceilings.

Although much has been written about rational and inflationary expectations, more needs to be done before we are in a position to understand what factors producers consider when forming expectations about the variability and levels of future relative prices and yields. Expectations of relative prices and their variability, for example, are major determinants in the decision-making process of producers, and influence both their investment decisions as well as their demand for loan funds. The extent to which these expectations are transmitted into asset values will also affect the risk position of lenders accepting these assets as collateral for new loans.

A better understanding of how to forecast more accurately future prices and their variability may help lenders better anticipate future inflation and their exposure to risk and to reflect these effects in their interest rates. From the mid-1960s until recently, for example, inflation rates have often greatly exceeded expectations, thus resulting in a transfer of wealth from lenders to borrowers. The greater use of variable interest rates and terms by lenders is aimed at minimizing this wealth transfer in the future. What effect a complete switch to variable rates and terms on loans and bonds will have upon the flow of funds in these financial markets, however, remains to be seen.

Inflation Effects on Farm Financial Management

Fred C. White and Wesley N. Musser

The issue of financial management under inflation is a relatively new topic for agricultural finance research. Research in this area traditionally has focused on inflation issues such as land price increases, capital gains in agriculture, and trends in farm prices and costs with an emphasis on aggregate issues rather than firm management. Firm growth research considered inflation, but it was not the major focus of such research (Brake and Melichar). This limited firm research can be related, in part, to the explicit exclusion of inflation in the net present value concept, which is a major theoretical foundation for financial management. This shortcoming has been overcome recently. Aplin, Casler, and Francis were the first to consider explicitly the impact of inflation on net present value calculations in their agricultural finance text, and subsequent texts have done likewise (Barry, Hopkin, Baker; Penson and Lins).

This paper has as its major purpose the review of recent developments in finance theory related to the consideration of inflation in a net present value framework. While an exhaustive presentation of the implications of these theoretical models for agricultural firm management is impossible, major methodological and empirical directions for future research are recognized. Theoretical and/or empirical consideration of particular issues, such as optimal replacement decisions, estate management, firm growth, income tax management, leasing versus purchase, optimum capital structure, and operating leverage, would have been beyond the scope of this paper.

Net Present Value Formulation under Inflation

The net present value (NPV) criterion is widely used to analyze projects that generate cash flows through time. While the NPV principle appears simple in concept, its application under inflation requires some modifications in standard methodology used for situations without inflation. Conditioned by years of relative price stability, the standard practice has been to estimate current cash flows and to use current interest rates as an estimate of the discount rate. Future revenues and costs in other studies have often been valued at current prices, implicitly assuming no inflation. With the emergence of inflation, this practice will result in a bias in NPV, possibly indicating rejection for some desirable investments (Van Horne). In modifying the NPV formulation to account for inflation, it is important to adjust both cash flows and the discount rate.

Cash Flows

All cash flows, especially in agriculture, are not expected to inflate at the same rate as the inflation rate in the general economy. Thus different inflation rates should be utilized for different cash flows. Cooley, Roenfeldt, and Chew explicitly incorporate such assumptions in an NPV model. A simple analytical method of accounting for the differential impact of inflation in NPV is to specify net operating income (NOI) as follows:

$$(1) \qquad X_j^i = X_j^0\ (1 = i\lambda)^j,$$

where X_j^i is NOI before taxes in year j with general inflation rate of i, X_j^0 is NOI before depreciation and taxes in year j without inflation, i is annual inflation rate, and λ is a measure of NOI sensitivity to inflation.

The next step in adapting the NPV concept is to give explicit attention to income taxes in the cash flows (R_j). An after-tax basis formulation of R_j can be defined as

$$(2) \quad R_j = X_j^i\ (1 - T_j) + T_jD_j = X_j^0\ (1 + i\lambda)^j(1 - T_j) + T_jD_j$$

where T_j is the marginal tax rate in year j, and

Fred C. White and Wesley N. Musser are professor and associate professor, respectively, University of Georgia. Musser was a visiting associate professor at the University of Minnesota when this paper was written.

D_j is the depreciation allowance in year j. Because tax law fixes the tax savings on depreciation, T_jD_j, that portion of R_j should not be subjected to inflationary trends. Cooley, Roenfeldt and Chew also note that components of cash receipts and expenses that are fixed in price for the life of the investment through long-term contract also will not be subjected to inflation.

The cash flows generated by the salvage value of the asset at the end of the planning horizon can be treated similarly to R_j. The salvage value of the asset S^0 without inflation must be adjusted to reflect inflation. It is assumed that S^0 inflates at an annual rate of $i\gamma$ where γ is the salvage value's sensitivity to inflation. The appropriate salvage value at the end of the planning horizon is $S^0(1 + i\gamma)^n$. However, a tax effect also results from the sale if $S^0(1 + i\gamma)^n \neq C_0 - \sum_{j=1}^{n} D_j$, where C_0 = the initial purchase cost. If $S^0(1 + i\gamma)^n \leq C_0$, any tax effects can be treated as ordinary income. However, if $S^0(1 + i\gamma)^n > C_0$, a capital gains tax liability is incurred. For nondepreciated assets such as land, inflation will result in capital gains tax liability. However, inflation increases the possibility of capital gains even for depreciating assets, particularly when rapid depreciation methods are used for taxes.

The terminal cash flows after taxes, Q, can be summarized as follows:

$$(3) \quad Q = S^0(1 + i\gamma)^n - T_n\,(gG) - T_nP,$$

where G is capital gain, g is proportion of taxable capital gain, and P is ordinary taxable income resulting from the sale. In the case when $G > 0$, $P = \sum_{j=1}^{n} D_j$. If $G = 0$, $P = S^0(1 + i\gamma)^n - C_0 + \sum_{j=1}^{n} D_j$. It can be noted that a tax savings results from the sale if $S^0(1 + i\gamma)^n < C_0 - \sum_{j=1}^{n} D_j$ so that $P < 0$ and the third term of (3) is positive.

Discount Rate

Following Fisher, the real cost of capital k_j is generally assumed to be invariant with inflation. Since income taxes are included in cash flow formulation in (2), k_j is defined as an after-tax cost of capital (Adams). In addition, k_j is a weighted average cost of capital rather than a target internal rate of return since debt service charges are not included in the cash flows in (2) (Plaxico and Kletke). Formally, k_j is defined as

$$(4) \quad k_j = k_e(1 - T_j)\,(1 - L) + r(1 - T_j)\,(L),$$

where k_e is the before tax cost of equity funds, L is the ratio of debt to assets in the capital structure, and r is the effective cost of debt.

The nominal discount rate d_j is derived by multiplying the real rate, $1 + k_j$, times $(1 + i)$:

$$(5) \quad d_j = (1 + k_j)\,(1 + i) = 1 + k_j + i + ik_j.$$

It can be noted that d_j is not simply the sum of the real discount rate plus the rate of inflation as is commonly assumed (Harris). Admittedly, the correction factor ik_j is quite small in a situation of relative price stability but could be significant for analysis of a combination of high values of i and k_j.

Two approaches could be used to estimate nominal discount rates. One method is to assume discount rates which were observed historically during periods with similar inflation rates as assumed for the cash flows. Harris and Nehring and Lee and Rask are good examples of this approach, except that they used an internal rate of return for a discount rate rather than a weighted average cost of capital. The other method is to estimate k_j for periods when prices were relatively stable and then use (5) to estimate the discount rate. This method would be appropriate for example to analyze inflationary trends larger than have existed historically. To use this approach one must use data during the last sustained period of relative price stability when the interest rates for agricultural loans were between 4% and 6%. Some readers may find the previous work of the authors on estimating weighted average cost of capital helpful for both approaches (White, Musser, Oosthuizen).

A final point which deserves emphasis is the treatment of risk in the discount rate. If R_j in (2) is considered the expected value of cash flows, then both k_e and r in (4) are a sum of a time preference component and a risk premium. Cooley, Roenfeldt, and Chew stress that risk premiums for inflation be added to k_j when nominal rates such as in (4) are used. Their view is based on the proposition that inflation rates cannot be perfectly anticipated. Cooley, Roenfeldt, and Chew also suggest that (5) only be used to discount X_j^i and a nearly risk-free rate be used to discount T_jD_j because

the tax savings will be earned as long as taxable income is positive. However, this procedure is not consistent with the conventional methods of estimation of k_j which do not separate T_jD_j from the remainder of R_j and is therefore not adopted in this paper.

Net Present Value

Using the concepts developed previously, the relationships in equations (2), (3), and (5) can be used to create a basic NPV formula under inflation:

$$(6)\quad NPV = \sum_{j=1}^{n} \frac{X_j^0(1 - T_j)\,(1 + i\lambda)^j + T_jD_j}{(1 + k_j)^j\,(1 + i)^j} + \frac{S^0(1 + i\gamma)^n - T_n gG - T_n T}{(1 + k_j)^n\,(1 + i)^n} - C_0.$$

Except for the complicating effects of inflation, (6) is used to analyze investment in the same manner as conventional formulas. If $NPV > 0$, the investment should be accepted if it is independent of other alternative investments. For mutually exclusive investments, the project with the highest value of NPV should be selected.

Inflationary Impacts of Investments

Examination of (6) readily indicates that inflation affects NPV and therefore the investment process. Inflation does not have a neutral effect on NPV for three reasons: (*a*) the sensitivity coefficients λ and γ are not equal to one, (*b*) the noninflating values of D_j, and (*c*) income tax liabilities generated by the salvage value of the asset. Consideration of the impact of inflation on NPV would require theoretical and/or empirical analysis of the special cases of these three factors, especially the third.

To illustrate the possible theoretical analysis, a simple case where $S^0(1 + i\gamma)^n = G = P = 0$, and tax rates are indexed for inflation ($\partial T_j/\partial i = 0$) is useful for analytical and expository ease. Under these assumptions, (6) can be simplified as follows:

$$(7)\quad NPV = \sum_{j=1}^{n} \frac{X_j^0(1 - T_j)\,(1 + i\lambda)^j}{(1 + k_j)^j\,(1 + i)^j} + \sum_{j=1}^{n} \frac{T_jD_j}{(1 + k_j)^j\,(1 + i)^j} - C_0.$$

Differentiating (7) with respect to i yields

$$(8)\quad \frac{\partial NPV}{\partial i} = \sum_{j=1}^{n} \cdot \frac{jX_j^0(1 - T_j)\,(1 + i\lambda)^j[\lambda(1 + i\lambda)^{-1} - (1 + i)^{-1}]}{(1 + k_j)^j\,(1 + i)^j} - \sum_{j=1}^{n} \frac{j(1 + i)^{-1}\,T_jD_j}{(1 + k_j)^j\,(1 + i)^j}.$$

First considering the case in which $\lambda = 1$, the first summation is zero because the term in brackets is zero. The value of the derivative would be negative because the only remaining term, the last summation, is preceded by a negative sign. With X_j^0 inflating at the same rate as the general inflation rate, the real value of the discounted cash flows are not affected. However, constant nominal tax savings will result in declining real values for the second term and therefore decreasing NPV. In this case, some investments will not be viable with inflation that would have been viable with stable prices. This relationship is consistent with the general finding that use of historical costs rather than current replacement costs as the basis for depreciation depresses investment (Nelson, Lintner, Hong).

A more interesting case results when $\lambda \neq 1$. Because the mathematics are quite tedious, they will not be presented, but are available from the authors for interested readers. A summary of this case is that NPV decreases even more than when $\lambda = 1$ if $\lambda < 1$. However, NPV can increase with inflation if λ is sufficiently larger than one. The intuitive interpretation of these results is that inflation increases the viability of many investments in sectors with profitability trends well above the average and severely depresses investment when profitability trends are less than the average inflation rate. Agriculture usually tends towards the latter case except in situations of high export demand and/or random reductions in production.

The theoretical model in (6) can be used to examine other interesting impacts of inflation. One general source of propositions is to differentiate $\partial NPV/\partial i$ with respect to one of the other parameters in (6). The authors have investigated the case of zero salvage value and terminal taxes with these methods. For the sake of brevity, these results will be summarized without the mathematics.

Depreciation

What is the impact of inflation on investments with higher levels of depreciation relative to operating income? The general answer to this question is that the higher the ratio of D_j to X_j^0, the larger the reduction in NPV due to inflation. Assets whose R_j contains more depreciation will therefore be impacted more by inflation. Land would be least impacted by inflation under this proposition. In addition, accelerated depreciation may help to mitigate the impact of inflation.

Marginal Tax Rate

Studies of inflationary impacts in the finance literature have been concerned with corporations for which the marginal tax rate can be assumed constant. For farm firms, exploration of the differential effects of the marginal tax rate allows consideration of the structural impact of inflation. As with many tax issues, the theoretical results are not very intuitive and in this case depend on the value of λ. If $\lambda \geq 1$, higher marginal taxes will have a negative effect in the change in NPV due to inflation. In beneficial periods of inflation for agriculture, farmers with the lower tax bracket will experience the greatest increase in NPV; and, in the opposite case, these individuals will also experience the most decrease in NPV.

Discount Rate

As with the tax rate, the results with respect to different levels of k_j depend on λ. If λ is less than the value such that $\partial NPV/\partial i > 0$, a higher discount rate results in a smaller decrease in NPV. If the λ is larger, a higher discount rate results in a smaller increase in NPV.

Other Important Issues

Several other important issues in financial management could have been considered in this paper. Since other papers have recently considered these issues, the decision was made to de-emphasize these issues. However, summaries of the results may be helpful to some readers. Bates, Rayner, and Custance recently considered the effect of inflation on optimum replacement. Their conclusion was that inflation increased the optimal replacement age. A corollary to this result is that inflation would encourage investment in durable assets with a longer life; on this point, it can be noted that Nelson made a theoretical mistake on this issue. Several other issues are the effects of inflation on equity and growth, and use of leverage under inflation, which Robison and Brake have recently considered. Inflation increases liquidity problems and slows growth. In addition, leverage is beneficial under unanticipated inflation in that the interest rates do not compensate the lender for loss of wealth. However, if the interest rates correctly anticipate inflation, no unintended effects of inflation occur (Hong). It can be added that realized inflation rates less than anticipated in the interest rates will have the opposite effect—some farmers may experience this situation in 1980.

Conclusions

This research has examined the theoretical consequences of inflation on financial management decisions of farmers. From the issues considered, it is evident that inflation is likely to have a significant impact in the area of financial management. In essence, the findings indicate that the investment decision is not neutral with respect to the rate of inflation even if nominal net operating income adjusts with inflation because nominal tax savings from depreciation do not adjust. The net present value of these future cash flows would thus decline with inflation and reduce the incentive to invest. This result differs considerably from the common proposition that NPV is invariant with inflation.

While the net present value formulation developed in this paper is a generalization of previous models, its interpretation was based on several simplifying assumptions: (*a*) market and tax salvage values of the asset at the end of its economic life were assumed zero, (*b*) the rate of inflation is constant over time, and (*c*) marginal tax rates are indexed for inflation. Relaxing these assumptions would complicate the analysis, because the impact of these interrelationships is complex. Further theoretical and empirical analysis is necessary to interpret these interrelationships. Because of the complex interrelationships, use of financial management theory will be helpful, if not necessary, to interpret empirical research.

The model to evaluate investment alterna-

tives under inflation presented in this paper was developed in the context of normative firm analysis. Application of the model would indicate whether or not a particular investment opportunity was economically feasible and should be undertaken. This model also could be used as a framework for positive analysis of investment in agriculture. An empirical analysis of the various components of the model should provide a basis to predict changes in agricultural investment in response to changes in various exogenous factors such as the rate of inflation and tax laws. One definite conclusion of this paper is that inflation should be included as a causal variable in investment models.

Inflation and Agricultural Finance: Discussion

Lindon J. Robison

On my high school football team was a large, slow defensive guard who sat on the bench most of the time while a smaller, more agile fellow enjoyed the action. In response to town-folk criticism about his personnel deployment, my coach responded: "I'd rather get there with a little than not get there with a lot." I will try to follow that prescription by focusing on one point which appeared in all three of these interesting papers. This lack of attention to the many other points in the papers should not be construed as agreement or disagreement, only a lack of time and space to respond.

Klinefelter, Penson, and Fraser began their paper with a review of inflation-causing factors and lender responses to greater and more uncertain inflation, such as shorter-term loans and variable or renegotiable interest rates. The best example of this response to uncertain inflation has been the Farm Credit System's adoption of variable interest rates as early as the late 1960s.

It should be evident that adopting variable interest rates and renegotiable rates result in all borrowers paying a more nearly equal rate. Moreover, if cost to borrowers is based on a weighted cost of funds obtained by the lenders, such as is the case with the Farm Credit System, interest rates will respond rather sluggishly to inflationary (deflationary) pressures. This suggests that, as all three papers appear to agree, inflation has differing impacts over time on input and output prices received by farmers. I will return to the implication of this point later.

Lins and Duncan discuss more explicitly the point made earlier. Inflation does not affect all prices equally, although for the unfortunate farmers, prices paid appear to respond more to upward pressures than prices received. But lacking from Lins' table of correlations was the correlation with interest rates. If interest rates equal a real rate of interest, say between 3% to 5%, and the rest equals an inflationary premium, then credit up to now may contradict Lins and Duncan's general statement that input costs rise more rapidly than output prices.

The impact of all this, Lins and Duncan hypothesize, is fewer but larger farms, a move to organize farm organizations as corporations, and vertical integration. Unfortunately, neither they nor I have time to explore these hypotheses.

White and Musser attempt to "equationize" the points already identified in the two earlier papers. They introduce a capital budgeting model which explicitly allows for differing inflationary impacts on the discount rate and net returns. Since, as Klinefelter, Penson, and Fraser point out, capital assets equal the discounted present value of their returns, Musser and White's approach appears justifiable and their conclusion that increasing inflation reduces net present value is reasonable. Moreover, they recognize, as do Lins and Duncan, that cash flows will not necessarily inflate at the same rate as inflation in the general economy.

Having identified the same point in all three papers, it seems that a statement about the effects of differing inflation rates is needed. I provide one. (See also Melichar.)

Let V be the price of a nondepreciating capital asset in a noninflationary economy which earns R net returns for n periods and is sold n periods later for the same price V. In addition, let r be the time preference rate which discounts both R and V to a present value. The relationship between R, V, and r is the familiar capitalization formula, V equals R/r.

Now, introduce inflation, which increases income and the capital asset s value in each period by $g\%$ and the discount rate by $i\%$ in each period.

Lindon J. Robison is assistant professor in the Department of Agricultural Economics, Michigan State University.

Michigan State University Experiment Station Journal No. 9563.

$$(1)\qquad V = \frac{R(1+g)}{(1+r)(1+i)} + \dots + \frac{R(1+g)^n}{(1+r)^n(1+i)^n} + \frac{V(1+g)^n}{(1+r)^n(1+i)^n}.$$

The result, after geometrically summing income, is a modified capitalization formula equal to

$$(2)\qquad V = R(1+g)/(r+i+ir-g).$$

Now, if g equals i, that is, both income and the discount rate are affected equally by inflation (in White and Musser's notation $\lambda = 1$), then V, of course, again equals R/r and V increases in each period by the inflation rate i.

The direction of the change in V, as i and g change, is apparent. The point to be emphasized is the magnitude of change. To illustrate, begin with a noninflationary economy and let g increase from zero to 1%. The result is a 25% increase in V. In contrast, a 1% increase in i (the discount rate) reduces V by 17%. Small wonder then, when interest rates (the discount rate) skyrocketed the first part of 1980, Iowa farmers were reporting land value declines of up to 10%.

Lins and Duncan quoted Samuelson who said: "the problem with inflation is not so much price increases, but rather the inefficiencies caused by changes in relative prices," to which we might add, that the problem with inflation is not so much that prices increase, but rather that they do so unequally.

Inflation and Agricultural Finance: Discussion

Eddy L. LaDue

It is obvious from reading or listening to these three papers that the authors' primary goal was to summarize, or at least indicate, the current level of knowledge of our profession relative to the impact of inflation on agricultural finance. This is a useful effort and they did a good job; but, if you accept that as their goal, you have to be impressed with how little we know. The really disappointing aspect of these papers was their nearly total lack of extension of our knowledge in this area. This is not unusual for invited paper sessions, and no research money comes with the invitation to prepare a paper, but, given the outstanding capacities of the individuals involved and the paucity of real knowledge in the area, I had hoped for more. The papers do provide a good basis for discussion.

White and Musser do a good job of mathematically incorporating inflation into the simple net present value model for investment evaluation. The interaction between inflation and the revised model is then used to look at a few factors in the model for an exceptionally simple investment situation. The pedagogically useful simple mathematical specification is the main contribution of the paper. All of the inflation-related characteristics contained in the model have been in use in operational extension models for five years (LaDue and Casler). In developing and using the model Casler and I developed in 1975, we have observed a number of problems, at least some of which might be considered deficiencies in the White-Musser model. These are:

(*a*) Representation of taxes must be more complete. Investment credit and the progressive tax structure that most farmers face must be included. White and Musser imply use of an iterative process to get income and the marginal tax rate consistent, but this is a burdensome procedure. The biggest problem with taxes is that they are paid on nominal income, are not indexed, and we have little knowledge of when future tax cuts will occur. We need to know the relative impact of indexing versus the irregular stair-stepping tax levels through time brought about by periodic tax cuts.

(*b*) Most major investments require non-year-zero capital expenditure either to complete the investment or to replace part of the investment which has a life less than the planning horizon used in analysis. Inflation is not neutral relative to these investments.

(*c*) Usefulness of the model is dependent on quality of inflation estimates. When components are considered separately, it is easy for farm operators and professors unintentionally to develop estimates that imply a relative change in the profitability of agriculture which the people making the estimate do not actually expect. Operationally, we find that it is hard for farmers to specify aggregate impact of inflation. It is much easier to think about inflation of individual items or components.

The greatest shortcoming of this paper is its narrow nature; under the title of "Inflation Effects on Farm Financial Management," the actual financing of investments is left to one sentence. My analyses to date (LaDue 1979) lead me to believe that the greatest potential impact of inflation on individual farms is the cash flow impact of financing, as was pointed out by Lins and Duncan. Certainly this implies financial management problems for a great number of farmers and may lead to the need for changes in financial arrangements used by all lenders but in particular the arrangements offered by public lenders such as FmHA. For example, would graduated payment mortgages allow beginning farmers to compete more effectively for farm assets?

As indicated in both of the other papers, an impact of recent inflation has been to shift the interest rate risk from lenders to farmers. This

---

Eddy L. LaDue is an associate professor, Department of Agricultural Economics, Cornell University.

is a new risk to farmers and could be devastating to the highly leveraged farm operator. The impact of this increased risk needs to be researched. The next time interest rates rise rapidly, it may be farmers rather than bankers who sustain the losses.

The Lins-Duncan paper focuses on the more aggregate impacts of inflation on agriculture. I laud them for their attempt to do more than repeat what others have said and what we all know. However, I have serious reservations about their ability to draw conclusions about the relative impact of inflation on various commodities from the correlation data presented. I would expect a high correlation between change in dairy prices and the consumer price index; but I do not see how that means that dairy farmers fared better than a crop farmer with a more variable price and, thus, a lower correlation. I could imagine the dairy industry following the consumer price index (CPI) lagged three steps behind but changing in the same direction as the CPI and being much more seriously disadvantaged than a corn farmer whose income varied greatly but varied on the up side as well as on the down side. The high price bonanza experienced by grain farmers in the 1970s never hit the dairy industry. Low correlation could occur because the price increased more rapidly, rather than less rapidly, than the CPI.

Lins and Duncan argue that inflation does not lead to higher real land prices because of the negative impact of inflation on cash flows. However, later in the paper they argue that the "buy now before the price goes higher" strategy leads to greater purchases and, thus, higher debt; and that ownership of farm assets has been desirable because of favorable growth in real values. Both of these latter factors lead to an increased demand for farm resources, particularly land, and likely at least offset any reduced demand caused by the cash-flow problems of small and beginning farmers, leaving unaltered the high correspondence between land values and cash returns to land observed by Melichar (1980).

In their concluding paragraph, Lins and Duncan raise the specter of declining inflation rates. I personally doubt that inflation will get below the 10% range for very long in the next several years. However, it would be useful to assess the real risk position of farmers should inflation rates decline substantially rather than remain at relative high rates or increase.

Klinefelter, Pensen, and Fraser (KPF) start out by trying to define inflation. Although everyone may not agree with their definitions, the identification of "steady-pace" versus "fits-and-starts" inflation is useful. Most economists assume steady-pace inflation, but it is the fits-and-starts variety that the United States appears to be experiencing.

The authors clearly portray the shift of interest rate risk from lender to farmer with increased use of variable rate mortgages. But they do not even raise the question of whether or not that is the appropriate move for all lenders. Presumably there should be some profit connected with the assumption of interest rate risk. Financial institutions may be better able to manage that risk than farmers. If so, it may be profitable, as well as a service to agriculture, for some lenders to continue to offer a fixed rate mortgage with an interest rate risk premium.

KPF also raise the question as to whether the Farm Credit System and FmHA have the capacity to handle larger market shares. However, they do not ask the potentially more important question of whether or not increasing the market shares of these lenders is good for agriculture. The Farm Credit System has done and continues to do an outstanding job. But, can financial market efficiency really be maintained when the only competition the Farm Credit System has is the U.S. government?

Finally, it is true that the loan volume of government lending agencies (FmHA, CCC, SBA) has skyrocketed recently. However, I would contend that the primary cause is drought, export variability, and cyclical price movements rather than inflation. Economic Emergency loans could result from changes in monetary policies and interest rates; but, so far, with the exception of one small area of the country (Melichar), I doubt that inflation-induced monetary and interest rate changes triggered many of the loans.

From a longer-run perspective, inflation could reduce the effectiveness of FmHA in its ability to serve beginning and small farmers. Since the loan limits and other regulations under which FmHA works, are set by Congress and require an act of Congress to change, it may be difficult to keep FmHA loan policies current. More general legislation with greater administrative flexibility or an inflation indexed loan policy may be required.

The Impact of Landownership Factors on Soil Conservation

Linda K. Lee

Although soil erosion has been a recognized problem in the United States since the 1930s, recent soil losses have generated additional concern. This concern has been prompted by reports that soil erosion losses are increasing, thus intensifying air and water pollution problems and reducing the productivity potential of cropland. These reports accompany evidence that suggests further productivity increases from fertilizers, seed technologies, energy, and pesticides are uncertain (Crosson). These productivity trends, coupled with irreversible losses of agricultural land to urban and other uses and the possibility of increased demands for U.S. agricultural products, make the issue of conserving soil quality increasingly important.

In response to these concerns, the Soil and Water Resources Conservation Act of 1977 (P.L. 95-192) requires a continuing appraisal of the soil and water resources of the nation and analyses of the effectiveness of ongoing conservation programs. A 1977 General Accounting Office report to Congress concluded, however, that effective conservation policies may require identifying and seeking out landowners whose lands have critical erosion problems. Hypotheses about the impact of landownership characteristics such as tenure, income, and owner attitudes on soil conservation have been investigated in studies since the 1940s. Events of the 1970s have renewed interest in these hypotheses and have suggested new ones. The attention focused on the changing structure of agriculture has led to the hypothesis that a larger, more corporate agricultural structure will have unfavorable consequences for soil conservation. The objectives of this paper are, first, to examine different organizational structures to determine if there are differences in average erosion rates among them, and second, to reexamine traditional hypotheses about landownership and soil erosion from a broader perspective than previous studies. If significant differences can be identified among landownership groups, this information could be used to develop and implement more effective conservation policies.

Factors Affecting Soil Erosion

Soil management decisions at the farm level have been analyzed in the context of maximizing expected net income over a planning horizon. The rational individual calculates the income effects of a proposed conservation program over time and compares these effects to his or her expected income over time without conservation measures. Within this framework, individuals sharing similar erosion problems may reach different conservation investment decisions depending on individual time preference or discount rates and the length of their planning horizon. A lower discount rate and a longer planning horizon are thought to encourage conservation decisions by increasing the present value of expected net revenues and by allowing sufficient time to recoup conservation investments. Recent research has emphasized the importance of low discount rates and very long planning horizons in conservation management decisions (Seitz, et al.).

However, numerous economic variables as well as personal characteristics of the owner can affect the individual's choice of a discount rate and planning horizon. Individuals with low current incomes and inability to obtain

The author wishes to thank Marilyn G. Kletke for computational assistance.

capital for conservation investments may not be willing or able to forego income to maximize expected net returns over a longer time period. Similarly, individuals in an uncertain economic situation will be inclined to use short planning horizons because they are unable to predict future costs and prices. It also is possible that older farmers with no heirs operate under shorter planning horizons than younger ones.

Institutional factors can affect the choice of discount rate and planning horizons as well. Lack of knowledge or nonacceptance of conservation principles can lead to unfavorable conservation decisions even where there are economically favorable alternatives. Insecurity of tenure, particular leasing arrangments, absentee ownership, small operating units, high property taxes and a lack of credit facilities have all been hypothesized to be further institutional obstacles to conservation.

Recently, it has been hypothesized that changes in the ownership and control of agricultural land will have important repercussions for soil conservation. A larger, more corporate agriculture, it has been suggested, will lack a conservation ethic and will choose a planning horizon and discount rate designed to maximize current income at the expense of future soil quality (Bible).

Researchers have previously examined many of these hypotheses through studies in small, relatively homogenous areas with similar soils, climate, and topography. By minimizing changes in physical characteristics, management and ownership differences, if they exist, are identified more readily. Both economic and institutional factors were found to influence soil conservation decisions. Higher incomes were found to be associated with higher degrees of soil conservation in areas of the Midwest (Anderson, McNall, and Inman; Heady and Allen). Tenure problems and owner resistance to conservation were found to be prevalent on high erosion farms in a series of studies conducted in Western Iowa since 1947 (Frey, Held and Timmons, Blase and Timmons, Hauser). Leasing arrangements, in particular, were examined by researchers; conservation practices under crop-share leases were found to reduce landlord's income (Jensen, Heady, and Bauman). However, because of the relatively small geographical areas studied, it is sometimes difficult to determine how representative these studies may be. Also, a disproportionate number of these studies have been conducted in only one region, the Corn Belt.

In the following sections of this paper, the influence of the organizational structure of landownership units on soil erosion will be examined on a regional and national basis. In addition, the economic and institutional hypotheses about landownership and conservation explored in earlier studies will be reexamined from a regional perspective.

Data

Data for this analysis were obtained from a merger of the 1977 National Resource Inventories (NRI) conducted by the U.S. Soil Conservation Service (SCS) and the 1978 Landownership Survey undertaken by the Natural Resource Economics Division (NRED), Economics, Statistics, and Cooperatives Service (ESCS), U.S. Department of Agriculture (USDA) (Lewis). The SCS/NRI provided basic data reliable at the state level on land use, land quality, potential cropland, and erosion. The survey was a two-stage sample of 70,000 primary sampling units (PSU) of generally 160 acres. Within each PSU, three randomly selected points were inventoried. The SCS provided NRED the name and address of the owner of the first point in each sample PSU. Of the 70,000 points, names and addresses for private landowners were available for 52,000 points and slightly more than 37,000 completed landownership questionnaires were returned after follow-up procedures. For these 37,000 responses, additional land use information from the SCS/NRI was available and utilized in this analysis.

Our initial analysis focused on key landownership variables hypothesized to influence soil erosion, including type of organizational structure, income, and tenure characteristics. As income and other landownership data were not available for the corporations in our sample, one model was formulated to test for differences in mean erosion rates on land owned by different organizational units, and another model was developed to analyze erosion differences among different income and tenure groups. Analyses at the national and farm production region levels were conducted, allowing a broader examination of earlier findings. However, many possibly relevant variables and interactions among variables were omitted from this analysis. A more comprehensive analysis is planned to look at additional rela-

tionships between landownership variables and soil erosion.

Rainfall erosion data for this analysis were estimated from the Universal Soil Loss Equation (Wischmeier and Smith). It is difficult to separate the influence of management and physical factors on erosion from the Universal Soil Loss Equation data as management practices are a reaction to a natural environment. Nevertheless, in an attempt to determine the relative importance of management and physical factors in erosion differences, means for management and physical factors within the Universal Soil Loss Equation were analyzed for ownership categories. Distributions of land with conservation measures of minimum tillage or residue practices in effect were examined as a management indicator, and prime farmland and erosion-prone land (subclass e) distributions were evaluated as a measure of physical factors.

Soil Erosion Rates and Organizational Structure

Dummy variables were used in a regression model to test for differences in mean erosion rates on cultivated cropland acreage owned by different organizational units (table 1). The model was weighted by the expanded acreage estimates associated with each observation to account for probability of selection and nonresponse in the survey data. *F*-statistics were used to test the hypothesis that no difference between mean rates of erosion exists on the acreage owned by these different types of landowners. Individual coefficients were examined with *t*-tests. Because nonfamily corporations were the excluded category in this analysis, a coefficient for a given category represents the difference between the mean rate of erosion for that category and nonfamily corporations.

The results of the structure analysis indicate that nationally there are no significant differences in mean soil losses between different types of ownership groups. Since the value of the *F*-statistic was below the critical *F*-value at the .05 level, we could not reject the hypothesis that mean soil losses between groups are equal. This conclusion applied to a majority of the farm production regions tested as well. However, for four of the ten regions in the U.S., *F*-values exceeded the critical value, indicating differences in mean rates of erosion between groups did exist. Significantly, in none of these regions were these differences the result of higher average rates of erosion by nonfamily corporations. In the Northeast, Mountain, and Lake regions, the data indicate

Table 1. Erosion on Cultivated Cropland by Type of Landownership Organization

Organizational Structure[a]	National	Northeast	Lake	Southeast	Mountain
	(tons/acre/year)				
Nonfamily corporation[b]	4.98 (9,242)[c]	4.53 (364)	3.29 (471)	5.14 (748)	1.39 (1,385)
Sole proprietor	.03[d] (147,548)	1.47 3,936)	−.74 (15,933)	1.09 (7,499)	.21 (10,777)
Family ownership	.32 (144,956)	.89 (6,596)	−.50 (20,796)	6.36*[e] (3,227)	.18 (11,787)
Partnership with family members	−.24 (40,111)	8.58* (1,210)	−1.02 (2,543)	2.87 (1,354)	1.60* (3,395)
Partnership with nonfamily members	−.34 (5,129)	−.89 (167)	6.50* (144)	−1.42 (290)	.63 (628)
Family corporation	−.51 (15,469)	7.62* (281)	−.58 (869)	.28 (201)	1.62* (3,541)
Other (includes no pluralities & estates)	−.13 (14,001)	1.66 (231)	−2.17 (667)	.62 (386)	1.01 (851)
F	.79	5.69	2.57	3.82	4.24
Degrees of freedom	11,263	666	1,282	490	833

[d] Total soil loss for nonintercept categories can be calculated by adding soil loss from the nonfamily corporation categories.
[e] Asterisk denotes significance at the .05 level.

that most of the reported differences in erosion rates among types of landowners probably can be attributed to physical rather than management factors. Landownership categories experiencing more erosion had higher percentages of land with conservation practices in effect, but also included considerably higher percentages of erosion-prone land.

The situation in the Southeast region appeared to be somewhat different. In this region family ownerships averaged 6.36 more tons/acre of soil loss annually than did nonfamily corporations. While distributions of physical factors appeared to be important, management practices also differed between the two groups. Almost 57% of land owned by nonfamily corporations was operated using minimum tillage or residue practices. Only 36.4% of land owned by families had these practices in effect. The data also indicated that cultivated cropland owned by families in the Southeast is apparently more susceptible to erosion than land owned by nonfamily corporations. While 45% of corporately owned cultivated cropland had a designated erosion hazard, 54% of such family-owned land had this classification.

Several explanations for the difference are possible. First, crops grown may differ between groups. Corporate influence in vegetable production is strong in this region, so erosion differences may reflect more erosive crops, such as tobacco or peanuts, grown by family farmers. It is also possible that owner attitudes toward conservation differ between corporations and family cropland owners in this region. Another possible explanation is that family landowners in the Southeast are smaller, less affluent, and have more problems obtaining capital for conservation investments than their corporate counterparts. These factors would result in shorter planning horizons and higher discount rates for conservation investments by family groups. While income data are not available for the corporations in our sample, income effects will be tested on data for noncorporate landowners in the following section.

Erosion Differences among Noncorporate Landowners

A second weighted regression model with dummy variables was formulated to examine mean soil erosion differences on cultivated cropland among income and tenure variables found to be important in previous studies. Leasing information was not available in sufficient detail to be included. A portion of this analysis, differences in mean erosion rates among income categories for full-owner-operators, is presented in table 2. F-statistics were used to test the hypothesis that mean rates of erosion on cultivated cropland owned by different income groups are equal, while t-tests were used to examine individual coefficients. As the income category of $0–$2,999 was the excluded category in this analysis, each coefficient represents the difference between the mean soil loss for that category and the low income excluded category.

The results of our analyses do not indicate that significant differences in soil erosion rates exist between tenure groups at the national level or within most regions. Significant differences between tenure group erosion means were found in two regions, but only in the Northeast region were average erosion rates on cultivated cropland owned by full-landlords higher than erosion rates for full-owner operators. Similarly, mean levels of erosion on cultivated cropland did not differ significantly among net farm income categories nationally and for most regions. Only within the Southern Plains region were lower mean levels of erosion associated with higher net farm income categories.

Instead, the relationship between net farm income and mean levels of erosion appeared to depend on the tenure category of the landowner. For full owner-operators, those who operate only land that they own, higher income levels were associated with lower rates of erosion, nationally, and within five out of ten regions in the United States. Nationally, mean levels of erosion for landowners reporting net farm incomes between $3,000–$9,999, $10,000–$19,999, and $20,000–$49,999 were 1.34, 1.49, and 2.31 tons/acre less, respectively, than lower farm income landowners reporting $0–$2,999 as annual income. Net farm income greater than $50,000 did not appear to result in significantly lower erosion rates. However, the acreage represented by this group is relatively small and therefore subject to more sample error. The Northeast, Corn Belt, Delta, Southern Plains, and Mountain regions displayed a similar trend to varying degrees. In the Corn Belt, for example, landowners with net farm incomes of $20,000–$49,999 averaged 9.4 tons/acre less erosion on

Table 2. Rates of Erosion on Cultivated Cropland by Net Farm Income, Full-Owner-Operators

Net Farm Income	National	Northeast	Corn Belt	Delta	Mountain	Southern Plains
	(tons/acre/year)					
\$0–\$2,999[a]	5.62 (8,189)[b]	1.69 (379)	13.78 (1,476)	14.29 (103)	.45 (364)	6.19 (549)

[e] Asterisk denotes significance at the .01 level.

cultivated cropland than did low income owners of \$0–\$2,999.

In the Northeast, Delta, and Mountain regions, full-owner operators who experienced net losses had the highest reported erosion rates. Since the excluded category in this analysis was net farm income of \$0–\$2,999, t-values for coefficients in these regions may not be significant, although differences between erosion rates for net farm losses and other categories are pronounced. For example, in the Delta, landowners with net losses averaged 26.4 tons/acre soil loss compared to 5.3 tons/acre by the highest income landowners in the region.

The association between net farm income and erosion was confined to full-owner operators. Off-farm income and total income variables were also tested for mean erosion differences within tenure groups and for all data, but no significant trends were detected.

The relationship between higher incomes and lower rates of erosion for owner-operators appears to result from a combination of less erosive land and more conservation practices. Nationally, only 40% of cultivated cropland owned by the most affluent landowners is classified as having an erosion hazard, while 59% of cultivated cropland owned by the lowest income group is labeled erosion prone. This trend can be found in most of the regions of the United States. In terms of management, 60% of cultivated cropland owned by landowners with net farm income greater than \$50,000 had minimum tillage or residue practices in effect, while 47% of such land owned by those with net farm incomes of less than \$3,000 had these practices at the national level.

In the five regions for which significant differences in mean erosion rates between farm income categories occurred, distributions of physical and management characteristics reflected the national trend. However, in two regions with major erosion problems, Appalachia and the Southeast, mean rates of erosion for full-owner operators did not differ among income groups. Furthermore, examination of land quality and management data for these regions did not reveal a well-defined pattern. One possible explanation is that for some of the crops important to these regions, such as tobacco, recommended tillage practices are erosive and higher incomes alone may not result in improved management practices. Owner attitudes toward conservation may differ in these regions as well.

Conclusions

Further research is needed to address the issue of landownership impacts on soil conservation. As noted earlier, this analysis is a

partial one. Additional analysis is underway to provide a more comprehensive analysis of landownership factors, including age and education, that might affect soil conservation decisions. Also, our analysis is based on cross-section data from 1977–78. However, many of the relevant questions about landownership and conservation refer to dynamics—what are the implications of a changing structure of agriculture for soil conservation? It is hoped this analysis will provide a first step toward subsequent long-run research on these questions.

With these qualifications in mind, this analysis does provide some insight into landownership impacts on soil conservation. First, these data indicate that corporations do not have higher average rates of erosion than other types of landowners. Nationally, and within most regions, there do not appear to be significant differences in mean rates of erosion on cropland owned by different types of organizational units. Furthermore, with the possible exception of the Southeast, no significant differences in mean rates of erosion between types of landowners were found to be principally due to management.

For noncorporate landowners, the results of this analysis are generally consistent with previous studies with respect to net farm income, although no significant differences between rates of erosion and tenure groups were found. However, net farm income was found to exert more influence within the full owner-operator tenure group than other tenure categories. It is possible that if additional information on the type and length of lease were tied to the erosion data, erosion differences among landlords would be evident. However, as a group, landlords do not automatically appear to have more soil losses than those who operate their own land or those who combine landlord, tenant, and owner-operator functions. Full landlords and part-owners do appear to have a different relationship between net farm income and erosion than full owner-operators. Thus, policies designed to encourage conservation through income incentives may not have similar effects in all tenure groups. Currently, our research indicates only 25% of cropland in the United States is owned by full-owner operators. Another 30% is owned by full-landlords, and the remainder is owned by those who are a combination of landlords, tenants, and owner-operators.

Finally, this analysis indicates regional differences do exist, at least with respect to income and tenure variables. Of five regions in the United States experiencing average rates of erosion on cultivated cropland above 5 tons/acre, income and tenure variables provided some explanation of erosion differences in the Northeast, Corn Belt, and Delta. For the Appalachian and Southeastern regions, however, another model may be more appropriate. The characteristics of the types of crops grown in these regions as well as owner attitudes toward conservation may provide some explanations.

Conversion of Noncropland to Cropland: The Prospects, Alternatives, and Implications

Robert N. Shulstad and Ralph D. May

A major conclusion of researchers in universities, government, and private research institutes is that the United States has adequate agricultural resources to meet and exceed any projected increases in the domestic demand for food and fiber and to provide these goods at reasonable prices. Most researchers would also agree that domestic demand could be accommodated without the conversion of noncropland to cropland and without significant environmental damage. However, the responsibilities of the U.S. agricultural machine have been broadened to include not only U.S. consumers but also the willing and able buyers of the rest of the world. Most of the world export market is currently supplied by the United States (Frey and Otte, Heady and Timmons).

Ericksen and Johnson present projections prepared by the Economics, Statistics, and Cooperative Service (ESCS) analysts which predict an expanding market for U.S. agricultural products. Their supply and demand forecasts indicate that the 1980s generally will be a period of intermittent tight supply which will test the ability of the United States to respond to an increase in demand for food and feed grains. The full production potential of U.S. agriculture will be needed to meet the anticipated level of demand.

The potential for increased production depends on the ability to increase yields or to increase the cropland base. Though technological innovations, such as improved varieties, planting rates, fertilizers, and pesticides, have combined to substitute for land to increase yields during much of the twentieth century, continued yield growth is questionable. Yield increases at rates comparable to those of the 1950s and 1960s are not realistic, especially in the face of increased fertilizer, chemical, and irrigation costs, decreasing budgets to support basic research in plant breeding, and more stringent regulations to control the externalities of agricultural production.

Production records through 1978 generally support the hypothesis that growth in yields has plateaued or actually decreased (Crosson). However, Heady recently argued that "when the record yields of 1979 are included, quantitative proof does not yet exist to indicate that U.S. crop yields generally are now plateauing" (Heady, p. 23). If they are not, the question is whether growth in yields will be adequate to compensate for growth in demand.

Should yields continue to increase at the 1972–78 rate, Crosson estimates an additional 70 million acres above 1977's 331.6 million acres will be required to meet the U.S. Department of Agriculture (USDA) projected demand for the year 2000 (Crosson, p. 102). This substantial increase in the cropland base must come from lands that have a potential for conversion to cropland rather than cropland held out of production under government programs (Ericksen and Johnson). Though set aside and diverted cropland amounted to 62 million acres in 1972, no land was set aside or diverted from 1974 through 1977. The upgrading of present cropland by drainage, landforming, and irrigation may also provide for increases in production.

Potential for Expansion

The potential of the United States to expand its cropland base has been the subject of numerous studies (Amos and Timmons; Cotner, Krause, Skold; Davis; Dideriksen, Hildebaugh, and Schmude; Frey and Otte; Lee; Shulstad, May, Herrington). Most re-

Robert N. Shulstad and Ralph D. May are associate professors of agricultural economics, Department of Agricultural Economics and Rural Sociology, University of Arkansas.

searchers have relied on the 1967 National Inventory of Soil and Water Conservation Needs (CNI), the *1975 Potential Cropland Study*, or the more recent National Resource Inventory (NRI) to provide base data for their estimates (Cotner, Krause, Skold; Dideriksen, Hildebaugh, Schmude; Frey and Otte; Lee.) The techniques used in these studies are similar—SCS district conservationists conferred with the local county agent, the Agricultural Stabilization and Conservation Service county manager, and the local Farmers Home Administration officer in order to rate each survey point on its potential for conversion.

The Soil Conservation Service *1975 Potential Cropland Study* identified 78 million acres of noncropland as having high potential for cropland development and an additional 33 million as having medium potential under 1974 agricultural product-price relationships. Thirty-five million acres of the high potential land was believed to have no limitations to development (Dideriksen, Hildebaugh, Skold). The preliminary results of the NRI indicate that nearly 36 million acres of pasture, range, forest, and other lands has high potential and 91 million acres has medium potential for conversion to cropland under the less favorable 1976 prices and production costs (Brewer and Boxley). It is further estimated that only 2.2 million acres could be converted quickly to crop production without major outlay for soil preparation or water facilities (Ericksen and Johnson).

Lee, in *A Perspective on Cropland Availability*, expands on the Dideriksen, Hildebaugh, Schmude *1975 Potential Cropland Study* to provide detailed accounting of convertible cropland by region and the associated limitations to conversion. Major difficulties include erosion hazards, clearing and/or drainage, limited water or fertility, and ownership problems. Lee and others who have published reports on the subject call for additional research into the cost, both public and private, of converting noncropland to cropland and more evaluation of the potential for conversion at various stages in the product-price relationship (Brewer and Boxley, Frey and Otte).

The General Accounting Office in a report to Congress criticized the USDA potential cropland study for failing to consider the current agricultural use of potential cropland and owner preferences. The General Accounting Office recommended that potential cropland estimates be developed in which consideration is given to current land use, production tradeoffs, development problems and costs, and other economic values such as changes in the relationship of production and development costs to commodity prices.

Regional Potential

Regional efforts to quantify the economic feasibility of converting noncropland to cropland are exemplified by studies conducted at Iowa State University and the University of Arkansas. The studies by Amos and Timmons in Iowa and Shulstad, May, and Herrington in Arkansas are part of a larger effort by Resources for the Future to project the potential for acreage expansion, its implication for soybean production, and the possible environmental consequences.

The Iowa and Arkansas studies evaluated the present land use and the opportunity costs associated with conversion, and enumerated the costs of the conversion process including clearing, drainage, land preparation, and maintenance. The gross returns to converted land were compared with the full private costs associated with that land—i.e., the conversion costs, the operation and maintenance costs, and the opportunity costs—to evaluate the feasibility of conversion.

In both studies a land type matrix was constructed whereby land is classified by soil productivity class and land use. Productivity classes are aggregations of soil-mapping units into groups that are homogenous in terms of yield, production costs, and management techniques.

The Iowa team used two sets of land-use data, the 1967 Conservation Needs Inventory and the 1977 National Erosion Inventory. Those sources could not easily provide data for the Mississippi Delta which is made up of subregions of several states. Therefore, a sample of seven counties was selected within Arkansas, which is proportionally representative of the Delta soils. Land-use data for these counties were obtained from the Resource Information Data System (RIDS) data bank. RIDS is a joint effort of the Soil Conservation Service and the Economic, Statistics, and Cooperatives Service to identify land use for the center of each square kilometer by field survey. Information is retrieved by soil-mapping units and can be aggregated into pro-

ductivity classes based on the characteristics believed most significant by the researcher.

Conversion costs were obtained from field surveys of commercial land clearers and drainage experts as well as farmers who had recent conversion experience; annual production and maintenance costs were those representative of the study areas. The Iowa study used the USDA production budgets and the Arkansas study used the 1978 Arkansas crop budgets.

Each study considered alternative scenarios to determine the potential for expansion on the extensive margin of production. Product prices were those used in the USDA Grain-Oilseeds and Livestock Model (GOL) and reflected 1985 baseline conditions and 1985 high demand conditions. Under baseline conditions, world grain trade prices in real terms are assumed to average closer to the low levels of the 1969/70–1971/72 base period than the high levels of the 1972/73–1974/75 period. Under high demand conditions, real grain prices would be substantially higher than those of the base 1969–72 period but still below the levels of 1972–75.

The scenarios examined in both studies involved 1985 baseline and high demand prices; normal regional yields and yields representing those obtained by the top 10% of managers; normal production costs and variable production costs increased by 33%; three alternative rates of discount; a twenty-year planning horizon; and alternative crop rotations.

Comparison of the Iowa and Arkansas findings shows the economic feasibility of the conversion process to be much more sensitive to changes in price and cost levels in Iowa than in the Mississippi Delta region.

Within the ranges of crop prices, input prices, conversion costs, and yields assumed, the elasticity of supply with respect to crop prices ranged from 6 to 13 in the Iowa study and from 0 to 3.4 in the Mississippi Delta Study. The elasticity of supply with respect to variable production costs ranged from −4 to −6 in Iowa and from 0 to −2.14 in the Delta.

Under the most optimistic assumptions examined, and under all scenarios assuming high management, all the remaining privately owned woodland and pastureland within the Mississippi Delta region that is not frequently flooded or too steep is economically feasible for conversion. This land amounts to 2.6 million of the 25.36 million acres within the region. Under the most unfavorable assumption the potential for conversion is reduced to 1.38 million acres. The potential for conversion in Iowa ranges from a high of 3.86 million acres to 50 thousand acres (Amos and Timmons).

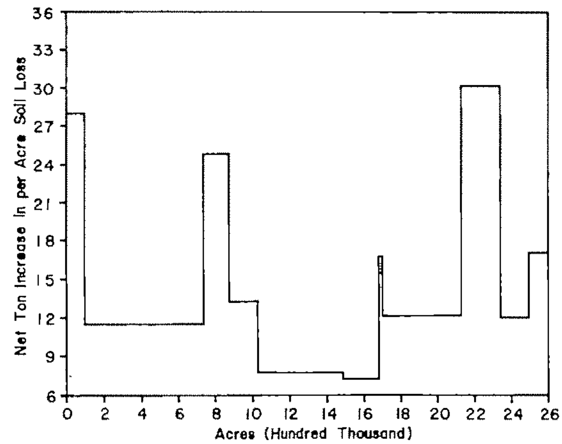
Both Iowa and the Mississippi Delta region have potential for significant increases in the cropland base—11% and 10%, respectively. Neither region, however, is representative of the potential 37% reported at the national level (Brewer and Boxley). Moreover, the results of regional studies must be examined in the context of the nationwide potential for increased production. Major increases in one region could easily be offset by decreases in other regions.

Environmental Effects of Land Conversion

The conversion of noncropland to cropland is analyzed through the comparison of private costs and returns. External costs and benefits are undoubtedly generated in the conversion process, and environmental regulations are now attempting to force the consideration of these costs and benefits by the farmer. An estimate of the external cost of the conversion process was developed in the form of increased soil erosion in tons per acre per year.

Several serious environment consequences result from additional land conversion. One is an increase in soil erosion. Woodland and pastureland are land uses which minimize soil loss. The conversion of woodland and pastureland to cropland will increase soil loss dramatically on those acres. The extent of the increase in soil loss depends on the particular soil group and the crop rotation selected.

Variation in the cost, price, and yield assumptions leads to variation in the crop rotations determined to be optimal for each soil productivity group and has major implications for the resulting erosion. Figure 1 is a plot of the per acre increases in soil loss caused by conversion of woodland and pastureland in the Mississippi Delta region under conditions of 1985 baseline prices, high yield management, normal production costs, and a discount rate of 10% (Shulstad, May, and Herrington). Per acre soil loss is plotted against the acreage of soil in each soil group. In all scenarios the first soil group to be converted consists of soils that have moderate permeability, loamy surface texture, and 1% to 3% or gently undulating slope. These soils provide the greatest private rate of return to conversion but also have the highest soil loss per acre after conversion.



Note: Figure shows per acre increases in soil loss resulting from conversion of woodland and pastureland in the Mississippi Delta region under conditions of 1985 baseline prices, high yield management, normal production costs, and a discount rate of 10%.

Figure 1. Soil loss from converted woodland and pastureland

Under most alternative scenarios, the soils having slow permeability, loamy surface texture, and 1% to 3% or gently undulating slope have the lowest potential for economical conversion. These soils are also very erosive. The remaining soil groups have lower per acre soil losses after conversion.

If land is converted in descending order of its rate of return, average soil loss will not be related directly to the quantity of land converted within the Mississippi Delta region.

Both the Mississippi Delta and Iowa studies indicate conversion of noncropland to cropland can be extremely detrimental to environmental quality if effective soil erosion control measures are not used.

Within the Mississippi Delta region, the weighted average increase in per acre soil loss ranges from 8.47 tons per acre per year with 2.4 million acres converted to 14.06 tons per acre per year with 2.6 million acres converted. Average soil loss for converted acreage in Iowa ranges from 15.4 to 98 tons per acre per year.

Amos and Timmons limited soil loss to no more than 5 tons per acre per year and introduced additional agricultural practices for soil loss control. In a controlled situation, the average percentage decrease in potential cropland in Iowa is 44%, ranging from 2.1% to 68.3%. Gross soil loss is reduced 97.5%, ranging from 95.6% to 98.6%, and net income decreased about 46%, ranging from 6.4% to 89.1% (p. 143). The average soil loss is generally less than 2 tons/acre/year.

Seitz and his associates at the University of Illinois found it unreasonable for farmers to restrict their production methods in order to decrease soil erosion if their planning horizon is of a normal twenty- to thirty-year length. This being the case, federal or state programs will be required to change the incentive structure faced by farmers. However, the relationship between erosion and soil productivity remains ill-defined. Research is underway to quantify the relationship. An extensive review of this research is provided in a recent SEA white paper.

Another adverse environmental effect of land conversion is an increase in chemical and fertilizer runoff. Table 1 shows the total increase in fertilizer and pesticides applied per year to converted land in the Mississippi Delta. Concern for excessive pesticide con-

Table 1. Total Increase in Applied Materials on Converted Land Per Year: All Crops

[a] All estimates are based on an average rotation year.

centration in Delta rivers is increasing and state pollution control agencies are attempting to monitor concentration levels. Enforcement of section 208 of PL 92-500 remains tied to voluntary participation, with the hope that federal funds will be available to subsidize control mechanisms.

The economic value of the environmental impacts of conversion of noncropland to cropland has not been quantified. However, institutional changes which force a restriction of soil loss or pesticide runoff will slow the conversion process.

Alternatives to Conversion

Though significant yield increases are not expected to occur at the national level, the potential remains for increased production on the intensive margin within some regions. The Mississippi Delta study examined the potential for the upgrading of present cropland through land forming as an alternative to land conversion.

Land forming is a process of cutting down high spots and filling in low spots to create a field of uniform shape and slope. The field is first surveyed to determine the areas to be cut, filled, or left alone. Tandem dirt buckets are pulled behind huge tractors to make the cuts and haul the soil to lower areas where it is dumped as smoothly as possible to create roughly the desired slope. When the dirt bucket work is finished, a land plane is pulled over the field to smooth the soil to the final grade. Because of the exacting nature of the land-forming process, many farmers prefer to hire custom land formers rather than do the work themselves. Only 0%–1% slopes and gently undulating slopes are considered for land forming.

Land forming is also performed to eliminate old, meandering sloughs and ditches that run through fields. Local soil experts estimate this filling often increases the farmable land area of a field by 10%.

The effects of slope creation and field consolidation are immense. Drainage is improved by the elimination of low spots and the creation of better slopes. Yields are improved as a result of better drainage. The acreage of farmable land is increased with the filling of old sloughs and ditches. The efficiency of time, labor, machinery, and chemicals is increased. However, land forming can be radical surgery on some soil groups, especially those having thin top soil. Some cuts may go below the top soil into the subsoil and create spots which yield poorly for a time. The lower areas and filled sloughs and ditches are spongy until the soil settles. For these reasons a period of adjustment is required before most soils reach their pre-land-forming yields. This period varies widely among soils as do the yield reductions in the years immediately following land forming. After this period yields increase over those of nonformed cropland of the same soil group.

Rice rotations are increasingly being used as a follow-up to land forming in the Mississippi Delta because rice returns higher levels of organic matter to the soil than most other crops and does not undergo the yield reductions associated with other crops.

Land forming does add an extra cost to crop production. The field must be land planed to maintain the desired slope. Most farmers prefer to make two trips over the field yearly with the land plane but time factors sometimes prevent them from doing so.

The acreage of present cropland that could be economically land formed in the Mississippi Delta region is estimated to be 12.6 million acres. The increase in soybean production which could result from land forming in the Delta region ranges from 50 million bushels or 18.5% of 1978 production to 58 million bushels or 21.5% of 1978 production depending on the scenario examined.

The increase in regional soybean production attainable through land conversion ranges from 26 million bushels or 9.8% to 71 million bushels or 26.4%.

The conversion of noncropland to cropland and the upgrading of present cropland can be conducted simultaneously. The total increase in soybean production attainable from conversion of new acres and land forming of present cropland in the Mississippi Delta region ranges from 76 million bushels or 28.3% of 1978 production to 121 million bushels or 45.0% of 1978 production. The low estimate is based on the assumption that all land forming and land conversion is done by average managers. The high estimate is based on the assumption that the conversion is done by the upper 10% of managers.

The change in soil loss after land forming was not computed. However, the forming process creates a uniform slope of smaller magnitude than the slope on nonformed land.

Thus, land forming decreases soil loss per acre.

Irrigation

Irrigation is another alternative for increasing production on the intensive margin at the regional level. A study of the potential for additional irrigation in the Mississippi Delta region currently underway at the University of Arkansas indicates that soybean output can be increased from 26% to 71% through the economically efficient application of irrigation.

The environmental consequences of irrigation in the region are not well understood, but are believed to be less severe than those associated with gaining an equal increase in production through land conversion.

The potential for productivity gains through irrigation at the national level is much less promising (Heady).

Summary and Implication

The National Agricultural Land Study estimates the United States has the potential to increase cropland acreage by 37% (Brewer and Boxley). Regional studies in Iowa and the Mississippi Delta project the potential to convert only an additional 10%, based on 1985 price levels.

The conversion of noncropland to cropland is proceeding rapidly throughout the Mississippi Delta region, time and capital restrictions being the primary limiting factors.

Increases in soybean production as great as 45% are economically attainable within the Mississippi Delta region through the simultaneous conversion of noncropland to cropland and the upgrading of present cropland through the process of land forming. Increases in the region's soybean production of up to 21.5% can be accomplished through the upgrading of present cropland alone without any environmental damage caused by increased soil erosion.

The decision to convert noncropland to cropland has been shown to be sensitive to changes in the levels of conversion costs, yields, and production costs. Thus, regional studies such as those examined here may be needed to predict accurately the rate of conversion and the implications for society.

Agricultural and environmental agency decision makers must examine closely the incentive system now influencing the individual farmer and determine its implications for regional, national, and world communities.

Economics of Soil Conservation from the Farmer's Perspective

Wesley D. Seitz and Earl R. Swanson

Examination of the private economics of soil conservation is particularly germane at this time of policy reassessment under the provisions of the Soil and Water Resources Conservation Act of 1977. An understanding of farmers' perceptions of their economic interests is essential in the development of policy instruments that will achieve social objectives.

We classify the evidence on the farmer's perspective into (*a*) what farmers say about soil conservation as indicated in surveys of opinion, (*b*) the record of what they are doing, and (*c*) the results of models which purport to show what farmers are, should be, or are going to do. A final section of the paper deals with modeling needs.

What Farmers Are Saying

Four recent surveys of farmer opinions provide a limited sample of farmers' perceptions relative to the soil erosion problem and the appropriate means to deal with it. Seitz et al., Hoover and Wiitala; Pollard, Sharp, and Madison; and Fisher, Boyle, Schulman, Bucuvalas conducted surveys in Illinois, Wisconsin, Nebraska, and the United States, respectively. While each of these surveys has some shortcomings, they provide a basis for understanding farmers' beliefs on soil erosion questions. They indicate, directly or indirectly, that farmers perceive the existence of a soil erosion problem and many believe they should improve soil conservation on their farms. Young farmers, new owners, and conservation-practicing farmers were the most likely to recognize the need for additional practices. Changing tillage practices and crop rotations were more popular with farmers than contouring and terracing. A joint effort between government and farmers is the approach most favored to address the soil conservation problem. Policies that allow flexibility in the means of achieving conservation are preferred by farmers.

Fisher found that 62% of farmers favored taking away farmers' benefits provided by the Department of Agriculture if farmers do not properly protect the soil and water. He adds (p. 87), "It is clear that it is not mandatory programs per se that farmers reject. They reject mandatory programs that do not provide some compensation or cost-sharing."

In summary, these opinion surveys indicate a recognition of the gap between conservation levels provided by private economic incentives and social objectives. There is a continuing need to explore how various policy instruments modify the levels of private economic incentives.

What Farmers Are Doing

Although not a perfect operational conservation goal, especially when both productivity and off-site damage are considered, we accept the soil loss tolerance (*T*-value) as a standard of performance to judge what farmers are doing. The average *T*-value on cropland, pasture, and forest land is about four tons per acre per year. The 1977 Natural Resources Inventory indicated that approximately 34% of the nonfederal cropland experienced sheet, rill, and wind erosion at rates exceeding the tolerance level (USDA., p. 8). The Comptroller General's report indicated that both cooperators and noncooperators have soil losses above *T*-values (p. 16). It is difficult to estimate national historical trends in these estimates. However, Timmons (p. 5) has estimated that erosion losses have increased in Western Iowa since the early 1970s. There is reason to believe that similar patterns characterize much of the Corn Belt and perhaps the rest of the nation

---

The authors wish to thank B. Eleveld and R. D. Walker for their comments on an earlier draft.

Another form of information on farmer actions, and one which may be an important factor in changing farmer opinions is anecdotal evidence from the popular farm press. We frequently find stories of individual farmers adopting conservation practices and they have indicated, within their accounting framework, that the conservation systems have increased returns (e.g., Cole, Gogerty, Anonymous, Vogel). While their accounting systems may be suspect, they indicate the economic potential that may exist by increasing the level of soil conservation.

Modeling Farmer Decisions

Whether the results of modeling efforts can be introduced as evidence of the farmers' perspective on the economics of soil conservation depends, of course, on the degree of correspondence of the model with reality. In the limited sampling of results which follows, we find that the private economic incentives for soil conservation are weak.

Fifteen years ago Held and Clawson appraised the strength of the economic incentive for soil conservation as follows:

> In the absence of public subsidy, much proposed soil conservation has a low profit potential, some is even negative, and only comparatively little promises to be highly profitable. . . . If this general conclusion is true, then it goes far toward explaining the modest progress of past soil conservation, both in many regions and nationally, and it has great significance for the future. (p. 265)

Much of the literature Held and Clawson reviewed consisted of studies of actual farms (e.g., North Central Farm Management Research Committee). Since that time there has been a shift from the use of forage crops to the use of a wider variety of practices, with emphasis on conservation practices that do not require rotation changes. Erosion control by use of crop rotations with forage implies the adoption of livestock to make soil conservation profitable. Thus the study of actual farms, whether by budgeting or regression methods, encountered considerable difficulties in isolating the consequences of the specific practices reducing soil erosion from such factors as the variability among farmers in the efficiency of livestock production. Further, these studies could not explicitly incorporate such critical relationships as those among crop yield, depth of topsoil, and optimal level of fertilization. These, and other features, such as discounting future costs and returns, awaited the use of the more formal planning models discussed below.

One of the reasons for the shift from the statistical study of actual farms to some form of optimization modeling was the difficulty in interpreting results of analyses of actual farms due to the confounding of the effects of soil conservation with other practices. One of the simplest modeling efforts is to use the capital budgeting model with the Universal Soil Loss Equation and to examine the profitability effects of the discount rate and the planning horizon (Swanson and Harshbarger). A large number of studies using linear programming methods, often at the watershed level, have contributed to our understanding of the problem as one of profit maximization constrained by soil loss tolerance levels (for a recent example, see White and Partenheimer). In general, these studies support the weak private economic incentive hypothesis.

Control theory has been used to a limited extent. Burt has illustrated the use of control theory in analyzing the economics of soil conservation in the Palouse area of the Northwest. His analysis suggests that, when compared to rotations with lower percentages of wheat, intensive wheat production with good cultural and fertilization practices is economically justified. In another control theory application, Frohberg and Swanson solved for the optimal levels of soil erosion considering off-site damage, various discount rates, and demand scenarios. They found that, from a societal view, the soil tolerance levels in the watershed studied provided reasonably good guides for determining appropriate soil conservation levels.

The study by Young, Taylor, and Holland is an example of the use of a simulation model to analyze the long-run incentives for adoption of soil-conserving tillage systems in the Palouse. They conclude (p. 55) that if soil conservation researchers develop farming systems that save soil but which decrease yields and/or increase costs, while at the same time agricultural scientists as a whole continue making advances that increase yields in spite of topsoil depletion, economic incentives will continue for many years to favor the use of more erosive systems.

Another simulation study predicted adoption rates for minimum tillage to increase from its 1974 level of about 10% to slightly more

than 80% by the year 2010 (U.S. Senate). These rates were based, in part on the patterns of adoption of other technologies and are perhaps higher than they might have been had the economic behavior been modeled in the same level of detail as in the study by Young, Taylor, and Holland.

Modeling Needs

If we can model the farmer's soil conservation decision process more completely, we can better understand the process and communicate more effectively with decision makers. We could begin with simple farm LP models with alternative crops and practice combination budgets. To these models one could add variables and constraints or use goal-programming methods until we have identified more of the relevant features (Willis and Perlock). While such an oversimplified annual profit maximization model, with a few constraints, may miss a great deal, it may be effective in encouraging the choice of profitable soil conservation practices. But simple models are not adequate to represent the more complex choice process, so let us explore some of the additional factors of concern to the farm operator.

Long-Term Time Considerations

The topic of the farmer's perspective is on today's agenda in part because of the implications of soil loss on productivity over time, so perhaps we should start with the need to stretch the modeling period to cover the farmer's planning horizon (Frohberg; Guntermann, Lee, Narayanan, and Swanson; and Nelson and Seitz). To do so, we need to know the impact of practices on soil losses and, in turn, on yields and incomes.

Within-Season Considerations

The choice of conservation practices affects the timing of farm operations. For example, fall plowing reduces the number of field operations in the spring when time is of the essence. Contours and terraces are inconvenient with today's large machinery. Some conservation practices reduce the number of trips required for seedbed preparation. Recommended pesticide application methods requiring incorporation often result in more tillage operations than desirable for soil conservation.

Investment Decisions

The switch to a new form of tillage generally requires the purchase of new equipment. In some cases, two sets of planting and tillage equipment must be maintained. Additional financial resources may be required to purchase this equipment. Other conservation alternatives require a considerable investment (some terrace systems can approach $1,000 per acre). Recognizing the impact of the uncertain nature of farm income on this decision process would further enhance the reality of the modeling effort.

Resource Control Arrangements

The modeling effort also needs to capture the important patterns of the acquisition and control of resources. With respect to land, we not only have the more common owner-operator, and the owner-renter situations, but with the advent of the professional manager explicit recognition needs to be given to the owner-manager-renter. Further, there are part-owners who rent land from various landlords, some of whom hire professional managers. Such a farm operator is likely to need to maintain several types of tillage equipment in order to satisfy preferences of all involved and match the conditions found on the several farms. In general, the optimal level of soil conservation is likely to vary among parties in the land-control arrangements and a reconciliation of these diverse objectives is important.

Influence of Public Policy

Another element influencing the adoption of conservation practice is the public policy environment in which the firm operates (Seitz et al., Nelson and Seitz). This environment includes the current federal and state programs and recognition of the uncertainty generated by the continual development of new programs. Our understanding of the general stance currently being taken by federal and state officials is that voluntary programs will be expanded and operated for the next five years or so. If this approach proves to be inadequate, movement will be toward a regulatory approach, which will provide an interesting challenge for the bureaucrats, and for modelers.

Environmental Interactions

Soil erosion is not the farmers' only environmental concern. They are also faced with recommendations or regulations on the appropriate use of pesticides. These choices are not independent of the soil erosion control practices chosen. For example, the shift from the conventional plowing to no-till operation involves the increased use of herbicides and perhaps insecticides, fungicides and rodenticides and changes in application techniques.

Stochastic Considerations

A number of the physical phenomena involved are not deterministic. The weather pattern in a given year may impact the yields of each tillage practice differently. For example, the weather will influence the movement of plant nutrients through the soil, the effectiveness of herbicides and insecticides, as well as planting and harvesting dates. Some systems are well adapted to dry years, others to wet years. While the previous elements of our modeling enterprise may be handled by artful adaptations of the linear programming process, here we need to shift other types of models including quadratic programming with risk considerations. This may be a particularly fruitful area in that yields are more variable with some conservation tillage practices.

As economists we recognize, but only occasionally model, the stochastic market environment in which the firm operates. We need to know the farmers' reaction to changes in prices of inputs and outputs and whether soil conservation choices will impact market prices (Seitz et al.).

Beyond Economics

Thus far, we have concentrated on translating the various factors relevant to the soil erosion control decision into economic terms. It is important to recognize that this class of decision is not made solely on the basis of economics (Seitz, Gardner, van Es). There is currently discussion about the need for a conservation ethic. The operator may feel peer pressure, pressure from owners, or may have a strong personal preference for certain practices over others. Many farmers have a preference for a cleanly tilled field and straight rows. To deliberately shift to methods resulting in a trashy field and curved rows may be difficult.

In essence we are painting a picture of a farm decision process that is much more complex than represented by the models we find in the literature. As we construct more appropriate models of the overall farm planning process, we may be able to improve our explanation of soil conservation decisions made by the farm operator. We also may identify changes needed in these decisions. We still have a long way to go to develop the types of models needed to characterize the full range of considerations that impact on farmers' decisions regarding soil conservation and to enable us to perform our educational function more effectively.

The Impact of Landownership Factors on Soil Conservation: Discussion

Daniel Bromley

The question of resource use patterns as influenced by institutional arrangements is at the core of any understanding of natural resource economics. All of the conventional explanatory variables, such as rates of time preference, prices, income, user costs, and risk preferences, are meaningless without being related to the nature of the decision-making unit. A family is clearly a different decision unit than is a corporation, and a partnership is different still.

Lee is to be commended for beginning an investigation which, if it ever succeeds, will be indispensible to our understanding of important resource use issues. While I am most supportive of the general enterprise, I am troubled by the specifics of her approach. In these brief comments I will raise questions about the empirical models, the data, and the conclusions. I will then offer a few closing remarks.

The Empirical Models

I am disappointed that she did not present the estimating equations for her two models, and in their absence it is not always clear what is being regressed on what. In Model I it is clear that non-family corporations are the excluded class in her dummy regression. Coefficients for other ownership classes then reflect differences in the mean rate of erosion for each class as against the excluded class. However, it would have been better if she had employed the more appropriate stance of testing the hypothesis that these other coefficients are equal to zero. While formally equivalent, it would have been clearer when consulting her table.

Turning to Model II, she tested differences in soil erosion among income and tenure variables, but only the results for income are presented in table 2. This is confusing since the discussion pertains to results which were not presented in the table. We are told that the "relationship between net farm income and mean levels of erosion appeared to depend on the tenure category of the landowner." Yet, the analysis behind this observation is not presented.

The Data

The universal soil loss equation was utilized to determine rainfall erosion data. It bears remembering that this relationship was derived from—and only really applies to—soil conditions in the upper Midwest. I am therefore worried about what went into the most crucial variable in her entire investigation.

Of equal concern is the partition of the explanatory variable. My friends who do empirical work in other areas of economics are always envious of the data base available to agricultural economists. But the bad news is that we often end up with data which are mere numbers rather than useful scientific information. I worry about the classification of ownership in this work. The ownership classes are legal descriptions which attempt to define different types of decision units, when in fact they merely define different types of income and cost accounting practices. I am skeptical that institutional arrangements designed for tax purposes are relevant to how people use their soil resource.

Conclusions

In a suggestion for more research, she states that age and education are important variables which ought to be included. One of these—age—follows from our neoclassical orthodoxy which places great stock in one's rate of time preference. Excluded, of course, because we are loathe to put it in our models, is ethnicity. We have found in Wisconsin some differences

Daniel Bromley is a professor in the Department of Agricultural Economics, University of Wisconsin-Madison.

in attitudes about—and thus behavior with respect to—soil erosion across ethnic groupings. Additionally, she mentions changing structural characteristics in agriculture as it relates to erosion. However, this seems of a rather longer-run nature than our data will reveal. I suggest that it is preferable to do impeccable cross-sectional analysis of existing structural differences. Then, employ the work of others to forecast likely structural changes, and finally infer what those structural changes would mean for erosion in light of our cross-sectional models.

In closing, I find that her analysis does not give me sufficient basis for accepting her results. There are severe data problems. Nowhere in tables 1 and 2 are we shown standard errors for the estimates which have been derived. And the very important results relating erosion, income, and ownership class were not presented. Moreover, the definitions of the explanatory variables are too gross to have analytical meaning. I do, however, applaud Lee's efforts at attempting this general kind of analysis. I urge her to continue to pursue the matter. But I also urge her to disaggregate her explanatory variables into analytically relevant categories.

Conversion of Noncropland to Cropland: The Prospects, Alternatives, and Implications: Discussion

Pierre Crosson

Shulstad and May have done a good job of identifying and giving perspective to the principal issues this country likely will face over the next several decades in managing its agricultural land and water resources. Their paper is well done, and I have no quarrel with either the main thrust or the details of their argument. I propose, rather, to use the paper as a point of departure to discuss some of the research and policy issues the paper suggests.

Current trends in demand for U.S. exports of grains and soybeans, combined with current trends in per acre yields of these crops suggest strongly that the demand for cropland will increase by tens of millions of acres over the next two or three decades. Judgments of the amount of the increase depend upon the details of one's expectations about export growth and yields, but I think it not unlikely that demand for harvested cropland could increase to 400 million acres by the first decade of the next century, some 60 million more acres than were harvested in 1979. Since our present cropland base is fully utilized, the additional cropland would have to come from conversion of land now in some other use.

The Soil Conservation Service's Natural Resources Inventory (NRI) indicated that under price, cost and yield conditions of the mid-1970s the nation had 127 million acres of land in pasture, forest and range that could be converted economically to cropland. This would seem to indicate a reserve more than adequate to accommodate any likely increase in demand for cropland over the next twenty or thirty years.

However, Shulstad's and May's estimates of potential cropland in the Mississippi Delta raise a question about the NRI's figures. Under the most favorable assumptions about crop and input prices, conversion costs and yields (assumptions more favorable than the conditions underlying the NRI figures), Shulstad and May estimate potential cropland in the Delta to be only about 10% of present supply. According to the NRI, in 1977 potential cropland in the Delta states of Arkansas, Louisiana, and Mississippi was 48% of supply. One would expect potential in the Delta proper to be less than in the Delta states as a whole, but I doubt that this explains much of the observed discrepancy.

The estimate of Shulstad and May is based on a detailed study. If one had to choose between their estimate and those in the NRI I believe theirs would have to be preferred. If this is correct then conversion of cropland in the Delta on the scale indicated in the NRI would entail substantially higher costs and would be undertaken only if crop prices were much higher than the prices underlying the NRI figures.

The contrast between the estimates of the NRI and of Shulstad and May for the Mississippi Delta suggests that detailed studies of potential cropland are needed in other major crop producing regions. The southeast, northern and southern plains, and cornbelt states, other than Iowa, are obvious candidates. (Iowa already has been studied by Amos, as Shulstad and May note.) If the nation's supply of potential cropland is as inelastic as the work of Shulstad, May, and Amos suggests, the sooner we know about it the better. Continued reliance on the NRI estimates would underestimate the pressure of current trends in exports and yields on the agricultural land base.

Shulstad and May, and Amos in his study of land conversion potential in Iowa, also estimate the increases in erosion that would result from converting land to crops. In the Delta conversion of all the potential land would increase erosion by 14 tons per acre on average.

Pierre Crosson is a senior fellow at Resources for the Future.

In Iowa erosion would rise to 15-to-98 tons per acre. While neither of the studies attempted to measure either the off-farm or on-farm costs of these rates of erosion, these costs clearly could be high. Moreover both studies indicate that the cost to farmers of holding erosion within SCS desired limits (5 tons per acre or less) would be high. Consequently farmers will not do this voluntarily.

The prospect that conversion of potential cropland to crops will impose sharply higher costs of erosion indicates that we need to know much more about these costs, both on-farm and off-farm. In this connection, the research now under way in the USDA on the relationship between soil erosion and yields, referred to by Shulstad and May, is most welcome. I hope it will be vigorously pursued. Because of the strong advantage of conservation tillage in reducing erosion, we also need to know more about the economics of this technology relative to conventional tillage. Judging from its rapid spread since the mid-1960s conservation tillage has significant economic advantages under many circumstances. If we knew more about these circumstances we could identify the factors limiting further spread of conservation tillage and could design research to extend these limits. This route offers a way to deal with the erosion problem which works with the farmer's economic interest rather than against it as, e.g., erosion control regulations or taxes on excess soil loss would do.

If we think the mounting pressure on the nation's agricultural land base will be too great we could seek to reduce it by limiting the expansion of exports or stimulating faster yield increases, or by some combination, of course. Export quotas would stir a political hornet's nest, and in any case go against the deep grain of American foreign trade policy. Imposition of an export tax to reflect the costs of erosion and other externalities is appealing in principle, but would be extraordinarily difficult in practice, in large part because we do not know these costs. An expanded effort to accelerate the growth of food production in developing countries is an attractive alternative, for reasons that go beyond reducing the pressure on the agricultural land base. If that pressure is high enough to be troublesome it will be associated with high crop prices, which should reduce farmer opposition to a policy which over the long term would reduce the growth of their foreign markets.

Policies to stimulate faster growth in crop yields are the most attractive of all in my judgment. The social return to agricultural research continues generally high in the United States (Evenson, Waggoner and Ruttan). If the economic and environmental costs of agricultural land rise, as my interpretation of Shulstad's and May's results suggests, the return over the next several decades to research on yield-increasing technologies may be very high indeed. In this connection, Shulstad's and May's conclusions about the yield-increasing effects of investments in land-forming are interesting. These investments evidently begin to pay off in three or four years, while the pay-off to investment in developing new technologies is much longer delayed. The studies mentioned earlier of land conversion potential in the Corn Belt and other main crop-producing regions should incorporate analysis of the yield-increasing potential of investments in land-forming. This potential may be significant. Better knowledge of the potential likely would suggest policies for quick capture of it.

Economics of Soil Conservation from the Farmer's Perspective: Discussion

Gordon C. Rausser

Unfortunately, Seitz and Swanson (hereafter referred to as SS) fail to provide us with a clear focus of the soil conservation problem or, for that matter, the principal issues that arise in attempting to solve the problem. Hence, in these comments it seems appropriate to address first the nature of the soil conservation problem, and then briefly examine some major analytical issues and critique the SS survey.[1]

Soil conservation can be thought of loosely as a redistribution of resource use into the future relative to the present and is the opposite of depletion. Soil conservation is, in effect, a problem in capital theory whose operational implementation is the management of soil resource over time. Since soil conservation is inherently dynamic, a number of thorny issues arise in the intertemporal specification of the problem. Soil conservation is most certainly a multidimensional problem which encompasses far more than just loss tolerance levels. The trade-offs faced are similar to most capital theory problems but in the case of soil conservation are compounded by the lack of knowledge, measurement problems, and important distinctions between quantity and quality dimensions.

In the above setting, a number of perspectives are possible. SS provide us with two perspectives. They begin their paper with a public policy perspective arguing that an understanding of farmers' behavior is essential in the development of policy instruments that will achieve social objectives. However, they end their paper with an educational function perspective in which we are charged the responsibility of developing optimal private strategies that might be pursued by farmers who fail to have adequate knowledge or know their own best interest. In this discussion, I will focus on the first perspective since it subsumes the second.

The public policy perspective requires some clarity of thought in terms of the nature, extent, and basis for market failure. Market failure can be interpreted broadly in terms of conventional exchange markets, contract markets, and political markets. In some quarters, the perception is that existing institutional and incentive structures result in suboptimal management of soil resources. Divergences between social and private net benefits may be caused by tenure, credit rationing, and uncertainty features of the agricultural sector; by discrepancies between the societal planning horizon and the planning horizons (myopic) of individual farms; by discrepancies between farmers' time preferences and the social rate of time preference; by externalities (runoff and sedimentation); by the differences between public and private risk preferences; and by "price divergences" generated from "political markets" reflecting transfers of wealth via governmental intervention (price supports and deficiency payments). What is needed at this juncture are fewer surveys and more serious measurements of such divergences.

The extreme heterogeneity and complexity of soil resources in an operational setting calls for "enlightened" partial analyses. The focus of such analyses should be on the relationships among important variables of the soil resource which trace systematically through time the important factors affecting productivity. As SS note, many of these relationships have not been estimated empirically. Nevertheless, an important first step in any empirical measurement is the conceptualization of the phenomenon to be measured. Here, we must recognize that soil is not a single resource but a set of individual interrelated components which have both stock and flow dimensions. Moreover, what information is available can be em-

Gordon C. Rausser is chairman and professor, Department of Agricultural and Resource Economics, University of California, Berkeley.

[1] A more detailed set of comments may be obtained from the author upon request.

ployed under uncertainty using advancements that have been made in stochastic models over the last decade.

An important but neglected issue relates to the joint product goods and bads associated with a number of important inputs, e.g., water, chemical pesticides, and certain types of machinery (Rausser and Lapan). In this framework, soil quality is not simply an afterthought but assumes direct importance. Unfortunately, soil quality is not easily monitored. Improvements in technology or the expectation of such improvements, for example, may mean that yields increase even if soil quality falls; hence, yields are not an unequivocal signal of the state of soil quality. Such effects may mean that soil quality is not incorporated in land values in an easily discernible manner.

Given the above brief sketch, what does the survey by SS offer us? The results that they summarize certainly make a case for governmental intervention by substantiating the weakness of private incentives for soil conservation. By themselves, however, these results do not necessarily imply a problem; if farmers are operating at or near an optimum, incentives for change ought to be weak. Only by testing properly formulated hypotheses can we hope to accumulate evidence of market failure and inefficient behavior of private agents. The principal message of the SS survey is that we need basic conceptual and empirical work to formulate more accurate models characterizing private behavior.

The directions for future modeling efforts outlined by SS can be seriously challenged. To be sure, farm LP models can only be of limited value in understanding soil conservation. Management of the soil resource is inherently dynamic, and thus static constructs modified by various bells and whistles provide little insight. Furthermore, the technique perspective implied by such recommendations as goal and quadratic programming methods strikes me as inappropriate. Similarly, the addition of soil-loss constraints in static models most likely detracts rather than enhances our understanding of the basic trade-offs that must be evaluated. Arbitrary levels of soil loss have little economic meaning, and most certainly such measures should be generated endogenously in any "sufficiently" accurate modeling approximation to the soil conservation problem.

While some areas of investigation suggested by SS appear promising, others should simply be dismissed. For example, the argument that farm owners over sixty-five years of age are not particularly concerned with long-run impacts of their land utilization practices runs contrary to available empirical evidence and intuition. Owners certainly place some value on their heirs; and since the quality of land transfer from one generation to another constitutes a portion of inherited wealth, sound judgment suggests that this argument should not weigh heavily in our investigations of soil conservation. It seems far more likely that land values which fail to reflect soil quality accurately contribute more as the source of this problem than does the age of landowners.

Abstracts

AAEA Teaching Workshop

(Southern Illinois University, Carbondale, 24–26 July 1980)

Evaluating Student Participatory Models for Teaching Economic Theory: Some Preliminary Results. Josef M. Broder (University of Georgia)
This paper discusses the purpose, design, implementation, and evaluation of student participatory models used to supplement traditional approaches to teaching economic theory. Preliminary evaluations indicated that students found these models useful and recommended their expanded use. A reduction in cognitive skill differences among students with unequal human capital was attributed to the models.

Teaching Agribusiness Management: Junior, Senior Level. Dennis M. Conley (University of Illinois)
The paper focused on the use of a computer game and field trips as tools for experimental learning. The game integrates lecture material on financial analysis, pricing and margins, inventory management, planning and organizing, leadership, and communication skills. The game also simulates experience in decision making and it reinforces the learning process.

Field trips are used to identify agribusiness industry and the internal operations of a firm. Students learn of potential employers' expectations and what course material is needed. The students then recognize the usefulness of certain course topics. An agribusiness management game and field trips are significant pedagogical tools.

Using Guided Design in a Classroom. Carl O'Connor (Oregon State University)
Guided design is an educational strategy that makes it possible for teachers to accomplish simultaneously two goals which have severely resisted integration: (*a*) teaching subject matter and (*b*) developing the decision-making skills required to apply what has been learned to the solution of real-world problems. The concept was first introduced into agricultural economics literature in 1976.

This teaching technique is useful in recitation classes, where the teaching goal is to extend the lecture and the material assigned as reading to an applied problem requiring decision-making skills. In guided design, a series of open-ended questions and feedback gradually expose a complex problem setting that the student must eventually grasp as a whole. One of the objectives of using this technique is to help the student handle ambiguity, an inherent part of almost all professional situations.

With guided design, the teacher models professional reasoning and shows students how the material they study can be used to make better decisions. This process increases the students' motivation and improves the retention of subject matter.

Selecting a Teaching Method. Carl O'Connor (Oregon State University)
College and university teachers are turning to alternative approaches to the conventional lecture. This response is being triggered by the increased demand by students for a "better education" in line with the demands and prerequisites of employers to come prepared to work with operational skills and knowledge. Other reasons for this pressure to consider alternative teaching methods are factors such as cost effectiveness, minimal standards and competency that must be reached by all students taking the course, administrative review and evaluation reports of teaching performance, peer pressure, and student feedback.

Three alternative teaching methods were demonstrated at this workshop: (*a*) conventional lecture, (*b*) audio-tutorial, and (*c*) guided design. To evaluate these methods, a matrix of thirty potentially important criteria are suggested.

Communicating in the Classroom. W. David Downey (Purdue University)
Using lecture, discussion, and small group exercises, basic concepts of communicating were demonstrated. Attention focused upon models of classroom communications, factors affecting communications, and methods of communications. These were examined in terms of classroom size and other variables. Participants presented and exchanged teaching ideas.

Agricultural Marketing Block Program. Thomas I. Gunn (California State University-Fresno)
An innovation in classroom instruction, the Agricultural Marketing Block Program by the Department of Agricultural Economics at California State University-Fresno, began during the spring semester 1975. The block is planned to bridge the gap between classroom instruction and the world of agricultural business and marketing.

The block program departs from the usual lecture format course. Some lectures are presented by the instructor, but extensive utilization is made of

closed-circuit television, field trips, future-trading games, roundtable discussions, student presentations, class demonstrations, educational films, and the participation of resource people from both inside and outside the university. Objectives, characteristics, evaluation, and potential uses of the block program are discussed.

Lecturing. L. H. Newcomb (Ohio State University)
The lecture method of teaching has situations for which it is suitable and unsuitable. In addition, there are a number of problems which must be solved. These problems are (*a*) inadequate preparation, (*b*) sloppy organization, (*c*) lack of animation, (*d*) failure to converse with the audience, (*e*) lack of clear illustrations, (*f*) monotonous tone, (*g*) too much or too little information presented, and (*h*) information presented too fast or too slowly.

Professors need to examine the characteristics of outstanding lecturers and compare those characteristics to their own individual characteristics. When this comparison reveals substantial differences, then professors need to be sure they are not using a method that unduly exploits their weaknesses. Most people will find that straight lecturing is seldom effective and need to consider a number of complements to the lecture. Some of these complements are boardwork, transparencies, slides, charts, concrete frames of reference, specimens, guests, role plays or skits, questions, and problems.

Identifying Learning Conditions. L. H. Newcomb (Ohio State University)
There are a number of conditions which affect teaching and learning. Some of these conditions deal directly with the student as a learner, while others deal specifically with the behaviors of teachers.

Teacher behaviors which are consistently correlated with improved student behavior are clarity, variability, enthusiasm, task-oriented and/or businesslike behaviors, student's opportunity to learn criterion material, and absence of excessive negative criticism.

Group Discussion: Marketing. Andrew Novakovic, moderator (Cornell University)
The purpose of the group discussion was to share course outlines, lecture materials, class exercises, and innovative ideas on teaching among instructors of agricultural marketing. The results of two surveys were presented. The first was a survey of marketing courses that included sixty-four undergraduate course outlines from forty-two universities (Cornell University). The second survey was of class exercises used in introductory agricultural marketing courses at thirteen universities (Purdue University). Further discussion in the group involved a variety of topics, including the appropriate orientation of marketing courses to meet the needs of a diverse student body, the use of games, field trips, labs, and the like to illustrate important concepts in marketing, and the development of instructional materials and readings for specific topics in agricultural marketing.

Experimental Learning Aided by a Microcomputer. D. D. Osburn, K. C. Schneeberger, M. R. Wilsdorf, and E. S. Reber (University of Missouri)
The use of the microcomputer to teach and reinforce concepts in farm management and agricultural finance courses is discussed and compared to other computer-assisted instructional techniques. Six microcomputer programs in the farm management/farm finance-related areas were written to be as user-oriented as possible so that students could operate them with a minimum of instruction. Procedures for effective use and evaluation of microcomputers were discussed.

The use of the microcomputer appeared to increase motivation among students. Other benefits included: (*a*) sensitivity analyses of several types were more readily achieved and observed by students as they changed input data, (*b*) students were able to approximate the real world with greater ease, and (*c*) students could put theory to a test in the models.

Requisites for Successful Undergraduate Programs in Agricultural Economics. Thomas R. Pierson (Michigan State University)
The following assumptions describe the likely planning environment for undergraduate program development during the 1980s: restricted resources from conventional sources of funding, limited growth in the numbers of traditional students, moderate growth of "mainstream" employment areas, increased opportunities to provide educational services for "new" clientele groups, the potential for stronger agricultural economics/industry and public sector relationships, and opportunities for effective market segmentation of educational programs.

Successful programs will serve the following requisite needs of students, employers, and society: quality advising and faculty contact with students, improved communication with potential employers and society, emphasis on the teaching of marketable entry-level and life-long career skills coupled with the development of general living skills and philosophies, and greater effectiveness in the recruiting and job placement processes.

Agricultural Economics in the 1980s. Phillip F. Sisson (Quaker Oats Company)
The dynamic changes in American agriculture over the past decade have vastly altered the analytical

approach of the agricultural economist employed in industry. No longer are the changes in domestic requirements the prime mover of commodity prices. Rather, the demand emanating from the foreign sector and the outlook for production in the major importing and exporting nations have surfaced as the important areas of analysis.

A better understanding of new factors influencing agriculture and agricultural trade is needed. These include foreign agricultural supply and demand, internal agricultural policies of other nations, trade and trade policies, weather and climate, foreign currencies, and precious metals.

An Audio-Visual, Self-Learning Program for Beginning Students in Agricultural Economics. Kelso L. Wessel (Ohio State University)

This paper describes the development, cost, and personnel required for Audio Video Institutional Supplement (AVIS) in a beginning agricultural economics course. Evaluation of AVIS was made in terms of study habits, use of student workbooks, problems completed and student performance. AVIS is an important supplement for students who encounter difficulty understanding the concepts from traditional type lectures. Student reaction to AVIS was very favorable.

Toward Excellence in Teaching. Neil E. Harl (Iowa State University)

Improving the effectiveness of teaching involves disaggregating the teaching-learning function into three components: the student, the educator, and the instructional process, all in the setting of the academic institutions.

The modern university, the major academic institution, occupies a unique role with respect to its teaching function. The essential mission of the university is the renewal of civilization by developing the potential for creative minds capable of critical and independent thought, with the ability to communicate effectively. Thus, the teaching-learning process should produce in students: (*a*) the ability to think and reason—creatively, analytically, thoroughly, and with reasonable alacrity, (*b*) the ability to communicate in writing—accurately, precisely, and with a richness worthy of the language, and (*c*) the ability to speak in a clear, articulate, and convincing fashion.

Excellence in instruction is difficult to define but includes, on the part of the educator, knowledge of subject matter, the ability to communicate with students, a boundless enthusiasm for the discipline and its power, a continuing interest in students, an ability to make the educational process interesting, the quality of encouraging students to search widely for grist for the analytical mill, and a professional approach to the teaching-learning process.

Curriculum for the 1980s. Ronald D. Kay (Texas A&M University)

An agricultural economics curriculum for the 1980s will need to recognize the trend toward nonrural backgrounds among many of our students, changes in the profession, and the market for our graduates. In addition to changing the content of many existing courses, additional courses may be required in the areas of technical agriculture, communications and interpersonal skills, computer technology and applications, accounting, and business management. Good teaching will also be needed to strengthen and improve the product of any curriculum.

Perspectives on Resource Economics Teaching. John A. Miranowski (Iowa State University)

The application of economic concepts to natural resource and environmental decision making is a relatively new field of teaching specialization that continues to undergo dramatic change. The objective of this session was to determine what educational methods and materials are useful for particular instructors and why. Many of the participants believed that capitalizing on the diversity of the students through "guided design" discussions was an effective, although sometimes difficult, teaching strategy. Also, illustrations with actual resource problems were particularly helpful.

Abstracts

Symposia

Agricultural Estate Planning: A Micro Perspective. Stephen F. Matthews, chairperson (University of Missouri); David Reinders, Michael Boehlje, and Neil E. Harl (Iowa State University); C. Allen Bock (University of Illinois); and J. W. Looney (Kansas State University)

Some estate planning decisions are made more easily if projected results of various options can be quantified. Computers can be useful by producing such specific information as estate tax costs of different alternatives under varying assumptions. Computer programs such as Iowa's Computer Assisted Estate Analysis can be of assistance but cannot replace professional counsel because computers cannot exercise judgment.

A "disclaimer" is a refusal to accept property otherwise passing to an individual by gift or inheritance. The property passes to a third party chosen by law rather than by the disclaimer. A "qualified disclaimer" occurs where the indirect transfer from the disclaimant to the third party is not treated as a taxable transfer for gift or estate tax purposes. Qualified disclaimers can provide built-in flexibility, rectify improper funding of the marital deduction, add assets to trusts with income to the surviving spouse, avoid generation skipping tax traps, modify powers that could have adverse tax consequences, and insulate property from creditors.

Internal Revenue Code Section 2032A "use valuation" allows qualifying farmland to be valued for estate tax purposes significantly below its value on the auction block. In practice, use valuation has resulted in savings to taxpayers beyond original predictions. Newly issued final regulations (31 July 1980) clarify some of the ambiguity present in the original legislation. These regulations state, *inter alia*, that simultaneous activities of multiple family members cannot be aggregated to find the requisite material participation and that the availability of cash rental data for comparable property is a prerequisite for utilizing the formula method of use valuation.

Export Marketing Performance of the Major Grain-Trading Nations. Lowell D. Hill, chairperson (University of Illinois), Reynold P. Dahl (University of Minnesota), William W. Wilson (North Dakota State University), Parr Parsons and Michael Cook (Texas A&M University), Leonard Schruben (Kansas State University), Ed Tyrchniewicz (University of Manitoba), and Alex McCalla (University of California-Davis)

Recent congressional interest in the creation of a national grain-exporting agency has focused attention on methods for evaluating alternative grain-marketing systems. The conventional structure-implies-conduct-implies-performance approach fails to address a number of issues peculiar to the international grain trade. The organization of this symposium resulted from a felt need for criteria and methodology useful in assessing grain-marketing system performance directly.

Four principal points were raised. First, the perfectly competitive model may be useful as a benchmark in evaluating the pricing efficiency of the U.S. system. The first paper concluded that price transmission performance between export terminals and county elevators in the United States closely approximates a hypothetical perfectly competitive market. Second, a comparison of alternative system organization can be drawn by contrasting pricing performance between the U.S. and Canadian systems. The second paper argued that, exclusive of transportation costs, price differences in the two systems are not statistically significant. Third, papers using the Australian and Argentinian systems as examples contended that a system performance evaluation cannot be made without a full appraisal of the economic and agricultural policy environment in which it operates. The final paper provided some subjective insights into possible problems and conflicts inherent in a shift in the U.S. system from private enterprise to one with more active government involvement.

Foreign Fishing Policy within the 200-Mile Limit: Its Impact on Domestic Fishery Development, Processing, and Consumer Welfare. Jon M. Conrad, chairperson (Cornell University), Mort Miller (National Marine Fisheries Service, Washington, D.C.), Dan Huppert (National Marine Fisheries Service, La Jolla), Bob Stokes (University of Washington), and Virgil Norton (University of Maryland)

Miller sought to (*a*) define the nature and scope of current foreign fishing within the 200-mile zone, (*b*) review the fee structure facing foreign vessels seeking to fish in U.S. waters, and (*c*) discuss some elements of the Breaux bill which seeks to amend the FCMA. Japan was the major foreign fishing nation, accounting for about 56% of foreign catch by value.

A foreign vessel is charged $1.00 per gross ton for a permit to fish in U.S. waters and 3½% of the ex-vessel value of the allocated catch (based on U.S. ex-vessel prices). Recently, a 20% surcharge on fees has been added with surcharge revenues going into a gear damage fund to compensate U.S. fishermen for gear damaged or lost by foreign vessels or severe weather. Estimates of the costs of enforcement vary, depending on methods of prorating Coast Guard vessel costs. One intermediate estimate puts the cost of enforcement at $65 million or

3.6 times the revenue generated by foreign fishing fees.

Huppert noted that foreign vessels off the coasts of Washington, Oregon, and California were predominately taking high volume/lower value species and processing them into frozen products at sea. Rapid processing is important to ensure the quality of many species such as Pacific hake. Development of large trawler/processing capacity may be essential if the United States is to harvest economically certain species. Alternatively, joint ventures where foreign processing vessels rely on catch from U.S. harvesting vessels might also play a greater role in domestic fishery development.

Stokes noted that development of U.S. capacity and interest in the Pacific groundfisheries has been slower than expected. As a result, policies governing foreign access to "surplus stocks" will be of continued importance. Consistent with the intent of FCMA the current fees are nominal, having little to do with the extraction of resource rents or efficient resource allocation. The State Department and other agencies may actually prefer the present nominal structure in that it allows them a certain amount of discretion in dealing with foreign governments seeking surplus allocations. Access to U.S. fish stocks may be part of a quid pro quo in tariff and trade negotiations. Stokes outlined an applied research agenda.

Norton concluded the symposium echoing some of the comments of earlier panelists calling for research into (*a*) the markets for auctioning foreign fishing rights, (*b*) the distribution of benefits between fishermen, processors, and consumers, and (*c*) the role that foreign fishing and domestic policies should play in achieving overall management objectives. Norton felt it important that the NMFS increase its capability to perform more detailed and longer-term analysis of the economic effects of alternative foreign and domestic fishing policies.

Preliminary Results from the Nationwide Food Consumption Survey 1977–78. Robert O. Herrmann, chairperson (Pennsylvania State University), Robert L. Rizek (SEA USDA), Rueben C. Buse (University of Wisconsin), Stanley R. Johnson (University of Missouri), and Barry M. Popkin (University of North Carolina)
This symposium discussed the progress of the 1977–78 USDA Nationwide Food Consumption Survey, methodological problems in the analysis of households analysis, and planned research with the survey data.

Rizek suggested, and it was generally agreed, that research is needed on the data needs of food survey data users and on ways to speed the collection and release of survey data. Rizek also noted the need for more research on household food waste.

Both Buse and Johnson argued that many methodological problems remain in the analysis of household food consumption data. These arise out of the nature of current consumption theory, the characteristics of data describing household consumption and household demographic characteristics, and the statistical tools available for data analysis.

It was suggested by Popkin that the 1977–78 survey is not completely adequate either for nutritional analyses or for study of program impacts. Better indicators of nutritional outcomes (e.g., measured height and weight) and information on health problems or concerns are needed. For program analyses, historical information on participation is needed as well as data to permit control of factors the effects of which would otherwise be attributed to program participation.

Methodological and Evaluation Issues in International Farming Systems Research. B. F. Stanton, chairperson (Cornell University), Larry Harrington (International Maize and Wheat Improvement Center, Mexico), Edward Price (International Rice Research Institute, Philippines), Richard Bernstein (Central Research Institute of Agriculture, Indonesia), and Earl D. Kellogg (University of Illinois)
Major issues regarding the methodologies to use in studying farming systems in a variety of settings were central to this symposium. Concentrating on target enterprises as they relate to the whole farming system was preferred over the holistic approach of trying to consider simultaneously all the variables that may affect a farming system. Target groups of farmers were identified in two ways: by common agro-climatic and socioeconomic factors and major differences in crops or livestock in the farming systems. These approaches may finally yield similar results but require different data for implementation.

There were differences of opinion regarding the usefulness of attempting to define productive research directions a priori. Efforts to prescreen technology and collect data regarding major farmer problems and goals by survey was given priority by some. Other participants thought scientists' observations of farmer trials yielded more useful information. Most agreed that economists should work with other agricultural scientists in identifying key problems and possibilities for research.

The need for evaluation methodologies that can be used by persons with modest economic training was emphasized. In some national programs where research staff resources are thin, standardized data collection and analysis procedures making use of programmable calculators can be emphasized. Evaluation of new technology as part of a farming system managed by current farmers was discussed. The problem of variability among farms and over time was recognized. The need for evaluation methods which focus on (*a*) stability and flexiblity of farming systems over wider areas, and (*b*) the

productivity of international and national farming system programs were considered.

Modeling Energy Use at the Farm Level with Emphasis on Crop Farms. Ken Schneeberger and Herman Workman, chairpersons (University of Missouri), Vernon Eidman (University of Minnesota), Robert Peart (Purdue University), Marvin Duncan (Kansas City Federal Reserve Bank), and John Holt (University of Florida)

The profession is poorly prepared to respond to questions on the economic feasibility of alternative conservation and self-sufficiency scenarios. Any modeling effort must be done in the context of the food and fiber system. As the price of energy relative to other resources changes, it may be economic to shift some functions from off-farm firms to farmers, and vice versa.

Three types of farm level studies are (*a*) technology assessment, (*b*) whole farm organization, and (*c*) structure studies. Technology assessment refers to studies that evaluate only one part of the business, e.g., solar grain drying or irrigation. Whole farm organization is a continuation of what farm management and production economists have done for a long time, but with a new dimension. Work under structure emphasizes management problems associated with different types of farms under changed energy conditions and the implications of higher priced or rationed energy on farms by size, type, and control.

Important considerations in energy modeling are (*a*) the time frame that is specified, (*b*) linkages to other units of the food-fiber system, (*c*) appropriateness of energy scenarios, (*d*) the multidisciplinary nature of many problems, (*e*) use flow of energy by form where possible, (*f*) fit in energy production options where it is logical, (*g*) incorporate uncertainty as feasible, and (*h*) do not overlook the management complexity of the options evaluated or included in the analysis.

There was strong agreement on need for greater cooperation and interaction of agricultural economists and scientists of other disciplines. The agricultural engineers, in particular, have been doing useful basic work in technology assessment and energy flows. Among gaps the agricultural engineers see in agricultural economics research are (*a*) not keeping up with current technology, (*b*) overemphasis on Btu accounting to the exclusion of energy form, and (*c*) tendency to ignore weather data and weather-related factors like good field working days.

Optimization of Simulation Models. James N. Trapp, chairperson (Oklahoma State University), Oscar R. Burt (Montana State University), Daryll E. Ray (Oklahoma State University), and C. Robert Taylor and James W. Richardson (Texas A&M University)

The symposium presented and discussed the experiences of five researchers using optimization methods in conjunction with simulation models. The purpose of the symposium was to (*a*) familiarize those in attendance with the concept and nature of optimization procedures that can be used to optimize simulation models, (*b*) review the experiences of the participants in using such procedures, and (*c*) contrast the appropriateness of such procedures to other methodologies.

Trapp characterized the nature of simulation models and noted that their informal structure necessitates numerical rather than mathematical optimization. He outlined the conceptual basis of two nonlinear numerical optimization methods, gradient search and direct search. Taylor commented upon his applications of gradient search procedures to several simulation models including a pesticide management model and a grain stocks model. Richardson reviewed his experiences using a direct search procedure in conjunction with a macroagricultural policy model. Ray discussed the need to match the optimization algorithm with the structural simulation model rather than constructing a simulation model that satisfies the requirements of a particular optimization methodology. Burt contrasted dynamic programming with nonlinear optimization and discussed the use of dynamic programming in stochastic models.

The Role of the Agricultural Economist. D. L. Debertin, chairperson (University of Kentucky), John M. Huie and Rodney L. Clouser (Indiana State Budget Agency), Richard L. Barrows (University of Wisconsin), Glenn Nelson (University of Minnesota), Fred C. White (University of Georgia), George McDowell (University of Massachusetts), and George Goldman (University of California-Berkeley)

This organized symposium discussed the role of agricultural economists working with state and local government decision makers from three perspectives: (*a*) state government personnel, (*b*) research, and (*c*) extension. Huie and Clouser argued strongly for an approach in dealing with state and local government workers in which issues are resolved by the agricultural economist specifying alternative solutions to problems and probable consequences of each alternative. Barrows felt strongly that an advocacy approach was not an effective way to deal with decision makers.

Nelson argued that agricultural economists should take a more active role in determining what ought to be with respect to public decision making and not to adopt goals that are always consistent with those who have economic and political power. He felt that researchers have an obligation to include recommendations while making clear the researchers' underlying values. These views were largely supported by White.

McDowell and Goldman stressed the difficulties in understanding and measuring a community welfare function. McDowell noted that decision mak-

ing within communities necessarily leads to conflicts among various groups affected by the decision. Agricultural economists need to recognize that the political process that leads to the resolution of these conflicts is usually not irrational or unpredictable.

Distribution Impacts of Agricultural Policies: Conceptual Framework and Data Needs. David Harrington, chairperson (ESCS USDA), Don McClatchy (Agriculture Canada), and Mike Boehlje (Iowa State University)

Issues related to the distributional impacts of agricultural policies have been given increased attention. It is becoming more evident that policies affect farms and related households with different characteristics in different ways. Consequently, questions about the adequacy and relevancy of already-available data have emerged.

Speakers pointed to: (*a*) the need for income and wealth data related to households as well as farming establishments; (*b*) advantages of clearly identifying the agricultural sector and the need to develop specific accounts that take into account inflationary conditions of the economy; (*c*) costs and difficulties of obtaining reliable data on variables that indicate income, assets, and wealth; and the (*d*) experience that access to farm taxfile data and linkages of this and census data over time have, in Canada, permitted progress in answering similar questions.

Discussion by participants emphasized problems of respondent burden, the need for priorities, and the need to examine alternative sources of data such as farm records and general surveys.

Food Demand Estimation: Issues and Alternatives. Robert Raunikar, chairperson (University of Georgia), Robert E. Branson (Texas A&M University), Karen J. Morgan (Michigan State University), Daniel S. Tilley (University of Florida), and Joseph Havlicek, Jr. (Virginia Polytechnic Institute and State University)

The symposium represented discussions on data, nutrition, and estimation procedures as they relate to food demand and consumption behavior. Increased attention on food demand and consumption behavior research by a southern regional technical committee with representatives from fifteen states including seven states outside the southern region provided the impetus for the discussions.

Branson discussed existing data sources and their characteristics. He focused on two new developments in data generation; namely, (*a*) the BLS continuing quarterly consumer expenditure survey and (*b*) food store scanner data.

Morgan focused on the opportunities for relating economics and nutrition and the need for a basic understanding of nutrition by researchers. Index nutrients and nutrient density were emphasized as excellent tools in applied nutrition research. She called for economics and nutrition to unite and contribute to food and nutrition policy formulation.

Tilley discussed partial demand systems, emphasizing the vertical market structure and a single level in the marketing channel. He pointed to the need for a theoretical treatment of several commodities within the vertical system.

Havlicek commented on complete demand systems, their theoretical foundations, stages of development, and estimation problems. Further progress would include incorporating noneconomic variables and estimation of linear and nonlinear dynamic systems.

A publication on food demand and consumption behavior is being prepared under the leadership of the symposium participants.

Investment Opportunities for Development Resources in the Less Developed Countries. John W. Mellor, chairperson (International Food Policy Research Institute), T. W. Schultz (University of Chicago), Dave Seckler (Colorado State University), D. W. Thomas (Purdue University), and Vernon Ruttan (University of Minnesota)

The symposium dealt broadly with the role of foreign assistance in the development processes of third world countries. Particular attention was given to Schultz's views on peasant agriculture, the role of incentives and distortions of markets, and the role of human capital in development including the particular contribution of the developed countries in facilitating human capital formation. These issues were found to interact importantly with the increasingly apparent conflict between current emphasis in the foreign aid donor community on direct action to reduce absolute poverty and measures to increase food production, thereby reducing poverty indirectly. There was general agreement on peasant-farmer rationality, the important positive role of production incentives, and the deleterious effect of price distortions. Conflict in the short run between broad-based human capital development through nonformal education and higher education to provide technical or administrative leadership was noted. Note was also made of the comparative advantages of the United States in building agricultural research, of the large role of the Consultative Group on International Agriculture Research and the complementarity of that group with the efforts of the land grant system. Both the panel and the audience expressed widespread dissatisfaction with current foreign assistance emphasis on programs that have proved to be ineffective, both in reducing poverty and in achieving growth, with some sharp dissent from the view that such programs have in fact been ineffective. Much of the session was devoted to interplay between the audience and the panel.

Survey of Annual Outlook Information: 1980. Richard K. Perrin, chairperson (North Carolina State University), Stanley Johnson (University of Missouri), Dean Chen (Wharton EFA), John Ikerd (Oklahoma State University), and Gene Nelson (Oregon State University)

The symposium was organized around the results of the third survey of AAEA members' forecasts of agricultural prices and production. A summary of the results was presented by John Ikerd. There appeared to be no consistent forecast differences associated with the respondents' institutional affiliation or outlook responsibility. Johnson and Chen each presented views on the value of composite forecasts based on weighted averages of forecasts from a number of sources. Nelson presented an analysis of responses to the previous two surveys, examining the frequency distributions of forecast errors by forecaster and by crop. Nelson also raised issues regarding the role of the survey and how it should be conducted in the future, if at all. After vigorous discussion, the task force members agreed to make recommendations regarding this to submit to the economic statistics committee and the president of the Association.

Marketing Alternatives—Direct Marketing with Emphasis on Extension Programs. Ed Watkins, chairperson (SEA-Extension USDA), R. Brian How (Cornell University), Hal Linstrom (ESCS USDA), and J. Hugh Winn (Colorado State University)

ESCS USDA now has available results of a six-state survey (Agr. Info. Bull. No. 436) which provides the first organized data on direct farm sales and products sold. Seventeen additional states have been or are now being surveyed; these results should be available in 1981. ESCS has contracted with states for case studies which will detail farmer direct-marketing costs and margins as they sell to consumers through roadside markets, pick-your-own, and community-based farmers' markets.

Extension programs have successfully featured statewide conferences for farmers who sell direct. These statewide conferences provide a nucleus around which farmers can efficiently and productively learn about direct marketing. Several states use newsletters for updating both farmers and consumers. Information is also provided to consumers through mass media, hot lines, 800 numbers, and directories about what, where, and when products are available. Direct marketing associations can provide farmers with support, information, and a "clearing house" type of action. States also are developing computerized mailing lists and directions that may be quickly, economically, and easily updated.

At the macrolevel, direct marketing likely will remain a small part of our food system. Direct marketing at the microlevel provides increased income opportunities for thousands of full and part-time farmers who are largely excluded from our increasingly concentrated food distribution system.

Priorities in Agricultural Economics: Teaching, Research, Extension. G. Edward Schuh, chairperson (University of Minnesota), Kenneth R. Farrell (ESCS USDA), James F. Tammen, Vernon W. Ruttan (University of Minnesota), Paul W. Barkley (Cornell University), James Bonnen (Michigan State University), Bobby R. Eddleman (Mississippi State University), and Richard A. King (North Carolina State University)

The questions addressed at this symposium had to do with (*a*) whether the Association should take a more active role in establishing priorities; (*b*) if so, how it should do it; (*c*) ideas on the scope of priorities. Participants reviewed the experience of other professional associations in establishing priorities. It was agreed that the search for priorities should come from the members of the Association, and not be imposed from above. The importance of establishing linkages with other professional associations also was stressed.

Some speakers called attention to the rapid change in institutional relationships at the federal level. The point was made that priorities are established at the federal level; the question is whether the Association and its members will be a part of the process. Reference was made to the inhibitions to creativity which formal priorities can bring. It also was noted that articulating a set of priorities is not sufficient to assure funding. It is what the profession produces that matters. Moreover, a major intellectual effort is required if such an effort is to be worthwhile. The consensus of those participating in the session was that a systematic effort to identify priorities and to strengthen funding for agricultural economics programs should be attempted.

Retail Food Price Reporting: Why and Why Not? Daniel Padberg, chairperson (University of Illinois), Robert D. Boynton (Purdue University), Tim Hammonds (Food Marketing Institute), Rod Leonard (Community Nutrition Institute), and William T. Manley (AMS USDA)

Boynton presented an overview of the recently completed Purdue/USDA food price-reporting experiment. A full factorial, longitudinal, matched city design (four city pairs) was employed to assess the impact of price reporting on price levels and dispersion. A modified Solomon-Four group design was used in obtaining survey data on changes in consumers' behavior due to the price report. Results of the six-month experiment indicate that (*a*) relative store price levels dropped in all four test cities during the reporting period, although the magnitude varied among cities from 0.2% to 3.7%; (*b*) prices rebounded strongly following the reports' termination; (*c*) the effect of information on price dispersion was inconsistent, (*d*) consumers' per-

ceptions of low- and high-priced stores changed but patronage patterns did not; and (*e*) price saliency did not increase among respondents.

Hammonds stated that price is ranked only fourth or fifth by food shoppers in most surveys and, therefore, it is improper to overemphasize this choice criterion through a price report. Because previous research suggests that store ranks differ by income class, a price report must incorporate several different marketbaskets. Hammonds felt that the Purdue/USDA results suggest little consumer support of such projects. The full price level declines were not sustainable according to the FMI representative. In addition, the difficulty of assuring accuracy in price reporting challenges its practicality.

The consumers' view of price reporting was expressed by Leonard. He chided the trade for the form and substance of their opposition to the Purdue/USDA study. The key to successful consumer information programs lies in strong community support from the earliest stages of such a project (which he said the Purdue/USDA study did not have).

The inherent desirability of buyer information in enhancing competition seems clear to Manley. He expressed the need for additional work in formulating the appropriate methodology for the complex job of food price reporting.

Some Concerns and Needs in Assisting Farmers to Use Computer Technology. Buel Lanpher, chairperson (SEA-Extension USDA), Steve Harsh (Michigan State University), George Greaser (University of Arkansas), and Harlan Hughes (University of Wyoming)

We are becoming increasingly aware of the advantages for exchanging materials and ideas in the computer area, including better utilization of our scarce resources and the hybridization of ideas and concepts that take place with interaction among professionals. There are several means by which an exchange can occur, including the sharing of computer source code and modeling concepts, supporting educational materials, and implementation experiences. Other alternatives include the multistate development of software and accessing software on other states' computer systems. For farmers who are interested in acquiring microcomputers, it is important to determine how they expect to use them before looking at the hardware, software, and communications aspects. Several key hardware characteristics should be carefully analyzed, such as: memory size, operating systems, and output mechanisms. A limited amount of agricultural software is available and it should be developed to run on a common operating system. The computer should be able to communicate with a host system to enable a two-way transfer of data and software. For transferring data, a producer can use his microcomputer to: (*a*) retrieve current market prices, (*b*) obtain current outlook and situation reports, (*c*) see who has hay or other items for sale, (*d*) retrieve timely news releases, (*e*) send and receive electronic mail, and (*f*) transmit drought conditions or other emergency agricultural information. Information networking directly to producers may well prove to be more valuable than the more traditional problem-solving applications.

Contributed Papers

Risk (Lindon J. Robison, Michigan State University, Chairperson)

"Utilization of an E-L Frontier to Evaluate Differences in Risk Preferences between Large and Small Farm Operators." W. Arden Colette and Steven P. Hubbard (University of Florida)
Field corn production practices typical of large and small farm operations are used to indicate revealed risk preference. On the basis of expected return and variance of returns, differences in attitudes and preferences are indicated. However, at the enterprise level risk preference characteristics in both groups are similar.

"Factors Affecting Farmers' Risk-Income Preferences." George F. Patrick, Suzanne H. Whitaker, and Brian F. Blake (Purdue University)
Risk-income preferences are derived for ninety-one central Indiana farmers using magnitude estimation. Variability-income and bankruptcy-income measures developed are related to socioeconomic variables. Wealth and education have limited effects compared with off-farm employment, percentage debt, and expected levels of income, percentage debt, and net worth growth.

"E,V Frontier Analysis Using Total and Random Variance as Measures of Risk." Boris E. Bravo-Ureta and Glenn A. Helmers (University of Nebraska)
A comparison is made of E,V frontiers using total and random (variate difference) variance for crop production for two counties in Nebraska. In one situation there is a marked difference between frontiers, with random E,V showing less risk for given income levels. In the second case, only a minor difference occurs.

"Risk-Taking Preferences of Farmers in Northern Thailand–Measurement and Implications." William Grisley (Pennsylvania State University) and Earl D. Kellogg (University of Illinois)
Risk-taking preferences were elicited from farmers in Northern Thailand to test the hypothesis of increasing partial risk aversion, quantify absolute risk aversion indexes, and determine if socioeconomic characteristics were associated with risk preferences. An actual pay-off experimental method was developed and utilized to elicit risk preferences.

Marketing–Futures Market (Alden C. Manchester, ESCS USDA, Chairperson)

"Beef Price-Hedging Opportunities for Food Service Institutions." Stephen E. Miller (Clemson University)
This paper evaluates the usefulness of fed cattle futures as a cross-hedging medium for selected wholesale beef prices. Minimum risk cross-hedging strategies generally reduce the variability of steer hinds, boneless beef, and top sirloin butt purchase prices without increasing the mean levels of those prices.

"Commodity Options as an Alternative to Hedging Live Cattle." Lowell B. Catlett (New Mexico State University) and Michael Boehlje (Iowa State University)
This paper examines whether commodity options are viable substitutes for traditional futures hedges for live cattle. Selected strategies for futures and option hedges were simulated with gross mean returns, variance, risk premiums, and risk differentials reported. Results show that options can be used as a hedging substitute.

"Does Hedging Increase Credit for Illinois Crop Farmers?" Kim S. Harris and C. B. Baker (University of Illinois)
Survey responses of lenders in east central Illinois suggest more credit for crop farmers who hedge than for those who do not, but the increment is less than the commitment required to finance margin maintenance. Differences by type and size of lender were not significant, though this conclusion may be limited by nonresponse bias.

"Should Futures Contracts Be Settled by Cash Payments?" Allen B. Paul (ESCS USDA)
The dispersal of cash markets for agricultural products tends to make it difficult to operate some futures markets without recurrent squeezes. Cash settlements, under some circumstances, may alleviate the problem but, as revealed by a recent case study, the mechanism must transcend deficiencies in cash as well as futures markets.

Farm Management (James C. Wade, University of Arizona, Chairperson)

"Economics of Wheat-Fallow Systems." Roger G. Johnson and Mir. B. Ali (North Dakota State University)
Income and risk aspects of wheat-fallow-cropping systems in western North Dakota are analyzed. Yields and prices giving equivalent returns for fallow and nonfallow systems are developed. Results indicate summer fallow is economical at low yields, low wheat prices, and high nitrogen prices. Income variability is reduced using summer fallow.

"Guidelines for Making Commercial Wheat Storage Decisions." James N. Trapp (Oklahoma State University)
Wheat storage profit potential was estimated to be highest when the supply/demand ratio for wheat is

low and stocks are declining. Specifically, supply/demand ratios less than 1.5 imply positive returns and each one million bushel decline in stocks, *ceteris paribus*, increases the rate of return by .05%.

"Weed Control Strategies under Uncertainty." R. P. King, D. W. Lybecker, E. E. Schweizer, and R. L. Zimdahl (Colorado State University)
Continuous corn weed control strategies under uncertainty are analyzed. The analytical model considers both flexible and fixed strategies and intertemporal relationships. At current prices annual herbicide use is optimal. At higher herbicide prices, alternate year herbicide use is optimal. The framework is applicable to a wide range of pest problems.

"Investment, Energy, and Labor Trade-Offs in Swine Production." James B. Kliebenstein and Stephen A. McWilliams (University of Missouri)
This study evaluates how energy and labor costs, and investment levels affect the investment feasibility of pasture, partial confinement, and total confinement swine production facilities. The pasture system provided the lowest present value of investment, labor, and energy costs for most energy-labor cost combinations studied. It was followed by partial confinement and then total confinement. System break-even feed efficiencies and labor costs were also calculated.

Agricultural Policy (Philip Warnken, University of Missouri, Chairperson)

"Price Implications of Farmers' Response to the Farmer-Owned Reserve Program." William H. Meyers and Robert W. Jolly (Iowa State University)
Firm level decision models are developed by viewing the farmer-owned reserve as an investment which is evaluated by means of stochastic efficiency criteria. Aggregate relationships for reserve placements and redemption are derived from the firm level models, and the implications for price level and stability are analyzed.

"An Analysis of the Extension of the Food and Agricultural Consumer Protection Act of 1973." Robert Green (NED USDA), Harry Baumes, Jr. (Virginia Polytechnic Institute and State University), James Johnson and Harlan Burnstein (NED USDA)
The 1973 and 1977 Farm Bills are two legislative acts specifying guides for agricultural policy. The major differences between the two acts and the consequences are discussed. An analysis of an assumed extension of the 1973 Act in lieu of the 1977 Farm Bill is presented.

"Food and Agricultural Act of 1977: Implications for Commodity Research." Maury E. Bredahl (University of Missouri), William H. Meyers (Iowa State University), and Abner W. Womack (University of Missouri)
The provisions of the Food and Agricultural Act of 1977 are briefly reviewed. The implications of the farmer-owned reserve program are discussed. A graphical and mathematical representation of aggregate demand based on the farmer-owned reserve and government-owned stocks is presented. This model is used to identify commodity research areas necessary to the economic modeling of the 1977 Act.

Developing Country Analysis (David E. Kunkel, FAS USDA, Chairperson)

"Progress with Lower Yields: The Case of Early Maturing Corn in West Africa." Hendrik C. Knipscheer (International Institute of Tropical Agriculture, Nigeria)
Early maturing corn varieties are bound to yield less than four-month varieties if grown under optimal growing conditions. The question is whether there is a loss under practical conditions and if so, whether the early maturity of the variety can compensate for the yield reduction. A series of on-farm trials and a simultaneous survey among corn growers were conducted in West Africa.

"Understanding, Quantification, and Modelling in Farming Systems Research: Results of a Simulation Study in Northern Nigeria." Eric W. Crawford (Michigan State University)
The paper discusses understanding versus quantification in farming systems research. The strengths and weaknesses of a large-scale and rapid exploratory surveys are compared. The value of a comprehensive rather than partial approach is illustrated with results from a recent simulation study of farm households in northern Nigeria.

"Food Aid and Induced Technical Change." Gary W. Williams (IED ESCS USDA) and G. Edward Schuh (University of Minnesota)
An analytical argument based on the induced technical change theory is presented in which, given adequate research and diffusion capability, food aid assumes the role of an inducer of technical change and increased agricultural production in the recipient country while facilitating a transfer of resources out of its agricultural sector.

"The Computer: An Appropriate Technology for Managing a Viable Agricultural Credit System in a Low Income Country–Upper Volta." Thomas Stickley (Michigan State University)
A computerized system for managing a viable agricultural credit system in a low income country—Upper Volta—was chosen over alternative labor-intensive methods to gain speed, accuracy, and regularity in production of the statistical reports, aids to field extension/credit staff, and calculation of commissions for loans collected.

Consumer Demands and Retail/Farm Price Spreads (Joseph E. Williams, Oklahoma State University, Chairperson)

"Economic Implications of Changing Household Away-From-Home and At-Home Food Expenditure Patterns." Stanley M. Fletcher (University of Georgia Agricultural Experiment Station)
Viewing a household as a producing and consuming unit suggests a household production model as a viable alternative in explaining a household's life cycle food expenditure patterns. The 1972–73 BLS Consumer Expenditure Diary Survey was used as the data base to empirically investigate a household's away-from-home and at-home food consumption across a life cycle.

"Impact of the Food Stamp Program versus Cash Transfers on the Aggregate Demand for Food: A Theoretical Perspective." Kathryn Phillips (Washington State University)
Comparative analysis of food demand expansion effects of a cash program, as compared to food stamp program, is important for measuring tradeoffs between goals of raising farm income and improving nutritional status of the poor. This paper presents a theoretical basis for assessing food demand impacts under each program.

"National and Regional Household Demands for Meats and Seafood in the U.S.: A Complete Systems Approach." Oral Capps, Jr. and Joseph Havlicek, Jr. (Virginia Polytechnic Institute and State University)
A complete systems approach is employed to identify and evaluate the factors which affect the at-home consumption of meats and seafood in the United States. Brown and Heien's S_1-branch systems is estimated using a full information maximum likelihood algorithm. The source of data is the 1972–73 BLS Consumer Expenditure Survey.

"An Analysis of Short-Run Changes in the Farm-Retail Price Spread for Beef." Michael K. Wohlgenant (North Carolina State University)
A static econometric model of the U.S. beef market was estimated and used to analyze monthly changes in the farm-retail price during the period January 1978 to June 1979. The results indicate that approximately one-third of the increase in the margin may be attributed to systematic changes in the predetermined variables of the model.

Regional Analysis (Fred K. Hines, ESCS USDA, Chairperson)

"Effects of Community Attributes on Total Employment Change in Nonmetropolitan Counties." William Gillis (University of Wisconsin) and Shahin Shahidsaless (University of Mottahedin, Iran)
Specific community attributes such as size and composition of the labor force, personal characteristics of local residents, geographic location, and area population are usually ignored in economic impact studies pertaining to nonmetropolitan areas. This paper demonstrates how specific community attributes influence the total employment impact resulting from an exogenous employment change.

"Distributional Consequences of Consolidated Community Service Provision." Webb M. Smathers Jr., Josef M. Broder, and John F. Porter (University of Georgia)
Cost-minimization decision criteria used to evaluate alternative community service delivery systems often ignore distributional incidence of public good provision and quality of service. Using public choice theory, relationships among transaction costs, political unit size, service quality, and interest group conflict are examined for a case study.

"Retail Sales Migration in the Midwestern United States." Kenneth E. Stone and James C. McConnon Jr. (Iowa State University)
Retail sales migration was traced for all counties in Iowa, Kansas, Missouri, and Nebraska from 1958 through 1977. Rural areas have been experiencing leakages while metropolitan areas have gained. Impacts on consumers include inconvenience and increased energy costs. Impacts on communities, including new and existing businesses, are discussed.

"The Spatial and Temporal Economic Impact of a Nuclear Energy Center—A Methodological Discourse and Application to a Southern Regional Site." Mark S. Henry (Clemson University)
A nuclear energy center site in South Carolina consisting of twelve 1,200 megawatt nuclear plants clustered in a single location is the subject of an economic-demographic impact analysis. A regional input-output model and gravity model are employed to make the analysis. A procedure is developed to allocate the employment, population, and income impact to the CCD level within the impact region.

Resource Economics: Water (Donald J. Epp, Pennsylvania State University, Chairperson)

"Evaluating the Costs of Alternative Water Quality Policies: Effluent Charges or Direct Controls?" Robert A. Solove (Chicago Board of Trade), Gary D. Lynne and Thomas H. Spreen (University of Florida)
Estimates are provided of the costs of water quality improvements to agricultural producers in Florida. Cost was lower with a charge system than with direct controls. This finding is in contrast to that of Jacobs and Casler and the theoretical arguments of Buchanan and Tullock. The key factor is flexibility.

"The Economic Value of Groundwater Recharge for Irrigation Use." Raymond J. Supalla and Dorothy A. Comer (University of Nebraska)
A conceptual model is developed to evaluate the economic benefits from groundwater recharge under conditions where the major water use is irrigation. Both pumping cost savings and aquifer extension benefits are considered. This model is then

applied to a Nebraska case where it was found that recharge benefits vary from less than $2 to nearly $20 as a function of aquifer response, the discount rate, commodity prices, and energy prices.

"Sediment Deposits in Drainage Ditches: A Cropland Externality." Girmai Ibrahim and D. Lynn Forster (Ohio State University)
One of the externalities of soil loss from cropland is sediment deposits. Costs are incurred in sediment removal, and estimates of these costs are made. Also, sediment deposits are found to be significantly related to gross soil erosion estimates from the Universal Soil Loss Equation, an environmental parameter commonly used in economic analyses.

"In Search of the Best Solution for Nonpoint Pollution: Effluent Taxes or Cost-Share Subsidies?" David John Walker (University of Idaho) and John F. Timmons (Iowa State University)
An empirical analysis compared the theoretically more efficient effluent tax with commonly used subsidies and with regulatory policies for reducing agricultural sedimentation in an Iowa river basin. The criteria used in comparing the policies were social cost, equity, administrative cost, political acceptability, and cost to farmers.

Marketing (Jean D. Kinsey, University of Minnesota, Chairperson)

"Food Distributor Procurement Practices: Some Implications for Food Price Policy." Larry G. Hamm (ESCS USDA)
With continued food price inflation, understanding the dynamics of grocery pricing is becoming a policy and research imperative. Retailers buy branded grocery items within the context of extensive standard manufacturer designed promotion programs. The interactions of buyer conduct and manufacturer promotions will, in the absence of local retail market competition, result in higher average food prices. This finding is consistent with recent structure-performance studies and demonstrates the value of including behavioral analyses in studies of U.S. food system performance.

"Price, Quality, and the Brand Image: Evidence from Consumers' Union." W. H. Lesser and R. T. Masson (Cornell University)
The brand image is sometimes seen as providing search reducing signals and enhancing competition. This paper proposes a counter theory for complex products infrequently discussed. Evidence from Consumer Reports supports this hypothesis and allows estimation of overcharges of 5% to 32% over identical nonbranded products.

"The Food Stamp Program's Impact on Low Income Households Food Expenditure Behavior." Larry E. Salathe (ESCS USDA)
Food Stamp Program participants spend on average 10% more on food—19% more on food at home, but 36% less on food away from home than similar nonparticipants. Participation in the program especially increases expenditures on cereal products, nonalcoholic beverages, pork, and processed vegetables.

"Assessment of the Price Impact of the South Carolina Cucumber Market Order." Gary J. Wells and Jerold F. Pittman (Clemson University)
In 1970 a cucumber marketing order was formed in South Carolina. The price impacting provisions of the order appear to be the most effective provisions. Empirical evidence suggests that as a result of the order formation, cucumber prices have increased while price variability relative to the average price has declined.

Farming Systems Analysis (Klaus F. Alt, ESCS USDA, Chairperson)

"Economic Impacts of Restrictions on Selected Soybean Insecticides: An Analysis of a Typical Indiana Farm." Marshall A. Martin, Christopher M. Cashman, and Bruce A. McCarl (Purdue University)
This study analyzed the farm-level economic consequences of possible restrictions by the Environmental Protection Agency on the use of three soybean insecticides commonly applied in Indiana. The empirical results indicate that improved insect control increases yields and income. The benefit-cost ratio for each insecticide was greater than two.

"Determination of the Economic Threshold for Control of Horn Flies on Beef Cattle: A Whole Farm Approach." Daniel V. Gordon and Kurt K. Klein (Agriculture Canada)
Horn fly attacks on beef cattle result in reduced gains on pasture. A whole farm approach was used to determine the economic threshold of horn fly control under various prices of output and cost of control. Six control strategies were evaluated; complete control (four-spray applications) had highest returns but may not be optimal for all farms.

"Farm and Off-Farm Labor: A Cross-Sectional Analysis of Iowa Farm Households." Mark D. Lange (St. Cloud State University) and Wallace E. Huffman (Iowa State University)
This paper presents an economic analysis of the time allocated to farm work and to off-farm by husbands and wives of Iowa farm families. Our econometric results show that husbands and wives allocate their time based upon income, wage, family size and composition, and size of farm considerations.

"The Economics of Organic Agriculture: Does Climate Make a Difference?" E. Canler and W. Arden Colette (University of Florida)
Previous studies have favorably compared organic with conventional production techniques, but have not considered climatic impacts on organic crop

response. Organic vegetable production is analyzed under rigorous climatic conditions in Florida. Cost per output unit is higher for organic crops. Labor-intensive organic production is commercially infeasible in the study area.

Natural Resources—Policy Applications (Ivery D. Clifton, University of Georgia, Chairperson)

"Trade-Offs between Agricultural and Urban Nonpoint Pollution Control." William M. Park (University of Tennessee) and Leonard A. Shabman (Virginia Polytechnic Institute and State University)
The relative cost effectiveness of agricultural and urban BMPs is investigated for the Occoquan River Basin in the Washington, D.C., metropolitan 208 area. Implications of agricultural BMPs being more cost effective than urban BMPs on acceptance and implementation of economically efficient nonpoint pollution control strategies are discussed.

"Assessing the Impact of Peak-Load Electricity Pricing and Solar Tax Credits on the Adoption of Solar Energy." Robert J. Procter and Wallace E. Tyner (Michigan State University)
A simulation model was developed to estimate the life-cycle costs of residential heat-pump, resistance, and active solar heating systems. Using Indianapolis, Indiana, as a case study, our results indicate that a move to peak-load electricity pricing can adversely affect any incentive for adopting solar energy provided by solar tax credits.

"The Impact of Tax Policy on Soil Conservation." Bruce Johnson and Maurice Baker (University of Nebraska)
Direct and indirect tax impacts on soil conservation objectives are mixed. Conservation expenditure deductions, cost-share exclusions, and use-value assessment can provide conservation incentives but real estate prices fueled by tax deductions are disincentives. Production practices are unresponsive to property taxes; thus, they are neutral toward conservation incentives.

"A Self-Financing Farmland Preservation Program." Charles A. Sargent (Purdue University)
A farmland preservation program is proposed that combines current growth management approaches with a transfer fee plan. Agricultural zoning, fees assessed on land sold for development, plus cash benefits, would create a combination of "sticks" and "carrots" to encourage preservation. Costs and benefits are analyzed and a hypothetical example is given.

Estimation of Demand (David Kelch, ESCS USDA, Chairperson)

"Incorporating Technological Change in Economic Relationships: An Application to the Demand for Formula Feed in France." Yves Surry and Karl D. Meilke (University of Guelph)
The use of a linear time trend as a proxy for technological change in economic relationships often leads to unsatisfactory econometric results. An alternative procedure based on variational parameter procedures is proposed and applied to the demand for formula feed, fed to hogs, in France. The need to incorporate the technological diffusion process provides the theoretical justification for the procedures used, while the empirical results are quite encouraging.

"Estimation of Demand Parameters Based on Factor Analysis." Chung-Liang Huang, Robert Raunikar, and Stanley M. Fletcher (University of Georgia, Experiment)
A regression equation is derived from factor analysis. U.S. regional demands for at-home consumption of ground beef are estimated for the 1972–73 BLS Consumer Expenditure Diary Survey. Empirical results suggest that factor analysis is a viable alternative to conventional OLS procedure when there is error in the variables.

"Discriminating among Alternative Changing Taste Demand Models." Richard D. Green (University of California-Davis), Rulon D. Pope (Texas A&M University), and Tim T. Phipps (University of California-Davis)
Economists have been concerned about the best way to model changes in taste in demand analyses. Recently non-nested testing procedures have been devised that, when applied to demand analyses, allow one to discriminate among the various changing taste specifications. Results from this paper address some of these interesting questions that economists in the past have not been able to treat in a rigorous fashion.

"Milk in the Fast-Food Outlet: Consumer Demand and Marketing Outlook." Kathy E. Gill and Joel S. Williams (Virginia Polytechnic Institute and State University)
Consumer demand for milk in Virginia fast-food outlets proved very elastic, −3.035. Milk consumed away from home appears to be a different good than milk consumed at home. The cross-price elasticity with soft drinks was also elastic, 4.075. The dairy industry should avoid price war with the soft-drink industry.

Value of Information (Josef M. Broder, University of Georgia, Chairperson)

"The Economic Value of Genetic Information in Selecting Sires." Richard K. Perrin (North Carolina State University)
Contributions by economists to the understanding of the genetic selection choice are reviewed. Concepts for determining the expected value of sire test information are then developed and applied to cen-

tral boar testing stations. For a producer choosing between a tested and an untested boar, the test information is estimated to have a value of about $160, less testing costs.

"The Value of Electronic Marketing—Some Empirical Evidence." D. P. Helmreich, J. E. Epperson, and C. L. Huang (University of Georgia)
Georgia feeder cattle teleauction prices are determined to be significantly greater than sale barn prices in 1979. Enhanced pricing efficiency in cattle marketing is indicated by results of the analysis. Further suggested are improvements in physical efficiency.

"Stochastic Effect of Weather on Crop Production: The Value of Weather Information to Individual Corn Producers." Thomas F. Tice (Oklahoma State University) and Rodney L. Clouser (Indiana State Budget Agency)
Stochastic weather events are critical in determining corn and soybean yields in the Midwest. Discrete stochastic programming techniques incorporate the probability of stochastic weather events in a decision model. By basing production decisions on current weather information and the probability of future weather events, the farmer is capable of increasing farm profitability.

"A Method to Measure the Efficiency of Feeder Cattle Grade Standings." Kim B. Anderson (University of Kentucky) and Alan E. Baquet (Oklahoma State University)
The objective of this paper was to present a methodology for determining the efficiency of a grading system. The methodology was used to compare the efficiency of the 1979 feeder cattle grading system with an alternative grading system. The potential economic gain of implementing the more efficient system was determined.

Societal Benefits from Alternative Activities (Donald F. Scott, North Dakota State University, Chairperson)

"An Economic Analysis of the Intertemporal Monetary Benefits to Coal Land Owners in Eastern Oklahoma." Christopher O. Obiechina, Daniel D. Badger, and Joseph E. Williams (Oklahoma State University)
To identify private from societal benefits/costs in coal development, a linear programming model was used to project the monetary benefits accruing to coal land owners. Using two alternative mineral rights transfer strategies (land trades) to leasing of coal land, it was concluded that private monetary gains to land owners are substantial.

"Use of a Dynamic Optimization to Evaluate a Buffer Stock for Cocoa." Seon Lee (Korea Development Institute) and David Blandford (Cornell University)
Optimal control theory is used to determine optimal buffer stock purchases/sales to stabilize price at systematic trend over the period 1956–76. Although the instability of price and of producer revenue falls and average revenue increases, the degree of market intervention necessary and its costs are substantial.

"Welfare Measures for a Price Distortion in a Multiproduct Multifactor Setting." Glenn S. Collins (Texas A&M University) and Daryll E. Ray (Oklahoma State University)
This paper investigates welfare measures in an economy comprised of vertically related multiproduct and multifactor industries, where a particular market is subject to a price distortion. It is shown that total welfare changes can be obtained with the use only of general equilibrium prices and quantities in the distorted market.

"Impact of Agricultural Export Trade on a State's Economy: The Case of Missouri." Emilio Pagoulatos (University of Florida), Robert Sorenson (University of Missouri-St. Louis), and Angelos Pagoulatos (University of Kentucky)
A methodology based on I-O analysis is developed and utilized to investigate the impact of agricultural and nonagricultural exports on the Missouri economy for 1963 and 1972. Agriculture was found to be by far the most important sector in terms of the impact of its export sales on state economic activity. Agricultural export sales contributed to 29% of state business activity, 34% of personal income, 49% of total state revenues, and about 34% of local taxes in Missouri in 1972.

Grain Transportation (L. D. Schnake, ESCS USDA, Chairperson)

"Estimation of Grain Transportation Demand Using Time-Series Data." William W. Wilson (North Dakota State University)
Peak period problems in grain transportation and the concept of peak-load pricing are addressed in this paper. A three-equation recursive econometric model was specified and estimated for wheat movement from North Dakota to Duluth-Superior. The results indicate that total transportation movements were inelastic with respect to prices received by producers. Elasticities were also derived for modal movements.

"The Impact of Demand-Sensitive Railroad Rates upon the Storage and Transportation System for U.S. Feed Grains." Linwood A. Hoffman (ESCS USDA) and Lowell D. Hill (University of Illinois)
A storage and transportation model of the U.S. feed grain industry was developed to measure the potential impacts of demand-sensitive rail rates. At the national level, a 5% to 15% change in rail rates simultaneously increased rail revenue and traffic

volume and reduced seasonality of rail demand. As a consequence, total system costs increased. Regional results differed slightly.

"Effect of Rural Road Development on Grain Assembly Costs." Jay Dean Tucker and Stanley R. Thompson (Michigan State University)
The possible effect of rural road development policies and selected maintenance programs upon grain marketing and transportation costs in southeastern Michigan is examined through a linear programming algorithm designed to minimize the aggregate transport and handling costs. The model's empirical results indicate a direct relationship between rural road development and maintenance policies and grain transport marketing costs.

"Alternative Export Wheat Distribution Systems for the Southern U.S. Plains." Stephen Fuller (Texas A&M University), Orlo Sorenson (Kansas State University), Marc Johnson (North Carolina State University), and Robert Oehrtman (Oklahoma State University)
This paper reports on alternative logistical systems for marketing export-destined wheat from southern U.S. plains. The study concludes (*a*) the region's export system is not economical when compared to alternatives which include multicar shipments, (*b*) efficiency gains are derived from the unit train concept, and (*c*) feasibility of subterminals and associated unit trains are not contingent upon rail abandonment.

Trade of Agricultural Commodities (Paul V. Johnson, ESCS USDA, Chairperson)

"Impact of Meat Imports on Least Cost U.S. Beef Production." K. E. Nelson (NED ESCS USDA, University of Illinois), N. R. Martin, and G. M. Sullivan (Auburn University), and R. J. Crom (NED ESCS USDA)
A linear programming model of the U.S. beef industry evaluates meat import policies for a least cost optimal beef cow herd. Regional adjustments in cow numbers and corn utilization are examined. Average cost for the United States is estimated for different levels of cow herd size and beef production.

"The Effect of the Suspension of Wheat Sales to the USSR on U.S. Prices and Exports." Alan J. Webb (IED ESCS USDA) and Leo V. Blakley (Oklahoma State University)
A world wheat trade forecasting model is used to compare a sales suspension of maximum effectiveness with a no suspension alternative. United States producer prices are shown to decline $.26 per bushel and exports fall 1.5 million tons in 1980. Increased market stability results from diminished influence of Soviet supply variability.

"A Comparison of the Impact of Alternative Government Policies: The Soviet Union Grain Embargo." Harry S. Baumes, Jr. (Virginia Polytechnic Institute and State University), Abner W. Womack, and Maury E. Bredahl (University of Missouri)
This paper examines alternative policy measures taken by the administration to support grain price in the wake of the Soviet grain embargo. Most notably in the analyses is the fact that exportation of grain has a stronger price impact than entry of grain into the farmer-owned reserves.

"Impact of Japanese Rice and Wheat Policy on Trade." Cathy L. Jabara and William T. Coyle (ESCS USDA)
The interaction of Japanese rice and wheat policy is described and analyzed through estimation of an econometric model. The trade impact of recently announced increases in wheat support prices and diversion payments is simulated. Results indicate the price change will reduce wheat imports, but the imports are not sufficient to balance rice production and consumption.

Production Economics—Specification of Supply Models (Eric Wailes, University of Arkansas, Chairperson)

"Statistical Tests of the Nonreversibility of Agricultural Supply Hypothesis." Mike Woods, Luther Tweeten, Daryll E. Ray, and Greg Parvin (Oklahoma State University)
Aggregate supply equations are estimated using the Wolffram and Houck methods to segment the output price into separate independent variables for increasing and decreasing prices. Null hypotheses of equal price response coefficients for falling and rising prices could not be rejected. The same conclusion was reached using Chow's structural stability tests.

"A Random Parameter Regression Approach to Estimating a North American Pork Supply Model." Bruce L. Dixon (University of Illinois), Larry J. Martin (University of Guelph), and Ellen W. Goddard (Latrobe University, Australia)
Equations modelling pork supply for North America are estimated assuming coefficients change both randomly and systematically. Results show predictive superiority of time varying models over least squares for sample period. *Ex post* forecasting does not exhibit similar superiority. Measuring structural change and effect of additional observations on estimates are considered.

"Estimation of the Supply of a Perennial Using Sparse Data." James W. Dunn and Richard P. Bellock (Pennsylvania State University)
Traditional methods of estimating the supply of perennials require acreage data, yet such data is usually not collected. In this study, a model for the supply of a perennial crop which does not require

acreage data is developed. The model is estimated for asparagus, strawberries, and eggs with satisfactory results.

"On the Use of Price Ratio in Supply Response." Jean-Paul Chavas (Texas A&M University)
Because of a lack of data or multicollinearity problems, it is fairly common to include only a subset of the relevant prices in an econometric model of supply response. This paper provides some evidence on the validity of using price ratios in this situation. A model of the U.S. poultry and egg industry where feed cost and output price are the only economic variables considered suggests that the use of price ratios would be inappropriate. If careful attention is given to model specification, it appears that homogeneity restrictions should not be imposed on supply response models unless the excluded prices are known to have little influence on production decisions.

Empirical Estimation Considerations (Peter H. Greenwood, University of New Hampshire, Chairperson)

"Elasticities and Dynamics: Conceptual Problems in Empirical Measurement." Ralph Semprevio and Kenneth Baum (Virginia Polytechnic Institute and State University)
Although the supply elasticity concept is a useful theoretical and analytical tool, empirical estimates of supply elasticities have not always been recognized as having restricted uses. Dynamic multipliers are not constrained by these restrictions and, therefore, represent more realistic measures of commodity supply response under either multimarket or multiperiod conditions.

"The Policy Relevance of Alternative Elasticity of Substitution Measures." Barry C. Field and P. Geoffrey Allen (University of Massachusetts)
Flexible forms increase the potential difficulties of interpreting and reconciling alternative estimates of the elasticity of substitution (ES). We stress differences between measures based on constant and variable output, provide a general expression for the latter, and suggest the usefulness of measuring short- and long-run ES by modeling input adjustments.

"Specification of the Profit Equation and Expected Profit Maximization." Roger Selley (University of Arizona)
Proper specification of the profit equation where profits are stochastic requires that special care be given to specifying the profit equation so that it is consistent with the characteristics of the profit maximization problem. It is shown here that the relationship of cost curves with the production function is not, in general, the same in the stochastic case as in elementary firm theory. It is also shown that although the "expected product price equals expected marginal cost" rule holds when expected marginal cost is interpreted as the expected marginal cost of planned production, the "expected input price equals expected marginal value product" rule for a planned input requires an adjustment for the increased cost of stochastic inputs.

"The Rational Expectations Hypothesis: An Empirical Application to the Florida Escarole Market." J. Scott Shonkwiler (University of Florida)
Empirical implementation of the rational expectations hypothesis requires that expectations be determined endogenously. Applications of both this methodology and the traditional adaptive expectations procedure to a model of the Florida escarole market are presented. The results suggest that escarole producers are not rational in the sense of Muth's hypothesis.

Commodity Models (David Armstrong, Michigan State University, Chairperson)

"A Quarterly Econometric Forecasting Model of the American Cheese Market." Joe H. Dewbre (Wharton Econometric Forecasting Associates)
This paper describes a quarterly econometric forecasting model of the American cheese subsector that includes equations for cheese production, commercial sales, CCC purchases, market prices, retail prices, and commercial stocks. Dynamic simulation exercises over the sixteen quarters from 1976 to 1979 were used to validate the model. Results of a dairy policy simulation experiment are also given.

"The Soybean Sector in the 1970s: An Analysis of Price Variability." Suchada V. Langley and William H. Meyers (Iowa State University)
Price variability in the 1970s is analyzed for the soybean sector using structural and time series models. The impact of changes in predetermined variables on the price level is analyzed with the structural model. Supply factors, trade factors, and domestic demand factors are evaluated over the period 1971 to 1977.

"Petroleum Prices and the Market for Natural Rubber." Abu Bakar Man and David Blandford (Cornell University)
An annual econometric model that reflects price competition between natural and petroleum-based synthetic rubber is used to project world production, consumption, and prices in 1985. The contribution of increasing petroleum prices to the projected changes in these variables is determined. The results suggest that substantial increases in the real price of natural rubber are likely.

"Market Demand for Residual Stocks and Price Variability: A Case Study of U.S. Wheat." Chung J. Yeh (USDA)
An ordinary least squares technique with dummy variable and several dummy-related variables is used to test changes in wheat demand structures and impacts of residual stocks on prices. Wheat demand structures appear to have changed significantly over time and prices are highly affected by residual stock levels.

International Trade (Patrick O'Brien, ESCS USDA, Chairperson)

"An Analysis of Ocean Freight Rates for Grains with Reference to Port Advantage." James K. Binkley (Purdue University) and Bruce Harrer (Battelle Pacific Northwest Laboratories, Richland, Washington)
Two equations relating ocean grain rates to cost factors are estimated. The major variables examined deal with distance, shipment size, overall shipping activity, and handling costs. The results are used to suggest reasons for rate differences associated with major port areas.

"Demand Elasticities for Soybean Meal in the European Community." Lowell D. Hill (University of Illinois) and Hendrik C. Knipscheer (International Institute of Tropical Agriculture, Nigeria)
An econometric model provided estimates of the effects of EC agricultural policies on their demand for U.S. soybeans. Disaggregating world soybean demand into geographical regions improved elasticity estimates over previous studies with respect to substitutes, own price, and profitability index. EC mills' power surpluses had significant but negative small effect on U.S. soybean exports.

"An Economic Analysis of Welfare Distribution among Trading Countries under Alternative Market Imperfections." Dae H. Song and Milton C. Hallberg (Pennsylvania State University)
A model of international trade that permits market imperfections from either exporters or importers is introduced and a quadratic program to find equilibrium solutions under alternative market structures is formulated. A procedure for the welfare analysis of a wheat exporter's cartel is outlined.

"Price and Income Effects of Devaluation—A Case Study of South Korea." Gene K. Lee (IED ESCS USDA)
An input-output model is used to examine price and income effects of devaluation. The results indicate that when exports are dependent upon imports of intermediate products, domestic output prices will increase significantly. Thus, the results suggest that the net export effect of devaluation is not as great as is usually expected when a country devalues its currency.

Natural Resources—Irrigation (Darrell Hueth, Lawrence Livermore Laboratory, Chairperson)

"Optimal Scheduling of Irrigation by Control Theory: Oklahoma Panhandle." Thomas R. Harris and Harry P. Mapp, Jr. (Oklahoma State University)
Continued irrigated production in the Oklahoma Panhandle is threatened by the declining groundwater supply and increasing fuel costs. A plant growth model and optimal control theory techniques were used to derive irrigation strategies which, when compared with contemporary irrigation practices, reduce water and energy use while maintaining producer net returns.

"Electricity Prices and Irrigation Development Feasibility." Joel R. Hamilton (University of Idaho), Gary S. Barranco (U.S. Forest Service), and David J. Walker (University of Idaho)
A methodology was developed to measure impacts of rising electricity prices on high lift irrigation development. Effects of farm size, crop prices, yields, lift heights, and distance from water source were also incorporated. Results indicate that rising electricity prices will make development infeasible in high elevation areas of southern Idaho.

"Irrigation and the Demand for Electricity." Ruth J. Maddigan, Wen S. Chern, and Colleen A. Gallagher (Oak Ridge National Laboratory)
In order to anticipate the need for generating capacity, utility planners must estimate the future growth in electricity demand. The need for demand forecasts is no less important for the nation's Rural Electric Cooperatives (RECs) than it is for the investor-owned utilities. The RECs serve an historically agrarian region; therefore, the irrigation sector accounts for a significant portion of some of the Cooperative's total demand. This paper develops a model of the RECs' demand for electricity used in irrigation.

"The Derived Demand for Irrigation Scheduling Services." Daniel J. Dudek and Gerald L. Horner (NRED ESCS USDA, University of California-Davis)
Scientific irrigation scheduling is a technique for systematically determining the proper data and quantity of each irrigation in individual fields. This technique is presently being used by government agencies and private companies in the western United States to assist farmers in planning irrigations. This paper presents the results of a case study of the regional economic effects of scheduling in the A and B district in Idaho. The analysis indicated that substantial reductions in total water use resulted from implementation of the service. However, the acreage of scheduled irrigation activity was found to be fairly sensitive to the cost of the service and the cost of irrigation water.

Scale Economies and Income Distribution (Roger G. Johnson, North Dakota State University, Chairperson)

"Scale Economies on Peanut-Rice Farms in Northeast Thailand." Aroon Auansakul (University of Kentucky)
The relative technical and economic efficiency for small and large rice-peanut farm size classes in northeast Thailand are compared. A theoretical model is developed and empirically tested with equal prices for inputs and products. Small farms, while more labor intensive, attain higher levels of both technical and economic efficiencies.

"Barriers to the Expansion of Small Farms." John Ellerman and Lyle Solverson (Southern Illinois University)
The major objective of this study was to identify factors that may act as barriers to the expansion of small farms. The study concludes that there are three types of barriers to expansion: (*a*) those barriers due to small farmers' inability to use existing methods, (*b*) those barriers that are due to small farmers' refusal to use available methods, and (*c*) natural barriers.

"Potential Effect of Small-Farm Technical Assistance Programs on Public-Revenue Accounts." Eldon D. Smith, Harry H. Hall (University of Kentucky), and Don Simon (ESCS USDA)
This paper presents a conceptual model for considering the tradeoffs between technical assistance and public-welfare assistance for impoverished limited resource farmers. The hypothesis is that a combination of technical assistance and welfare assistance will be more cost-effective than welfare assistance alone. For a sample of 120 limited-resource farmers in the Appalachian region of Eastern Kentucky, some on welfare assistance, the potential effect of technical assistance on public-revenue accounts is evaluated.

"Agricultural Pricing Policy and Income Distribution in a Multiobjective Framework: A Dominican Republic Example." Elizabeth B. Erickson (University of Akron) and Robert M. House (OICD USDA)
A large-scale LP model is used to analyze the effect of pricing subsidy alternatives. Results are expressed to reflect performance with respect to government multiple objectives. Trade-offs and complementarities are presented in a form designed to be of assistance to decision makers, using factor analysis and policy frontier functions.

Incorporating Risk in Decision Making (Sidney C. Bell, Auburn University, Chairperson)

"Theoretical Criteria and a Proposed Empirical Method for Computing Historical Risk Measures." Linda S. Calvin (ESCS USDA), Ron C. Mittelhammer and Douglas L. Young (Washington State University)
Suggested criteria for evaluating the appropriateness of historical risk measures are presented. A continuously adjusted weighted moving average (CAWMA) method for calculating historical risk is introduced and compared to past historical risk computation procedures both in terms of the suggested criteria and in the context of specific empirical examples.

"Risk Preferences and Perceptions in the Use of IPM." W. Michael Hanemann (University of California-Berkeley) and Richard L. Farnsworth (ESCS USDA)
The risk preferences, the actual returns, and the subjective probability distributions of returns of a sample of forty-four cotton growers in the San Joaquin Valley are studied; twenty-eight growers use IPM, sixteen use conventional chemical pest controls. The choice of strategy is explained in terms of differences in risk perceptions rather than preferences.

"A Method of Incorporating Risk Management into Extension Programs." Judy Ohannesian, Wesley N. Musser, Fred J. Benson, and Vernon R. Eidman (University of Minnesota)
This paper proposes the use of a lower confidence limit for profits as a method to incorporate risk management into a general extension program. The confidence interval approach is adapted from portfolio analysis. The method is illustrated for a crop enterprise-planning program in Minnesota.

"A MOTAD Risk Analysis of Swine and Competing Farm Enterprises in the Virginia Tidewater Area." Larry Johnson and Kenneth Baum (Virginia Polytechnic Institute and State University)
A MOTAD analysis of the risk and economic impact of three alternative swine enterprises has been evaluated in the Virginia Tidewater region. Although alfalfa hay and corn competed with feeder pig and finishing enterprises at lower income levels, farrow-finish operations were elected at higher income levels.

Marketing Decisions and Price Analysis (Donald E. Farris, Texas A&M University, Chairperson)

"Supply and Demand Considerations of Agribusiness Marketing Portfolios." Steven T. Buccola (Virginia Polytechnic Institute and State University)
Conditions are derived for determining the product volumes which expected utility-maximizing firms would sell or buy under alternative contract arrangements. Supplies and demands under each arrangement are related to contract parameter levels. An application is made to negotiations between farmer and processor concerning terms of fixed-price, forward deliverable contracts.

"The Consumer's Use of Futures." Peter Berck and Stephen G. Cecchetti (University of California-Berkeley)
This paper shows that futures should be included in an efficient portfolio and that the degree of their inclusion depends critically on the evaluation of income in real terms. As planned consumption is balanced toward items traded in the futures market, holdings of futures are shown to increase.

"Causal Relationships in the Fed-Beef Cattle Market." Thomas H. Spreen, J. Scott Shonkwiler, and Julio Chang (University of Florida)
The causal relationships among feeder calf prices, feed cattle prices, and feed costs are investigated using three alternative statistical tests. Employing the Granger concept of causality and using monthly data, it is determined that feed costs lead both animal price series, but no lead-lag relationship is found between feeder steer and Choice steer prices.

Marketing—Structure, Concentration (John M. Connor, ESCS USDA, Chairperson)

"The Commodity Implications of Expansion of Sales of Food-away-from-Home." A. Desmond O'Rourke (Washington State University)
The relative increase in expenditure on food-away-from-home at the expense of the at-home market has been well documented. However, little work has been done on the differential impact of this shift on agricultural producers, processors, and marketers in different locations and faced with different marketing institutions. This paper reports on the changing impact of the away-from-home phenomenon on major commodity groups, processed products, and institutional sales. It appears that the manner in which the away-from-home market has evolved has had significant impact on many commodities, products, and their respective producers and processors.

"Changing Structure of the Fluid Milk-Processing and Distribution System." Richard F. Fallert and Harold W. Lough (ESCS USDA)
The size distribution and firm organizational structure of fluid milk processors under federal milk markets orders is presented for the months of December 1971 and 1977. Forces impacting the industry and bringing about a rapidly changing market structure are presented. Likely future impacts are explored and implications for policy makers and industry decision markers are outlined.

"The Effects of Market Concentration on Urban Food Prices." R. McFall Lamm, Jr. (NED ESCS USDA)
This paper explores the effects of concentration on urban food prices utilizing different measures of market concentration. An econometric model of urban food price determination is developed and estimated using pooled cross-section and time-series data. Results indicate that food prices are higher in markets where concentration is greatest.

"Advertising and Concentration Change in U.S. Food and Tobacco Product Classes, 1958–72." Richard T. Rogers (FMS ESCS USDA, NC-117 Food System Research Group)
There is increasing evidence that advertising plays an especially prominent role in structural change. Herein the author examines the effect advertising has had on changes in concentration in U.S. Food and Tobacco Product Classes. Regression results indicate that television advertising has had a strong positive influence on concentration change.

Application of Quantitative Techniques to Agriculture (Kenneth H. Baum, Virginia Polytechnic Institute and State University, Chairperson)

"A Review of Monte Carlo Applications in Agricultural Research." Leonard E. Burman (University of Minnesota)
Monte Carlo Programming (MCP) is a means of dealing with problems which are too mathematically complex to be treated with deterministic methods (such as QP). Its principal drawback is cost. Methodology and applications are discussed. Promising directions for future research are suggested.

"Use of Cluster Analysis to Identify Size Structure in Irrigated Agriculture." James C. Wade (University of Arizona)
Analysis of structure in American agriculture often overlooks both the subtle and complex differences among farms of varying sizes within a relatively small production area. The resource components of farms of various sizes significantly affect the size and crop mix structure of each group of farms. To examine this structure sample farms have been grouped using cluster analysis. The multivariate data observations are grouped without preconceived hypotheses. Statistical analysis of the results reveals that farms group somewhat by size and crop mix. However, small farms do vary substantially in composition from larger farms and avoid significant production of risk-oriented crops.

"Tests of Exogeneity in Bivariate Regressions: Some Empirical Results for Slaughter Cattle and Hogs." David A. Bessler and Jon A. Brandt (Purdue University)
The paper investigates exogeneity tests between hog prices and sow farrowings and between cattle prices and cattle on feed inventories. The tests, which are useful in constructing dynamic bivariate regressions, suggest that sow farrowings is empirically exogenous with respect to hog price and that cattle price is exogenous with respect to cattle on feed inventories.

Crop Acreage Estimation (John Groenewegen, ESCS USDA, Chairperson)

"A Behavioral Model of Corn Acreage Response under Conditions of Uncertainty." Harlan Burnstein (NED ESCS USDA)
This paper investigates the impact of corn price variability on planted acreage. The results of an economic analysis indicate corn acreage to be inversely related to corn price variation with the negative impact decreasing as the average level of past prices increases.

"Demand for Crop Acreage: A Structural Approach." Lloyd D. Teigen (NED ESCS USDA)
The demand for land as a productive input responds to the price of land relative to the price of the commodities produced by that land and the price of other inputs. Acreage control policies are quantified in terms of the maximum percentage of land which could be diverted from commodity production. This specification is tested using 1967–78 data for wheat, corn, soybeans, oats, and sorghum.

"Policy Control of Corn Acreage: A Re-Examination." Robert D. Weaver and Amy Krainik (Pennsylvania State University)
Parameters of a corn acreage response function estimated for the Corn Belt states are found to be unstable over the three economic regimes established by postwar feed grain programs. Market price elasticities are larger when programs imposed acreage restrictions. Supply elasticities with respect to policy instruments and fertilizer prices are also reported.

"Multiple Crop Supply Component of the World Grains, Oilseeds, and Livestock Model." Karen Liu (IED ESCS USDA)
The purpose of this paper is to resolve conceptual problems in the crop supply component of the present GOL model and to develop the conceptual framework for a multiple-product production system of a multiple-commodity agricultural trade model. The major emphasis on the revision of the crop supply system is structural consistency in order to assure consistent acreage allocation among crops and to impose total arable land area constraints on supply.

Farm Management—Beef (Timothy G. Baker, Purdue University, Chairperson)

"Recycling Paper Mill Wastes as Cattle Feed in Small Livestock Operations." Donald J. Epp and Trond Grenager (Pennsylvania State University)
Recycling paper mill waste "fines" as a livestock feed ingredient reduces feeding costs for small (100 head) operations 31% for cow-calf operations, 35% for stockers, and 28% for feeders. This savings can pay for transporting the fines up to 250 miles and reduces landfill requirements near the paper mill.

"The Inclusion of Beef Cattle in the Optimal Enterprise Organization." J. Walter Prevatt, John E. Reynolds, and Bryan E. Melton (University of Florida)
A profit-maximizing model that included many of the diverse aspects of beef cattle production and interrelationships among beef cattle, forages, and field crops was developed within a dynamic linear programming framework. The optimal resource organization was determined given price levels that existed during 1973–77.

"Economics of Beef Cow Culling and Replacement Decisions under Genetic Progress." Bryan E. Melton (University of Florida)
Beef herd managers alter the genetic composition and thus the profitability of their herds through culling and replacement. Because genetic change is a form of technological progress, a general replacement criterion for assets undergoing either exogenous or endogenous progress is derived. Its application is then illustrated through an empirical example.

"Economic Evaluation of Beef Cow Size and Milking Potential." Kenneth W. Stokes, C. Richard Shumway, Terry C. Nelson, and Tom C. Cartwright (Texas A&M University)
Feeder calf classes (sex, age, and condition) and cull sales are simulated for herds which differ in size and milking potential genotype. Pricing equations, cost, and net returns are calculated for the 1972–78 period. Results indicate higher returns and lower variance associated with increased cow size and decreased milking potential.

Aggregate Analysis (James D. Johnson, ESCS USDA, Chairperson)

"The Rate of Return to Investment in Agriculture and the Measurement of Net Farm Income." Bruce L. Gardner (Texas A&M University) and Bruce Hottel (NED ESCS USDA)
This paper investigates three problem areas in the measurement of returns to agricultural assets. First, measuring returns as a residual creates inevitable choices among alternative procedures, none of which is exactly suitable, and which make a substantial quantitative difference. Second, annual rates of return, even if properly measured, have a quite limited economic meaning. Third, in an inflationary environment, current USDA measurement results in a substantial understatement of net farm income because the inflation premium in interest costs is charged against current income flows.

"A New Look at the Relationship between Farm Real Estate Prices and Expected Returns." Larry D. Hauschen (Federal Land Bank of St. Paul) and William McD. Herr (Southern Illinois University)
This study employs the capitalization approach and the polynomial lag model (Almon lag) to examine the changes in farm real estate prices from 1950

through 1977. The study found that when net returns to real estate are measured more accurately and expectations regarding net income are based on incomes earned in the seven previous years, the capitalization model explains changes in farm real estate values since 1950.

"The Differential Effects of Inflation on Selected Food-Related Sectors of the U.S. Economy, 1967–78." Gerald Schulter (NED ESCS USDA) and Gene K. Lee (IED ESCS USDA)
A consistent economic model for measuring the price-induced income effects of relative price changes is reported and used to analyze sectors within the food system. Since 1972 the farm sector has benefited from relative price changes but export-oriented crop sectors have done better than domestic-oriented crop sectors and livestock.

"Relationships among Households and Farm Establishments in the 1980s: Implications for Data." Lyle Schertz (ESCS USDA)
Data and related research presently available does not provide approximate income and wealth distribution indicators for households that provide resources to farming. These kinds of data are necessary for dealing with structural issues. Such data should be part of the larger system of data related to farm establishments.

Natural Resources—Empirical Estimation Approaches (Tony M. Grano, ESCS USDA, Chairperson)

"Proper Estimation and Specification of Sustained Yield Functions: An Application to Deer Harvesting." Roger Mann, Kenneth Baum (Virginia Polytechnic Institute and State University), and Ronald Shane (University of Nevada)
Correctly specified economic models have not always been utilized for the empirical measurement of sustained yield functions necessary for determining optimum effort allocations for renewable natural resources. In this analysis, empirical sustained yield functions for deer harvesting are successfully estimated with both current and lagged hunter efforts as explanatory variables.

"Estimating Social Values of Sport-Caught Fish: A Suggested Approach." Karl C. Samples (University of Hawaii) and Richard C. Bishop (University of Wisconsin)
A promising new approach to estimating values of sport-caught fish is introduced as a practical alternative to theoretically questionable methods currently in use. An empirical example of application of the proposed approach is provided using results from a multiple-site travel cost study of Lake Michigan fishing.

"Externalities and Joint Supply Response in Outdoor Recreation Research: An Example from Irrigation Development." Scott C. Matulich (Washington State University)
Outdoor recreation research is criticized for failing to evaluate temporal impacts of federal water project development upon recreation resources. Joint supply response is offered as a conceptual framework to analyze the inevitable externalities attending passage of time. An empirical analysis of pheasant productivity resultant from irrigation development is then presented.

"Resource Stocks and Supply Estimation: An Alternative Approach." Ivar E. Strand and Robert G. Chambers (University of Maryland)
An approach to resource supply estimation is developed which circumvents the need for direct observations in the resource stock. Estimation of supply response in this framework also will permit direct estimation of several important biological parameters from economic data.

Implications of Pesticide and Herbicide Restrictions (Paul H. Gessaman, University of Nebraska, Chairperson)

"Ecology and Economics: Differences in Philosophy." Gary D. Lynne and Roy R. Carriker (University of Florida)
Ecology has been referred to as the "subversive science," as man is argued part of the environment, having only limited control. Economics is based on man as a sociocultural being, as opposed to man the animal. Recognition of differences in philosophy must be explicit before real communication can begin.

"Economic Consequences of Restrictions on Herbicides Currently Used on Indiana Farms." Christopher M. Cashman (Smith-Kline Corporation), Marshall A. Martin, and Bruce A. McCarl (Purdue University)
This study analyzed the farm-level economic consequences of possible bans on herbicides commonly used in corn and soybean production. The empirical results indicate significant short-run yield and income losses, harvest delays, and increased use of labor and machinery from most herbicide bans.

"Multiple Cropping and Pest Control Intensity—Preliminary Economic Results." James E. Epperson and John R. Allison (University of Georgia, Griffin Experiment Station)
The ability to multiple crop in the southern coastal plain of the United States may allow cultural means that favor less intensive pest control. One of three cropping systems under investigation which was selected for economic evaluation showed that within the range of pest control intensities studied, less intensive control resulted in higher net returns.

"Restrictions on Herbicide Use: An Analysis of the Economic Impacts on U.S. Agriculture." Robert O. Burton (West Virginia University) and Marshall A. Martin (Purdue University)
This study analyzed the national and regional economic consequences of restrictions on herbicide use in the United States. The impacts of restrictions on a single corn or soybean herbicide would be small because alternative herbicides would be available. The impacts of restrictions on all herbicides would be much larger.

Quantitative Approaches (W. Arden Colette, University of Florida, Chairperson)

"A Comprehensive Evaluation of Interrelated Pesticide Regulations." Wen-Yuan Huang, Reuben N. Weisz, Gail Willette (NRED ESCS USDA), and Earl O. Heady (Iowa State University)
A hybrid model which links a national econometric model with an interregional programming model is used to evaluate national and regional economic impacts of a DBCP ban on soybeans, a toxaphene ban on cotton, and a simultaneous ban of both pesticides. Preliminary results indicate: the DBCP ban has no production and price changes on soybeans and other major crops. However, the toxaphene ban and the simultaneous ban have a decrease in production and an increase in price of cotton. Some cross-commodity effects are also noticed. The Delta region suffers the greatest net income reduction, followed by the Southeast and Southern Plains, while the Mountain, Appalachian, and Corn Belt regions have substantial increases in net income over time.

"The Grange's Method for Plant Location Studies." Robert L. Beck and J. Don Goodin (University of Kentucky)
The Grange's Method, a subroutine of the Stollsteimer model, was used to identify the optimum number and location of plants needed to process current and future suppliers of manufacturing milk in Kentucky. The use of existing plant sites and capacities adds a dimension of "real world" acceptability to the results.

"Planning and Evaluating Research on Poultry Nutrition: The Role of a Bioeconomic Model." Kurt K. Klein, Greig A. Birchfield, and Raymond E. Salmon (Agriculture Canada)
A linear programming model of turkey production was constructed to help in evaluating research results and planning new projects. It maximizes profits per lot subject to nutrient, ingredient, feed quantity, sex ratio, and production capacity constraints. Applications to date include analyses of feeding trials involving various protein sources and establishing priorities for new research.

"Use of Computer Graphics in the Development and Evaluation of Production Response Surfaces." Richard A. Schoney, Ted F. Bay, and John F. Moncrief (University of Wisconsin)
Various statistical measures and prior knowledge of functional relationships traditionally have been the main guides in developing production response equations. Computer graphics provide a valuable addition to this developmental process. Through graphics, the characteristics of a large volume of data can be analyzed visually. In addition, the physical characteristics of alternative functional forms can more easily be compared to the original data. Computer graphics were used to analyze raw data through surface and contour plots and to compare three alternative functional forms chosen to represent the data. The example cited demonstrated the potential advantage of using computer graphics as a visual research tool in production studies.

Editor's Note:

Award-Winning Theses

Callaway, John M., Jr. "The Optimal Use of Surface Water with Return Flows Present: A Theoretical Model for Deriving Alternative Allocation Rules." M.S. thesis, University of Minnesota, 1979.

In many of the river basins in the western United States, downstream appropriators of surface water are heavily dependent upon return flows generated by upstream uses. As a result, transfers of surface water rights between nonadjacent appropriators have the potential to disrupt the configuration of surface flows at both intermediate and downstream locations. While the provisions governing the transfer of water rights in most western states deal with this problem by protecting third parties from potential injury caused by reduced streamflows, the objective of economic efficiency is not well served in the process.

In view of the problem of mutually interfering use associated with return flow externalities, the purpose of this study was to develop alternative rules for allocating surface water that are consistent with the objective of economic efficiency. This was accomplished through the formulation of a static analytical model of a hypothetical river basin, the objective of which was to maximize the sum of producer's willingness to pay for surface water subject to the physical constraints of the water delivery system in the basin which included the availability of return flows. Subsequent analysis of the Kuhn-Tucker conditions for this model yielded optimal pricing rules that were consistent with conventional wisdom regarding depletable externalities. A quadratic programming model was then used to show how these pricing rules could be applied in practice to achieve an optimal allocation of surface water by the alternative means of sole ownership pricing, the creation of return flow markets, and the reassignment of property rights in the event of subsequent transfers. An examination of the institutional problems associated with these methods suggested that economic efficiency could be achieved more easily through decentralized management of return flow markets and reassignment of property rights.

Sanchez, Manuel. "Updating Methods for Adaptive Econometric Models." M.S. thesis, University of Missouri, 1979.

This study examines the problem of updating simultaneous equations models of the agricultural sector. The topic is specialized, as updating is assumed to take place in the structural representation of the system. It is also assumed that the new information is in the form of added sample observations and/or alternative parameter hypotheses. Updating with alternative parameter hypotheses is a method for incorporating the a priori information about how the structural coefficients will evolve over time. The specific components of the study include: (*a*) characterizing the problem of updating with variational parameter hypotheses and additional sample observation, (*b*) developing efficient estimation methods for updating when the two sources of information are used separately or merged, (*c*) illustrating the process of updating in an applied context, (*d*) evaluating the results of the applied updating exercise, and (*e*) assessing the implications of the incorporated additional information and developing guidelines for use of updating in large-scale modeling for the agricultural sector.

Major conclusions of the study relate to updating methods and the applied modeling exercise. For the former, various optimal design concepts were integrated with mixed estimation, forecasting, and simultaneous equations methods to develop an approach for updating in situations with passively generated sample data. These results provide an operational basis for updating large-scale models and for evaluating updated structures. In the application, the results showed that the introduction of variational parameter structures should be justified on a priori grounds if updating is to result in improved model representations. These results are somewhat at variance with those which have been derived for updating reduced form representations.

Stavins, Robert N. "Forecasting the Size Distribution of Farms: A Methodological Analysis of the Dairy Industry in New York State." M.S. thesis, Cornell University, 1979.

This study has five main objectives: (*a*) to describe and analyze patterns of structural change in the New York State dairy industry in terms of the number and size of producers, (*b*) to compare alternative methods of forecasting the future size distribution of producers, (*c*) to select and apply the most appropriate forecasting method to an actual prediction of the future size-structure of dairy farming in the state, (*d*) to analyze the implications of the forecast in terms of the future supply of milk, and (*e*) to demonstrate a technique which may have a wide range of uses in market structure analysis and also may facilitate reasonable supply predictions.

As a means to identify an appropriate method for predicting the 1985 size distribution of New York dairy farms, sixteen approaches are considered. Nine of these are judged to be potentially credible methods and so are examined in greater detail, each being evaluated in terms of theoretical soundness,

data requirements, computational costs, and predictive accuracy.

A variable Markov multinomial logit model is identified as being the most appropriate predictive method and is utilized in making conditional forecasts of the 1985 farm size distribution.

Results of the study indicate that although future change in the size-structure of New York State dairy farming will continue to be mainly in the form of increased mean size of farm; it is also likely that the shape of the size distribution will change significantly more than it has in the recent past, its skewness becoming more pronounced.

Capps, Oral, Jr. "The Impacts of Selected Nonfoods, Foods, Socioeconomic, and Demographic Characteristics on the Decision to Purchase Various Meats and Seafoods for Home Consumption." Ph.D. thesis, Virginia Polytechnic Institute and State University, 1979.

A static complete systems framework was employed to identify and assess factors that affect choices among various meats and seafood for home consumption. The traditional econometric model of food demand was extended to provide a more comprehensive analysis of food consumption and information for decision making and policy formulation for the meat and seafood industry. Additionally, a comparison of alternative statistical models in terms of both their theoretical properties and empirical usefulness was provided and some general principles for workable criteria of model specification for demand systems were developed.

Two issues in empirical demand analysis were explored: (*a*) estimation of complete systems of demand equations using household budget data, and (*b*) incorporation of household characteristics into such systems. The 1972–73 BLS Consumer Expenditure Diary Survey was the data source. Demand systems under consideration were the S_1-branch system and constant elasticity of demand. For each, both with and without household characteristics, estimates were obtained of own-price, cross-price, and income elasticities, marginal budget shares, and system parameters for four regions and the United States as a whole.

The S_1-branch system, and to a lesser degree the CEDS, presented reasonably realistic pictures of national and regional household demand patterns. Although the former system generated more reliable structural estimates, the latter was useful in forecasting quantities purchased. Demands for meat and seafood commodities were extremely sensitive to own prices and income changes. Substitute and complementary goods prices and household characteristics, although important in terms of magnitude of impacts, were of less consequence. Under the assumption that future changes in prices, income, and household characteristics would resemble those occurring 1977–79, quantity demanded and total revenue of pork and poultry products at the retail level increased substantially, while quantity demanded and total revenue of beef products decreased dramatically.

Johnson, Donald Allan. "Investment, Production, and Marketing Strategies for an Iowa Farmer-Cattle Feeder in a Risky Environment." Ph.D. thesis, Iowa State University, 1979.

The purpose of this study was to analyze how a farmer-cattle feeder could manage risk arising from fluctuations in prices as well as crop yields. A model was developed which allowed a farmer to react to risk through choice of investment, production, and marketing strategies.

Maximization of expected utility was assumed to be the farmer's goal. To justify using quadratic programming, a set of sufficient conditions for transforming expected utility problems into mean-variance analyses was developed. These conditions, plus others already developed, were considered appropriate to risk problems typically analyzed.

The actual model was structured as a multiperiod quadratic program using maximization of expected utility of net worth as an objective. Initially, capital gains on assets were included in the net worth; later, for comparison purposes, capital gains were excluded. Options that a farmer could choose among included (*a*) investments in land, machinery, and feedlots; (*b*) production of corn, soybeans, and slaughter cattle; and (*c*) a number of cash and futures marketing activities for produced commodities.

Three different parametric quadratic programming models were solved and a number of empirical results of interest to farmers were obtained. One of the key findings was that a farmer must reduce the scale of his farming operation to reduce risk. Another important result was that using additional marketing strategies would allow a farmer to assume more risk in production and investment. Finally, cattle feeding was found to be a feasible addition to cash grain farms even when risk is considered.

Nygaard, David F. "Risk and Allocative Errors Due to Imperfect Information: The Impact on Wheat Technology in Tunisia." Ph.D. thesis, University of Minnesota, 1979.

This thesis estimates the importance and effect of producer uncertainty, risk preferences, and imperfect information on wheat production in Tunisia, particularly with respect to the use of modern inputs and the adoption of new varieties. First, a model is presented which permits the estimation of the risk preferences of agricultural producers.

Based on producer's perceptions of the production process and response to these perceptions, a risk parameter is estimated.

Second, producer perceptions of the production process at the time of seed bed preparation are compared with the production process realized at harvest. Mistaken perceptions of input-output relationships cause allocative errors which result in lower economic returns to wheat production. It is hypothesized that the errors are larger for the production of newer unknown varieties than for the ordinary varieties and that the allocative error decreases as a producer gains experience growing a particular variety.

The model is empirically tested on durum wheat producers in Tunisia. One hundred and twenty-five farmers in northern Tunisia were visited twice during the 1976/77 season. The first visit occurred shortly after the wheat was planted and most input decisions had been made. A second visit took place after the grain was harvested.

Results indicate that 73% of the farmers in the sample are risk-averse. Farmers with poorer soil and/or smaller holdings tend to be more risk-averse than younger ones. This risk aversion discourages farmers from using economically optimum levels of modern inputs, resulting in a significant cost to Tunisia in foregone wheat production. Risk aversion also inhibits the adoption of high-yielding varieties of durum wheat which are perceived to have more variable economic returns than ordinary varieties.

Comparisons of perceived and true costs indicate that substantial allocative errors are made, caused by misperceptions of the production parameters. Errors are significantly higher for high-yielding varieties and decrease as farmers gain experience.

The impact of income variability and risk aversion on wheat productivity encourages efforts aimed at stabilizing incomes. Perceptions of production processes are subjective and uncertain. Efforts to influence these perceptions can increase the rate of adoption of a new technology and economic returns to that activity.

came at the expense of *Journal* advertising income. The miscellaneous expenses include $498.70 for refunds already recorded as income, $148.44 loss on a bond purchased, $54.00 for copyright fees, $1.00 registration fee, $250.00 dues for statistics, $58.00 for workmen's compensation, $5,000 in grants, $692.12 for exchange charges, bad checks, etc.

The National Registry project started 1979 with a negative $19,741.80, but we received $23,535 toward the USDL grant and spent $2,555.02, leaving a balance of $1,238.18 (table 4). The project was modified in June 1980 for the thirteenth time and was extended to 30 June 1981, at which time the balance of the grant, $10,404, will be forthcoming upon completion of the final report.

In accordance with the policy established in 1973, the Editor provided the income-expense statement for editorial support for 1979 and it is incorporated as a part of this report (table 5). It showed a deficit of $1,500.11.

The Balance Sheet for AAEA showed again considerable improvement, with $114,600.71 added to our net worth as compared to $88,894.62 in 1978 and $48,617.00 (table 6). Officially, the assets are carried on the books at cost. However, market values are shown for your information. Based on cost, the net worth of AAEA has quadrupled during the past four years. A serious problem has suddenly emerged, and that is the accounts receivable. We are increasingly having trouble collecting our bills on time. One additional comment is that over $500,000 went through the bank from about 14,000 checks and something more than that amount went through our stockbroker at my direction. The point is that this represents many thousands of transactions and record keeping, and it is getting larger.

This report covers my tenth year. The Association is currently healthy, viable, and active. With inflation and pressures for increased support for more and more activities, the question soon to be faced is, what services do you want from the AAEA and are you willing to pay for them? I sincerely enjoyed serving as your Secretary-Treasurer for the past decade.

John C. Redman, secretary-treasurer

Report of the Investment Committee

The portfolio subcommittee of the Finance Committee was active during 1979. The portfolio, which went through many changes, produced an income of $28,788.95, or a 72% increase over 1978. All assets carried on the books at cost of $422,044.36 had a market value of $465,010.86 at the end of the year (table 1). However, a large part consisted of near cash. The detail on our stocks—the issue, amount, cost, dividends, market value, including sales and purchases—is shown in table 2, and the detail on our bonds is shown in table 3. Because of the high interest rates, we chose to let debt issues constitute a large portion of our portfolio. I use our Money Mart Asset account heavily to earn a high rate of return on funds not invested or not needed for immediate payment of bills.

The portfolio subcommittee, consisting of chairman John Brake, Richard Feltner, and me, has been active in trying to manage the portfolio well.

John C. Redman

[d] Purchased $40,000 @100 + 2.00 = $40,002.00 on 25 Oct. 1979.
[e] Purchased $25,000 @100-19/32 + 277.50 (int.) = $25,425.94 on 2 Feb. 1979. Matured 1 Oct. 1979, giving 148.44 loss and $277.50 recovery of interest.

Report of the Finance Committee

This annual report covers the activities of the Finance Committee for the period August 1979 to July 1980. The primary activities of the Finance Committee during this period have been to monitor AAEA income and expenses, prepare the 1981 budget, recommend changes in the investment portfolio, and evaluate budget implications of transferring the secretary-treasurer's office. Members of the committee are Joe Coffey, chairman (Virginia Tech); John Brake (Michigan State); John Hopkin

(Texas A&M); Dick Feltner (Louisville (FIBC); and John Redman (Kentucky).

AAEA Financial Condition

The Finance Committee submitted to the December 1979 Atlanta Board meeting a report on the income and expenses of the Association. This report has been updated and is included herein as tables 1 and 2. These tables indicate that the AAEA is in a healthy financial condition. Income exceeded expenses during the calendar year 1978 by $88,894 and in 1979 by $114,601. Currently, it is projected that 1980 income will exceed expenditures by $9,350. Because AAEA operates on a cash rather than an accrual accounting basis, the income and expense balances must be interpreted with care because in some years, the expenses may reflect payments for four issues of the *Journal*, while in other years, it may reflect payments for seven issues. Furthermore, sales of stocks show up as income. Despite these distortions inherent in a cash accounting system, AAEA has strengthened its financial position during the past three years without a membership dues increase.

Portfolio Changes

The investment portfolio committee of the Finance Committee, under the chairmanship of John Brake, with Richard Feltner and John Redman as members, has closely monitored AAEA's investment portfolio and recommended changes in the portfolio which have been approved by the Finance Commit-

tee. In October, the Finance Committee received Board approval for the sale of $28,500 of common stock, the purchase of $50,000 of common stock, and the purchase of a $40,000 eight-month bond at 14.35% interest.

The Finance Committee exercised its authority twice to buy or sell common stocks equal in value up to 15% of the portfolio between Board meetings. Three hundred shares of CIT were sold at $60 on 5 October and 400 shares of Diamond Shamrock at $29-7/8 per share and 600 shares of Browning-Ferris at $17-1/8 per share were purchased on 10 June 1980.

Portfolio Earnings and Market Value

The market value of assets in the AAEA portfolio increased from approximately $360,000 on 31 December 1978, to $505,000 on 31 December 1979. The major source of this difference is an increase in accounts receivable of $35,000 and an increase in Ready Asset account of $140,000. During the 1979 calendar year, the Association had a return including appreciation in the market value of stocks and dividends of $40,810, resulting in a combined yield on stocks of 17.3%. This compares with a 17.1% return based on the Standard-Poor Composite. As of 31 December 1979, the investment portfolio consisted of $161,334 of money market assets, $84,919 of bonds, and $212,667 of stocks.

Changes in the 1980 Budget

On the income side, the budget changes are (*a*) an increase from $36,000 to $47,000 in page charges due to the expected reimbursement from ESCS for the November 1979 special *Journal* issue on regulation; (*b*) a decrease in Newsletter ad revenue from $4,200 to $3,000; (*c*) an increase in investment portfolio revenues from $23,000 to $30,000; and (*d*) an increase in annual meeting revenues from $3,000 to $5,100.

The combined effect of these changes is to change the 1980 budget from a project deficit of $12,500 to a surplus of $9,350.

1981 Approved Budget

The 1981 approved budget follows closely the budgets for 1979 and 1980. The key items are as follows:

(*a*) A $3,200 reduction in *Journal* printing costs based on an assumed 1,100 pages at $79 per page and an increase in editorial support.

(*b*) The AAEA has an agreement with the University of Minnesota Press to guarantee $10,000 for the printing of each volume of the *Survey of Agricultural Economics Literature*. In return, the AAEA receives a 22.5% royalty. In 1981, it is expected that the fourth volume will be printed requir-

ing a guarantee of $10,000, but royalty income is not expected until 1982.

(*c*) A new item in the 1981 budget is a $400 fee to be paid to the Federation of Scientific Agricultural Societies (FSAS). The purpose of FSAS is to provide a forum for interdisciplinary communication and to enhance the capability of the scientific agricultural societies to speak with a unified voice.

(*d*) The Board voted at the 1979 Pullman meeting to join the Committee of Professional Associations on Federal Statistics for three years at $2,000 per year.

(*e*) The proposed budget for the new Secretary-Treasurer's office at Iowa State includes $43,100 for personnel and $19,500 for postage, phone, supplies, printing, etc.

(*f*) The Association jointly sponsors a Literature Retrieval Documentation Center with ESCS and the $19,000 is the Association's anticipated expenses.

Overall, the 1981 proposed budget has a total expenditure of $267,200, an increase of $11,500 over the 1980 approved budget.

Income from dues and subscriptions are the major revenues for the Association. The 1981 proposed budget revenues are based upon the 1976–79 average number of subscriptions in each of the classes of membership multiplied by the subscription rate resulting in a projected revenue of $170,672. The other revenue estimates are similar to those for previous years. The total projected income of $254,472 is lower than expenses resulting in a $12,728 deficit.

Due to the uncertainties of the Secretary-Treasurer's expenses, the inclusion of a $5,000 miscellaneous expenses, and a sizeable investment portfolio, a dues increase does not appear needed at the present. However, the projected deficit does indicate that a dues increase may be needed in 1982.

Joseph D. Coffey, chairman

Report of Tellers Committee

Ballots received from the secretary-treasurer of the American Agricultural Economics Association were counted in accordance with the bylaws of the Association to preserve the secrecy of the ballots. Candidates receiving the largest number of votes were: G. Edward Schuh for president-elect and William E. Martin and Richard G. Heifner for directors.

Joe T. Davis
Angelos Pagoulatos

Report of the Editor

A total of 276 new manuscripts were submitted in 1979–80, compared to 307 last year and 269 in the first year of our editorship. We accepted 111 manuscripts for an acceptance rate of 40.2%. We expect to publish 67 Proceedings papers. Herb Stoevener reports that during the past three years, he processed 357 volumes for the Books Received list, of which 78 books were reviewed in the *Journal*.

Because of my position as editor, I participated in the editing of the Proceedings of a research priorities conference of the animal sciences. To be published this fall, the Proceedings will be entitled *Animal Agriculture: Research to Meet Human Needs in the 21st Century*.

Manuscripts are submitted much more frequently from some institutions than from others. During 1978–80, the top five universities in submissions were: Purdue (44 manuscripts with one or more authors at Purdue), Texas A&M (39), Illinois (31), Georgia (31), and California/Berkeley (29). USDA/Washington led the employer list with 54 submissions.

Multiple authors are fairly common. The 852 manuscripts had a total of 1,450 authors—an average of 1.7 per manuscript.

The *Newsletter* seems to be going well. However, its tardy delivery overseas has been an aggravation that cannot be solved short of extraordinary costs.

Considerable difficulties have been encountered this year with Heffernan Press in both their tardiness in meeting publication deadlines and in billing incorrectly. We hope that both problems have been solved as we pass the editorial task to the new editors.

As outgoing editor, it seems appropriate to reflect a bit on the *Journal*. I am quite aware that it does not contain the variety of lively, broad, policy-oriented papers that a great many of our members say they want to read. Few such papers arrive at an editor's desk. An editor faces an impossible task of bridging the gap between what authors—and most reviewers—want published and what many members say that they want to read. Certainly it is within the prerogative of various segments of the membership to press their desires upon its leadership. My modest point is in tune with the political and economic times: as readers, please moderate your expectations.

The sorting process is difficult. Manuscript quality appears to be distributed much like a normal curve. There are some obvious acceptances and more obvious rejections, but a majority of manuscripts are in that middle arena. I appreciate the self-restraint with which authors have received their rejection letters. I believe that most good manuscripts will be published somewhere if the author is persistent. Nevertheless, I know the sting of the rejection slip; sending so many is one of the more onerous parts of this job.

The editorship has its rewards. One of the greatest is the continual contact with the many active minds of authors and reviewers. The profession is indebted to their contributions. Another reward

Committee Reports

Report of the President

This has been a busy year for the officers of your Association. The format and content of this meeting was designed by the Executive Board sitting as a program committee last November here in Urbana. The mid-year Board business meeting was held in conjunction with the ASSA assembly in Atlanta between Christmas and New Year's Day. A special Board meeting was held in Atlanta in April to consider arrangements for the Secretary Treasurer's office. And, as is the usual practice, a two-day meeting of the Board was held here last Saturday and Sunday to receive committee reports, prepare budgets and to conduct the regular business activities of AAEA.

This three-day meeting is an example of the wide participation in the affairs of the Association. As President, I had the responsibility for inviting speakers in our general sessions. The President-Elect took responsibility for putting together the nine invited paper sessions with the assistance of board members. The selected papers committee chaired by Don Mitchell and Dave Watt and their 16 committee people chose the 132 papers that are being read here. Bud Stanton, Luther Tweeten, and I studied 44 organized symposium proposals that were received from members before choosing 16 for the program.

Progress during the past year can be attributed largely to the work of the many committees of the Association. In the next few minutes I would like to touch on some of the highlights of their activities. These may be grouped in three categories: (*a*) membership services, (*b*) outreach and liaison efforts, and (*c*) management of association affairs.

Membership Services

The work of the several awards committees and the chairmanship of Dan Padberg will be completed this evening in the recognition of outstanding achievement in eight different areas of activity of the profession at the annual awards banquet. Many hours by more than eighty members of the Association go into the successful completion of this selection process. An updated version of these awards conditions will be prepared and distributed this fall to make sure they are readily accessible to all members of the Association.

The Postwar Literature Review is nearing completion. Volume 3 will be going to press this fall, and the final volume dealing with economic development will follow early next year. Distribution of this series is in the hands of the University of Minnesota Press with a 30% discount to be extended to AAEA members who purchase volume 3 when it is released.

The Resident Instruction Committee is to be congratulated for its outstanding teaching workshop held last week in Carbondale. The theme was "Are You Communicating?" Bill Herr and his associates are already thinking about the sponsorship of such workshops on a regular basis. Financial assistance for travel grants was provided by the Farm Foundation and registration grants by AAEA. Some seventy-five persons participated, representing thirty different institutions. Abstracts will be printed in *AJAE,* December issue.

The Student Section of AAEA adopted a new constitution yesterday and the Executive Board amended the Bylaws of AAEA to provide for a more effective relationship between undergraduate student chapters and the Association. The change provides for three faculty advisors on the Student Section Executive Committee, more independent operation of financial affairs by SS-AAEA, and better coordination between SS and AAEA committees and Executive Board. You will note the wide range of student activities at this meeting.

The Industry Commitee has been active this year under Dick Crowder's able leadership. An invited paper session was organized, a highly successful banquet arranged for last evening, and lots of activity on new ideas for expanding membership and services to this important segment of our membership.

Extension folk have been most helpful in proposing organized symposia, submitting papers, and participation in Executive Board work. John Ikerd's committee met yesterday to discuss plans for an Extension workshop at the time of the Clemson meeting next summer. We will hear more about that later.

The International Committee, too, had a highly successful banquet last evening. The AAEA-AID Cooperative Agreement for an International Training Study was successfully completed with a wide variety of papers and publications coming out of this effort, much due to the months of effort devoted to this by Hal Riley and Darrell Fienup but with many other associates. The list of conferences, symposia, seminars, and discussion groups will not fit on two single-spaced typed pages! Congratulations on a fine piece of work.

Now for two areas of membership services where we have some problems. Our Professional Registries work under a Department of Labor contract has been beset with problems of computer changeover, but placements have been going well. The Employment Registries form has been revised and approved with final programming to be completed this fall. Greater use of this service is urged.

A blue-ribbon Literature Retrieval Committee has been at work this year to evaluate this service. I hope you have visited Cynthia Kenyon's stand outside this hall. Some of you may not know that she runs this service year-round at 500 12th Street. Dan Badger's group is working on the problem of visibility for this potentially valuable service, financed in part by your membership dues. Use it!

Outreach and Liaison

Ten travel grants were awarded for AAEA members to attend the 17th International Conference of Agricultural Economists at Banff last September. It was a fine conference in a glorious setting. Talk to Allen Paul or Jim Hildreth to get details on Conference Eighteen, to be held in Jakarta in August 1982.

SEA has expanded contacts with professional agricultural societies in the matter of setting priorities for research, extension, and instruction. The Board is seeking more effective mechanisms to participate in this work. You may wish to drop in on the organized symposium tomorrow morning to add your ideas. The Executive Board has approved participation in a proposed Federation of Scientific Agricultural Societies to assure full consideration of economic dimensions in priority identification and funding.

Although AAEA is not a member association of CAST, many members have made important contributions to the work of CAST task forces, including a number of task force chairpersons. I am sure that Luther Tweeten will continue to receive requests to recommend names of persons with skills particularly suited to new CAST task forces this year.

AAEA will cosponsor a national soil and water research priorities workshop next year. Emery Castle has been asked to serve on the conference planning committee and nominations for committee assignments have been invited. If you have an interest in this area, please mention this to Tweeten or me.

A number of agricultural societies are at work to encourage preparation of a thesaurus of agriculture. We think AAEA participation may be important to see that economic concepts are fully and appropriately represented if such an effort does receive funding.

AAEA will cosponsor two other activities this year. One is an energy symposium with the American Society of Agricultural Engineers, to be held in Kansas City, Missouri in late September. The other deals with the value of weather information, cosponsored with the American Meteorological Society in Boston next January.

Bruce Gardner and his Economic Statistics Committee have provided important inputs into data resources planning, including the Committee of Professional Associations on Federal Statistics (COPAFS) for a trial three-year period and continued representation on the Federal Statistics Users' Conference (FSUC). Gardner also is our representative on the Census Advisory Committee on Agricultural Statistics. Ed Schuh is the AAEA Director for the National Bureau of Economic Research.

AAEA Management

Editorial direction for the period 1981–83 will be provided by the new editor of *AJAE*, James Houck and his associate directors Frank Smith and Ben Sexauer. Ron Schrimper will be the book review editor for volumes 63–65 of our *Journal*. Our sincere appreciation is extended to Jim Rhodes, *AJAE* editor for volumes 60–62, his associate editor Stan Johnson, and their editorial council members for their fine work.

Membership recruitment has been organized by Gene Mathia through regional and local representatives. Suggestions for improving the data base for management of Association affairs have been provided by a committee chaired by Ken Farrell. These efforts should be most helpful in coming years.

During the past year, a great deal of study has gone into planning future arrangements for the office of secretary-treasurer of the Association. You have been kept up to date through the *Newsletter* of the work of John Stovall's committee charged with the responsibility of considering alternative arrangements for the office of secretary-treasurer and a business office, as proposed in the Sundquist committee report that has been discussed in earlier meetings of the Association. Modification of the present structure was called for when the University of Kentucky, having provided generous support for this office for more than ten years, asked that the present arrangement be terminated at the close of the current fiscal year.

Specific actions of the Executive Board are reported in the minutes that are printed with this report. To summarize briefly, the Board reviewed four proposals and by secret ballot unanimously agreed that the Iowa State proposal should be accepted, to take effect not later than 1 January 1981. Dr. Sydney James was appointed Secretary-Treasurer for a term of one year, as provided by Article VI, Section 2 of the Constitution, and the the Board confirmed a commitment of three years, as provided by Article VI, Section 4 of the Bylaws, subject to a performance evaluation each year preceding reappointment.

Dr. James was authorized to create a business office for the Association at Iowa State University and to retain the services of individuals to implement the establishment of this office. Iowa State proposed that Sydney James be named director of the office and Wesley Ebert be named associate director. The Secretary-Treasurer would receive no pay for services in that role but would be paid on a part-time basis as Director of the Business Office. A three-man committee consisting of John Hopkin,

chairman, Tom Brown, and Earl Swanson has been named to formulate and implement plans for transferring the office from the University of Kentucky to Iowa State University.

A resolution of appreciation and special commendation to John Redman for meritorious service as Secretary-Treasurer of the Association since January 1970 was drafted for presentation at this meeting.

In closing, let me express my thanks for your warm support of our efforts during the past year. It has been great. We hope to see you all next year at Clemson.

Richard A. King, president

Report of the Secretary-Treasurer

The AAEA membership for 1979 reached an all time high (table 1). Each year, about 500–600 new members join and about 500–600 drop out, leaving a small gain or loss, depending on response to our efforts. The big turnover occurs in our junior membership and with our A.I.D. memberships. Unless they become rather involved professionally, they join until they graduate or for three years and then drop out. The practice of charging a differential registration fee and of inviting only members to participate in the AAEA activities has been good for the Association. To get the last 1,000 members and last 200–300 libraries to pay requires considerable perseverance.

The number of members who paid their dues on or before 1 April and therefore received a ballot to vote increased by 248, but only 67 more were returned (table 2). This was aided by the fact that if dues were not paid on or before 15 January, the member did not receive the February issue of the *Journal*.

The operating statement for the AAEA business during 1979 showed a record net gain of $114,600.71, as compared to $88,894.62 in 1978 and $48,617.00 in 1977 (table 3). Caution should be noted because in analyzing operating statements, the extraordinary items often convey normal activity. Included in the $114,600.71 gain is a capital gain of $29,050.73, but on the expense side also included are seven issues of the *Journal*, including Part II of the November issue for which AAEA should be reimbursed.

The amount for regular dues was down due primarily to the way A.I.D. pays and the accounting system. The income from subscriptions was up because special effort was made to contact former subscribers encouraging renewal. We provided back copies of the *Journal* for previous years, for which we collected several thousand dollars, and, hopefully, these people will become regular subscribers.

Journal sales were up primarily due to USDA purchase of Part II of the November issue and Canadian purchase of the December 1978 issue. Income from page charges is up but becoming harder to collect. The investment income is up, thanks to the high interest rates and the careful watch on

[a] For six (6) issues of the *Journal*.
[b] For five (5) issues of the *Journal* and *Handbook-Directory*.
[c] For four (4) issues.
[d] For seven (7) issues, including Parts I and II of November 1979.

cash flow. We have a nice little income from the sale of address labels.

While the actual income exceeded by a wide margin the estimate when the budget was prepared, the expenses were about as expected. Compared to last year, the biggest increase in the outlay was for seven issues of the *Journal*. The *Newsletter* for 1979 cost $9,455.32 plus some other costs incurred by my office, but it produced an advertising income of $2,570.00. It was likely that some of this income

is the opportunity to work closely with the Board, a dedicated and impressive group.

It has been a pleasure working with Jim Houck in the transfer of the editorship. He has not only taken my advice, but also my assistant editor! My best wishes to him and his associates at the University of Minnesota.

At the top of my thank-you list must be Stan Johnson, who did a lion's share of the work; Herb Stoevener, who did a great job as Book Review Editor; and our right-hand assistants, Marti Luzader and Donna Taylor. I appreciated the many behind-the-scenes contributions of our Secretary-Treasurer, John Redman, to the publishing and distributing of the *Journal*. My thanks also go to an understanding department chairman, Charles Cramer, and to the Editorial Council. Finally, I extend my utmost appreciation to the many reviewers whose unselfish efforts helped to make this year's *Journal*.

Daniel I. Padberg, chairman

Minutes

Minutes of the Executive Board Meeting, Chicago

The meeting was called to order by President Stanton at 8:30 a.m., 18 January 1979.

Present: Voting members:
Stanton, Hildreth, King, Coffey, Brown, Crowder, Lane, Schuh, Hopkin
Members ex officio:
Redman, Rhodes
Guests:
Loomis, Barr, Connor

1. Stanton reviewed the agenda to be followed during the next two days.

2. Lane moved the approval of the minutes of the Executive Board meeting held at Blacksburg, Virginia, on 5–6 August 1978. Seconded. Passed.

3. Redman, as secretary-treasurer presented a preliminary report on income and expenditures as well as membership statistics for 1978, indicating that results were fairly consistent with the budget. Lane moved acceptance of the report. Seconded. Passed.

4. Rhodes reported as editor, indicating that the total cost for the 1978 *Journal* will be within the budget; the *Journal* is on schedule; authors have paid the page charge for about 88% of the pages; and he presented some concerns associated with *Journal* content. He presented Board with advance copies of the *AAEA Newsletter*, a new activity of the Association. Approximately 6,500 copies were printed to be sent initially to all members and subscribers. Rhodes is to report at the summer meeting on problems and experiences with the Newsletter and, if needed, an advisory committee will be appointed. Crowder moved acceptance of the report. Seconded. Passed.

5. Redman reported for an ad hoc committee to explore the copyright issue. Redman gave a brief summary of the material he prepared on copyrighting the *Journal*. Harl, as our attorney, had received the material but had not had time to offer comments. It was recommended that (*a*) a form be developed to obtain all rights from the author and his employer; (*b*) use the notice "copyright 19____ by the American Agricultural Economics Association" at the bottom of the title page of each article; (*c*) since the AAEA would own all rights, permission for reproduction by professors, libraries, and nonprofit agencies be given liberally up to specified limits; and (*d*) members of AAEA be made aware of copyright restrictions. Lane moved that the *AJAE* place on the title page of each article the notice "Copyrighted 19____ by the American Agricultural Economics Association." Seconded. Motion lost. It was suggested that the committee continue its study of the copyright issue, secure an opinion from our attorney, and report again with recommendations at the 1979 summer meeting.

6. Stanton reviewed the plans for the 1979 summer meeting. The invited paper sessions are well organized. Nerlove was selected by the Board from a number of suggestions to give the Kellogg lecture. Loomis, chairman of local arrangements for 1979 summer meeting, reported on plans made, proposed budget, etc. Brown moved that the registration fee be $20.00 for singles and $25.00 for families. Seconded. Passed.

Hildreth moved that any surplus which may result from the registration fees after meeting all expenses be divided on a 50–50 basis and any loss be sustained by the AAEA. Seconded. Passed.

Hopkin moved that the registration fee for undergraduates be set at $5.00. Seconded. Passed.

7. Each year the AAEA has the opportunity to make a nomination for the Browning award. Since the AAEA's nominee won the award last year, the special committee chaired by Breimyer recommended that AAEA wait until 1980 to make a nomination. Crowder moved that AAEA not make a nomination this year. Seconded. Passed.

8. Conner reported as chairman of an ad hoc committee on CAST, giving general description of purposes, organization, operation, financing of its activities, and the possible costs and benefits involved in membership. Crowder moved that an ad hoc CAST committee report and a questionnaire be sent to the membership under the President's signature asking that the questionnaire be returned to the chairman of the ad hoc CAST committee by a given date for analysis and pointing out that a vote will be taken at the time of the annual meeting on whether AAEA will join CAST. Seconded. Passed. The statement and questionnaire are to be sent via "permit mail" to North American members as soon as possible.

9. Sundquist reported as chairman of the Management, Structure, Methods, and Procedures Committee, listing the major issues surfaced from the study as follows: (*a*) Any modification in organization and management of AAEA which weakens the broad base of participation by members in policy making, activity planning and programming would be viewed with disfavor. (*b*) Other than bylaws, there is little currently available in the way of formal position descriptions, identification of responsibilities, and specification of operating procedures for officers, board members, and committees. (*c*) Keen interest and strong performance by individual officers, board members, and committee chairpersons is crucial to AAEA, with its broad-based committee structure and high turnover of individuals in positions of responsibility. (*d*) An ac-

cessible, up-to-date data base of AAEA membership is a key "missing ingredient" for effective planning and management for a broad set of current and potential activities. (*e*) Some restructuring of management responsibilities in AAEA policy making, program planning, and implementation might be needed in order to reduce the workload of the president. (*f*) The changing from the present organization to one that includes an executive office raises sub-issues of additional cost, the possibility of the director unsurping the current broad decision-making involvements of AAEA members, and the felt need to move in direction of a central administrative office to reduce the heavy workloads and subsidizations currently inherent in the offices of the president and secretary-treasurer and to undergird the provision of more effective current services and additional programming for numerous special interests. King moved that AAEA affirm items (*a*), (*b*), and (*c*) above. Seconded. Passed.

Crowder moved that AAEA adopt the recommendation to continue and strengthen the current practice of assigning responsibilities to individual members of Board to design, monitor, and manage the programmatic, financial, and administrative activities of AAEA. Appropriate mechanisms for accountability should be developed and implemented. Seconded. Passed.

Crowder moved that AAEA adopt the recommendation that a task force be established immediately consisting of the immediate past president and the president-elect, augmented by not more than two additional members, to develop operational position descriptions for the Association's president-elect, president and immediate past president with the objective to outline a three-year sequence of responsibilities to spread more evenly the workload of the AAEA presidency so more attention can be given to policy planning and innovative programming. Seconded. Passed.

Crowder moved that the recommendation be adopted to establish immediately a small working task force to specify an operational data base, needed for use in the effective management and programming activities of AAEA, to estimate the cost of developing and maintaining the data base and to specify specific steps needed to implement the operation. Seconded. Passed.

Crowder moved to table the recommendation that a task force be appointed immediately, consisting of both current members of the board and other members to plan the establishment of an executive office for the Association to be operational by no later than 1983 and to be located in either Washington or Chicago. Motion died for lack of second. Hildreth moved that the recommendation be an item on the agenda for the summer 1979 board meeting. Seconded. Passed.

10. Barr reported for the committee to establish a position description and list of responsibilities for the office of secretary-treasurer. Lane moved the adoption of the report and it be made a part of the bylaws as Section I, entitled "Organization and Operation of the Office of the Secretary-Treasurer." Seconded. Passed.

11. Bromley sent a statement concerning a recommendation and procedures concerning sponsorship of conferences and symposia. The AAEA should actively seek proposals prepared according to prescribed guidelines. These will be evaluated by the Professional Activities Committee and a recommendation made to the Board for final action. Lane moved the approval of the statement and its incorporation in the statement of Board policy. Seconded. Passed.

12. Hildreth reviewed the recommendations on the proposal for establishing a special committee on large models of the agricultural sector. After discussion, Hildreth moved that the recommendation be adopted. Seconded. Passed.

13. The report by Meenen on evaluation of annual meetings was discussed. It was the consensus that the chairmen of the various sessions at the 1979 meeting should be asked to evaluate their sessions according to criteria to be supplied to each chairman by those establishing each of the major sections of the program.

14. Redman presented a letter from Cal Conner and an accompanying report covering the 1978 summer meeting at Blacksburg. The meeting produced a surplus of $8,838.79 of which 60%, or $5,302.27, reverted to the AAEA. Hopkin moved acceptance of the report with appreciation to the Department at VPI. Seconded. Passed.

15. Coffey reported for the portfolio subcommittee of the Finance Committee. The recommendations were to (*a*) convert all AT&T preferred to common stock; (*b*) sell 200 shares of Texaco October options at about 26; (*c*) purchase $15,000 of Farm Credit 6-month bonds; (*d*) purchase $15,000 of Farm Credit 9-month certificates; (*e*) purchase 300 shares of American Home Products at about $28 or 400 shares of Continental Corporation at about $24–$25. Lane moved acceptance of recommendation (*a*) and (*b*) and moved that $25,000 of short-term obligations of six to nine months be purchased. Seconded. Passed.

Crowder moved that 200 shares of American Home Products be purchased at about $28 or better, with a stop placed at about $25. Seconded. Passed. He suggested that all of AAEA issues be studied by the Finance Committee with the idea of placing stops on each issue.

Hildreth moved to authorize the secretary-treasurer to place short-term funds not needed for operations into money market funds or passbook savings accounts with the criteria for choice to be the rate of return. Seconded. Passed.

16. Lane presented a proposal for rewording the criteria for eligibility for outstanding Ph.D. and M.S. degree program awards. After considerable discussion, no action was taken. Lane agreed to

work with the Awards Committees to redraft these criteria again.

17. Lee Martin sent a status report on the sales of volumes 1 and 2 of the *Postwar Literature Review*. A total of 1,444 copies of volume 1 and 1,009 copies of volume 2 have been sold. Martin expects volume 3 to be ready by end of 1979.

18. Stanton reported that an extension of the USDL contract had been requested to 30 September 1979, with no change in amount of funds required. Completing the contract by that date is strongly encouraged.

19. Coffey presented the plan to be followed in evaluating and obtaining proposals for the *Journal* printing contract. Bids will be sought from four or five printing firms and will be evaluated from both monetary and nonmonetary standpoints.

20. Hildreth reviewed the possible future sites and invitations for AAEA annual meetings. After discussion, Lane moved that AAEA accept the invitation to meet on the campus of Clemson University 26–29 July 1981. Seconded. Passed.

Lane moved that AAEA accept the invitation to meet at Utah State University during the last week of July or first week of August 1982. Seconded. Passed.

21. Hildreth reported on the symposium on food regulation jointly sponsored by ESCS, Farm Foundation, and AAEA. It was proposed that USDA publish the papers from the proceedings in a special issue of *AJAE* with ESCS covering the costs. It was agreed that USDA and AAEA should proceed to work out the details on publication, with the privilege of veto by the president and editor.

22. Hildreth presented an updated set of Bylaws as well as an up-to-date statement of policies of the Board. Lane moved the approval. Seconded. Passed.

23. Stanton reported on a request from Science and Education Administration (SEA) seeking suggestions of high priority problem areas deserving further study and analysis. Five problem areas selected were (*a*) identifying sources of agricultural productivity, (*b*) establishing new criteria for evaluating agricultural research, (*c*) emphasizing the economics of human nutrition, (*d*) improving the efficiency of transport in food industry, and (*e*) understanding the impact on rural communities of migration to and from urban and suburban areas. Each issue is to be described with 100 words or less and sent to the director of SEA by the AAEA president.

24. Crowder commented on current budget allocations to individual activities of AAEA, raising questions on what would have been the result if different allocations had been made and encouraged use of the opportunity cost principle in considering alternatives.

25. The Executive Board went into executive session to review the nomination for Fellows and make the selection of those to be presented to the Fellows Election Committee to be elected as Fellows.

26. Board adjourned at 1:30 a.m., 19 January 1979.

Respectfully submitted,
John C. Redman
Secretary-Treasurer

(These minutes were inadvertently omitted from the 1979 Proceedings.)

Minutes of the Executive Board Meeting, Atlanta

The meeting was called to order by President King at 1:00 p.m., 27 December 1979.

Present: Voting members:
King, Stanton, Tweeten, Brown, Coffey, Dennis, Harl, Hopkin, Schuh
Members ex officio:
Redman, Rhodes, Colyer
Guests:
Padberg, Halcrow

1. King reviewed the agenda and obtained its approval.

2. Local arrangements for the Allied Social Sciences Association meeting were reviewed briefly. All sessions sponsored by AAEA will be held at the Hyatt-Regency including the reception-cash bar for AAEA members on 28 December.

3. Stanton moved the approval of the minutes of the Board meetings at Washington State as distributed. Seconded. Passed.

4. Secretary-Treasurer Redman reported that membership for 1979 was the largest in history, with 6,538 in all categories, a net increase of 221 over 1978. The Association's cash-flow position was strong. He indicated the likelihood of a substantial positive balance for the year when the books are finally closed. No specific balances could be presented because the year was not yet completed.

5. Editor Rhodes reported for operations with respect to the *Journal* and *AAEA Newsletter*. For the year December 1978–November 1979, the *AJAE* published 1,288 pages, at an average cost of $65 per page plus some additional charges for mailing billed directly to Redman's office. He concluded the *Journal*'s costs were within budgeted estimates. Page charges had been collected on 84% of those to which they had been billed compared to 88% in the previous year.

The Newsletter has been well received. There has been a problem of including all the material proposed within sixteen pages on a bimonthly basis. The Board agreed that the current format should be continued.

Editor Rhodes reported that 17 of the 100 contributed papers presented at Pullman, Washington,

had so far been submitted for review as notes or articles.

6. The proposal from Johnson Associates to obtain a nonexclusive agreement from AAEA to microfiche the *AJAE* was discussed. No formal action was taken, given our continuing relationship with University Microfilms.

7. Halcrow as arrangements chairman presented the plans for the summer meeting of the Association at the University of Illinois, Champaign-Urbana. The proposed budget was reviewed. It was moved, seconded, and carried that registration fees be set as follows: Member \$30, student \$15, member's spouse \$10, all children in one family \$7, nonmember \$55 (\$25 for AAEA membership), nonmember undergraduate and graduate student \$27.50 (\$12.50 for AAEA membership). AAEA guaranteed 1,000 member registrations to the University of Illinois to cover basic costs. Illinois will impose a late registration fee of \$20 for members and \$10 for students after 15 June. Refunds of registration fees in full will be made to registrants if requested by 15 August 1980. Other details of facilities available and costs were discussed. Refunds on banquets and dormitory fees will be made if requested by 15 July. The budget and tour schedule was approved as presented after substantial discussion.

8. Announcements for the Selected Papers (Contributed Papers) and Organized Symposia were distributed by President King. These were approved and will appear in the January 1980 Newsletter. Mitchell and Watt will serve as co-chairmen of the Selected Papers Committee. Proposals for symposia will be sent to President King for review by him, the president-elect and past president. Tweeten reviewed the progress in the development of the Invited Paper sessions chosen by Executive Board at the program planning meeting held at Urbana, Illinois, 13 November 1979.

9. Schuh, chairman of the ad hoc committee to solicit nominations for a new editor, reported. Six proposals were received and briefly reviewed. After discussing the criteria used for evaluating the proposals received, the committee recommended further consideration of three of the nominations by the Board as a whole. All three proposals received substantial discussion. A secret ballot was taken and the proposal from the University of Minnesota with James Houck as editor assisted by Sexauer, Eidman, and Smith was selected and approved.

10. Coffey reported for the Finance Committee and distributed an eight-page written report including projection of income and expense for 1979, and updating the events affecting the 1980 budget since the budget was passed in July 1979. It was projected that AAEA will have a surplus of approximately \$25,000 for 1979. (Later, after the books were closed, surplus was \$115,000).

A statement on portfolio holdings distributed by Redman was reviewed. After the July Board meeting the following actions recommended by the Portfolio Subcommittee were taken: (*a*) 5 October 1979, 300 shares of CIT were sold at \$60 per share; (*b*) 10 October 1979, 400 shares of Standard Oil of Indiana sold @ 71-¼; (*c*) 9 October 1979, 400 shares of Continental Corporation were purchased @ 25; (*d*) 10 October 1979, 400 shares of Foremost-McKesson were purchased @ 25, 300 shares of Southern Pacific purchased @ 33-¾, 400 shares of Gerard purchased @ 26-½, 200 shares of MMM purchased @ 52-⅜; (*e*) 1 November 1979, purchased \$40,000 Federal Farm Credit Bank's 9-month bond yielding 14.35% interest.

No new transactions or changes in the portfolio were recommended to the Board by the Subcommittee on Portfolio, chaired by Brake, with Feltner and Redman as other members.

The Finance Committee recommended to the Board a new wording on its policy with respect to stop-loss orders, and actions to be taken by the Portfolio Subcommittee between Board meetings. After substantial discussion of the new proposal in comparison with the existing policy, the proposal was withdrawn by Coffey for further review by the committee and discussion at the next Board meeting.

The overall report was accepted with appreciation by the Board for the continuing work of this key committee.

11. Redman presented a proposed time schedule for publication of the next *Handbook-Directory*. No action was taken.

12. Coffey and King reported for the ad hoc committee chaired by John Stoval, which was asked to investigate alternatives for the future location and handling of the business and office operations of AAEA.

Coffey reviewed tentative budgets or costs associated with different methods of operating the Office of Secretary-Treasurer under possible alternatives suggested by the ad hoc committee.

King distributed a letter from Robert Rudd, Chairman of the Department, University of Kentucky, dated 7 December 1979. It proposed that AAEA reimburse the University for time and services rendered to support the Office of the Secretary-Treasurer. In return, the University would make services of Redman available officially on a full-time basis to operate and manage the office of AAEA and to perform other assigned duties, starting 1 July 1980, or sooner if possible, and to continue for a period of five years terminating with his retirement. Kentucky indicated no interest in continuing a part-time commitment on Redman's time, arguing that this was unfair to both Redman and the University.

Redman called the Board's attention to the several pages of job description developed by the Board. He detailed a long list of questions on duties to be performed should the AAEA employ the American Dairy Science Association to manage its

office. He noted also that he had given ten years of personal and enthusiastic service and that the University of Kentucky had permitted him for a number of years to devote virtually full time to do the increasing amount of work efficiently. It was suddenly realized that Redman had experienced a sizable financial penalty for lack of productivity to the University. Both Redman and the University thought this proposal was a fair, equitable, and reasonable way to solve a dilemma.

The Board went into Executive Session to consider the proposal and respond to the Rudd letter. It was moved, seconded, and carried unanimously that the following statement be made:

> The President reported that a communication had been received from the University of Kentucky relative to future arrangements for the office of Secretary-Treasurer. After extended discussion, it was agreed by the Board that, in light of financial considerations and duties of the office as presently defined, it would not be feasible to move to employment of a full-time individual in an executive position with the Association. The President was instructed to so advise the University of Kentucky.
>
> The Board reviewed the efforts to date in evaluating alternatives for the management of financial, accounting, and clerical aspects of Association activity and concluded that further evaluation was needed but that a consensus existed favoring a move toward an off-campus arrangement.

13. The Board continued in Executive Session to consider the report of the Board Advisory Committee on AAEA Fellows nominations. Redman had distributed previously to the Board twenty-two formal nominations that had been received from departments or groups. All nominees from previous years were considered along with a group of names generated by the committee and the Board. By a series of secret ballots, the list was narrowed and eight names were selected and forwarded to the Fellows Election Committee for final decision.

The meeting recessed at 10:00 p.m. and reconvened at 8:30 a.m. 28 December 1979 in the same location.

14. The Professional Activities Committee, chaired by Bromley, prepared a written report which was distributed to the Board. Hopkin led the discussion on its proposals. It was moved by Hopkin, seconded by Harl, and carried that AAEA sponsor the teaching workshop as proposed by the Resident Instruction Committee, entitled "Are You Communicating," and that AAEA allocate $1,000 to support this workshop, with the requirement that a minimum of $600 be allocated for awards to young agricultural economists (including Ph.D. candidates) for registration fees. It will be held at Southern Illinois University the Friday and Saturday preceding the summer meetings at the University of Illinois. Herr from Resident Instruction Committee was present and answered questions about the proposed program. It will be promoted through departments and the *AAEA Newsletter*. King appointed Hopkin to serve as the Board liaison with the workshop. The Board commended the committee for its revised proposal and planning efforts.

The Professional Activities Committee recommended that AAEA cosponsor the Symposium on the Value of Weather Information with the American Meteorological Association in Boston, January 1981, on the recommendation of a special subcommittee chaired by L. Eisgruber. Hopkin moved, seconded, and carried that sponsorship by AAEA be given and that the President appoint a liaison person to work with AMA on the symposium. Hopkin was appointed as Board liaison.

On recommendation of Wally Tyner and his ad hoc committee, Hopkin moved that the AAEA join the American Society of Agricultural Engineers in sponsorship of a National Energy Symposium. Seconded. Passed. Miranowski, of Iowa State, and Doering, of Purdue, were suggested as AAEA liaisons. Schuh was designated as the Board liaison.

15. President King distributed a listing of all committee appointments to the Board. These will be published in the Newsletter as rapidly as possible.

16. Other standing committee reports:

(*a*) No special action was required on an oral report from Economic Statistics given by Hopkin.

(*b*) Mathia sent a report from the Membership Committee. Recruitment is organized on a regional basis. The new brochure has been distributed; special targets for 1980 are graduate students and extension workers.

17. Other special committee reports: Oral briefings or comments were made by Brown with respect to the plans of the Extension Affairs Committee. Chairman Ikerd has already commented to the membership through the Newsletter. A special program effort during 1980 is planned.

Dennis reported that Crowder had activated the Industry Affairs Committee which has met once in Chicago and is planning activities for the summer meetings. Johnson sent a report for the Professional Registries Committee. The changeover to a fully documented program managed and handled by the Illinois State Employment Service has proceeded slowly. President King reported briefly on progress in publishing the final two volumes of the *Postwar Literature Review*, indicating that volume 3 should be available during 1980.

18. AAEA has again been requested by SEA, USDA to provide the Association's suggestions for priority areas for funding in the next USDA budget. The Board responded to a similar request for the first time a year ago in January 1979. It was generally agreed that the Board should respond formally to this initiative as effectively as possible. An open discussion of possible priority items in the areas of research, extension, and instruction was led by President King. Some materials prepared in ad-

vance by Board members were distributed and reviewed. Rather than try to operate as a committee-of-the-whole Schuh was asked to form a subcommittee consisting of Tweeten, Brown, and Harl to develop a set of statements with the help of other Board members. It was agreed that Schuh would summarize these priority statements in the form requested by SEA and present them to Bertrand in written form. If possible, Schuh was encouraged to seek a meeting with the SEA administrator to present these priorities personally and emphasize the need for greater emphasis on social science research and outreach activity. Copies of the final documents were to be distributed subsequently to all Board members.

19. The Board reviewed the invitation from the Department of Agricultural Economics, Cornell University, to host the meetings in Ithaca on 5–8 August 1984. The Board voted unanimously to accept the invitation. This means that the summer meetings will be held in 1981 at Clemson; 1982 at Utah State; 1983 at Purdue; 1984 at Cornell; and 1985 at Iowa State. Redman and Farris were to be asked to explore alternatives should Purdue desire to withdraw.

20. Redman presented the report by Loomis on the results of 1979 annual meeting at Washington State University, and noted that a check for \$2,122.19, representing one-half of the net surplus, had been received. Stanton moved that the report be accepted and again express our gratitude to Loomis and Washington State for an outstanding meeting. Seconded. Passed.

21. King reported that a communication had been received from M. Johnson of North Carolina State proposing that an individual rather than two nominees be presented each year for the office of president-elect. The consensus of the Board was that the membership was firmly on record favoring the present method of paired nominations.

22. Breimyer, Chairman of the Browning Award Committee, reported via letter that documentation for a candidate for the Browning Award would be provided in the near future. His committee suggested that a nominee for the von Humboldt Award not be forwarded this year. The Board concurred and the President agreed to forward to the Board members the supporting information concerning the nominee for the Browning Award when received from Breimyer.

23. Appreciation was extended to Gold Kist, Inc. and Glen Glover for their support of the social hour on 28 December for AAEA members.

The meeting was adjourned at 12:10 p.m.

Respectfully submitted,
John C. Redman
Secretary-Treasurer

Minutes of Special Executive Board Meeting, Atlanta

The special session called by President Richard King met first in an informal session on 10 April 1980, at 7:30 p.m.

Present: Voting members:
King, Coffey, Hopkin, Brown, Stanton, Dennis, Tweeten
Absent: Voting members:
Harl, Schuh (who was present on April 11)
Members ex officio:
Redman
Guests:
Hildreth, Rudd

1. King presented a summary of events leading up to the purpose of the call of the special board meeting and opened the floor for general informal discussion.

2. Rudd reviewed the University of Kentucky proposal which called for AAEA to reimburse the University for time and services rendered to support the office of Secretary-Treasurer, and in return, the University would make services of Redman available officially on a full-time basis to operate and manage the office and perform other assigned duties for a period of five years terminating with his retirement. Discussion followed, including the possibility of a part-time arrangement with Kentucky and AAEA.

3. Stovall presented the report of the Ad Hoc Committee on Establishing an Office for AAEA. It recommended that the Executive Board of AAEA begin negotiations with the American Dairy Science Association to conduct the business and management affairs of AAEA commencing 1 January 1981, at a cost of \$5 per member, or approximately \$35,000 per year.

The committee presented some concerns and issues which the Board should consider. They were:

(*a*) *Loss of control by AAEA*. Turning the business over to another organization might be construed by members as a loss of control and as a threat to the special character of AAEA.

(*b*) *The AJAE*. The Dairy Science Association provides editing and publishing services for several journals. The AAEA will have the option (i) continue the current arrangement with our editor and printer and exclude Dairy Science, (ii) include *AJAE* as a part of the arrangement to be negotiated, or (iii) defer action now and decide at a future date, after a committee has studied the choices and made recommendations. The committee recommended option (iii).

(*c*) *Investment portfolio*. For other associations, Dairy Science handles the investment. The committee recommended that AAEA continue to handle long-term investments but allow Dairy Science to manage the short-term investment and cash-flow requirements.

(*d*) *Handbook-Directory*. The negotiations with Dairy Science should include consideration of a directory and the cost that would be incurred.

(*e*) *Data processing*. It was the belief of the committee that AAEA could benefit from modern computer hardware and software to handle much of our data base and for developing financial reports, accounts, membership lists, etc. The ADSA does not have nor does it plan to obtain such capability. This issue should be discussed fully with ADSA prior to any agreement and that a condition of such agreement be a study of the feasibility of ADSA converting to a computerized system and that AAEA participate in such study.

(*f*) *Duties of AAEA secretary and/or treasurer*. If the agreement with ADSA is consummated, a change would be needed in bylaws specifying the duties of the secretary-treasurer. Most associations affiliated with ADSA continue to have one of their members serve as secretary and/or treasurer whose major duties would be to record the proceedings of meetings of the Board and conduct certain financial or legal transactions. The committee recommended that bylaws be changed to recognize ADSA responsibility for handling the business and management affairs, defining a more limited role for the secretary and that there not be an office of treasurer.

(*g*) *Transition*. It appears that the best time to transfer the office would be at the end of the calendar year, with an audit and accounts transferred as of 1 January 1981. A period of transition would be necessary to phase out operations at the University of Kentucky and to begin at Champaign, Illinois. The ADSA should begin the transition during the fall of 1980 and begin certain functions, such as mailing out notices of dues and the transfer of membership lists to the ADSA system.

The committee suggested a special committee be appointed (composed mainly of Board members) to begin negotiations with ADSA.

4. Redman gave a long and detailed list of tasks, duties, and responsibilities of the secretary-treasurer, which apparently would not be performed by the ADSA. He estimated that ADSA would perform about 30% of the current workload, and raised questions on the desirability of separating the financial and business records from other records of the office.

The Board recessed.

5. The Board reconvened at 8:00 a.m. on 11 April 1980 and went into executive session.

The following action was taken:

It was moved by Coffey, seconded by Schuh, and carried unanimously that the Board reaffirm its decision made 27 December 1980 at Atlanta and reported as Item 12 in the minutes. It was further moved, seconded, and carried unanimously that in light of financial considerations and the duties of the office as presently described, it is not feasible to employ a full-time individual in an executive position with the Association and that the Board move toward establishing an off-campus arrangement for handling the business affairs of the Association.

It was moved by Hopkin, seconded by Stanton, and carried unanimously that the Association commend Redman for his long and faithful services and express appreciation to Redman and to the University of Kentucky for providing these distinguished services. In deference to the position taken by both the University of Kentucky and Redman which precludes Redman continuing these services, the Board shall initiate a search for a secretary-treasurer who will serve without financial compensation and who will assume this office 1 January 1981.

6. Hopkin moved and it was seconded by Schuh that the report of the Stovall committee be accepted in principle and that the President appoint a committee to delineate the services to be performed by the office of the secretary-treasurer, the Finance Committee, and the American Dairy Science Association (ADSA), and that the committee negotiate the terms of contract with ADSA under which the desired services will be performed and report to the July 1980 meeting of the Executive Board. Motion carried. King appointed Hopkin as chairman, Harl and Stovall as members of the committee.

7. Tweeten moved that the Stovall committee be discharged with thanks. Seconded. Passed.

8. King will prepare items for the Newsletter and a letter to departmental and agency heads informing members of the decision and soliciting expressions of interest in the position of secretary-treasurer.

9. Other business which came before the meeting was as follows:

(*a*) Schuh moved that abstracts of papers presented at the proposed Teaching Workshop be published in the December issue of the *AJAE*.

(*b*) Schuh indicated that the budgetary allowance made for editorial support at the University of Minnesota was insufficient for the last six months of 1980 (transition period). He will request $17,400, as compared to $12,000 budgeted and will request $42,000 for 1981.

(*c*) A concern was expressed on the nature and characteristics of the data being collected by the Registry. No specifics were discussed but it was indicated that this was a concern to be discussed at another Board meeting.

The meeting was adjourned at 12:15 p.m.

Respectfully submitted,
John C. Redman
Secretary-Treasurer

Minutes of the Executive Board Meeting, Urbana, Illinois

The meeting was called to order by President King at 8:30 a.m., 26 July 1980.

Present: Voting Members:
Brown, Coffey, Dennis, Harl, Hopkin, King, Schuh, Stanton, Tweeten
Members ex officio:
Andersen, Koch, Houck, Menzies, Redman, Rhodes
Guests:
Halcrow, Heifner, Martin, Padberg

1. King reviewed the agenda and obtained its approval.

2. King announced the results of the election and congratulated the winners. Schuh was elected as president-elect and Martin and Heifner were elected as directors.

3. Halcrow reported for the Local Arrangements Committee. He indicated that 857 had preregistered and all arrangements were in order. The problem of members attending the meeting without registering was discussed. Various suggestions, including checking name tags at the door, were made to cope with the problem. None were adopted, but President King was instructed to explain why it was important for a member to register and wear the name tag.

4. Redman presented the Minutes of the 27–28 December 1980 Atlanta meeting and of the 10–11 April 1980 Atlanta meeting. Schuh moved the approval of the minutes as revised. Seconded. Passed.

5. Redman distributed copies of the report of the Secretary-Treasurer for 1979 and the report on investment activity for 1979, which will be presented at the annual business session.

6. Padberg reported for the Awards Committee. He suggested some modifications of the awards program for clarification purposes.

Stanton moved that Article V, Section 3, of the bylaws be amended by replacing the statement, "Three awards are offered" to "Three awards are given." Seconded. Passed.

Tweeten moved that Article V, Section 6 of the bylaws be amended to clarify further the nominations by the insertion of "Individual or group efforts may be nominated. In groups, the name and contribution of each person must be identified in the nomination," before the last two sentences in the section. Seconded. Passed.

Hopkin moved that Article V, Section 1, of the bylaws be amended to give two Extension awards—one for an individual and one for a group. Seconded. Passed.

King raised the issue of developing a brochure to announce the awards program by the end of the year. The consensus was to use the *AAEA Newsletter* and "other appropriate" means.

7. King reviewed the events which took place since the 10–11 April 1980 Executive Board meeting concerning the location of the Secretary-Treasurer. The American Dairy Science Association indicated they were not interested in providing the management services for AAEA. King offered to have a representative from AAEA present at the next ADSA board meeting should they desire.

The ADSA board reconsidered the proposal but decided not to take on the task. King then sent a letter to various departments and agencies asking for an expression of interest in the office of Secretary-Treasurer. From this, four responded—Kentucky, American Economic Association, Iowa State, and Mel Janssen with USDA support.

The Kentucky proposal was essentially what was presented at the Atlanta meetings, involved reimbursing the University in the amount of $35,000 for professional time expended, with the University providing adequate office space, fringe benefits, equipment, purchasing advantages, etc. With $20,000 allocated for secretarial and clerical assistance, the total personnel cost would be $55,000, including fringe benefits. The Secretary-Treasurer officially would be assigned full-time duties to the AAEA and the office would provide an uninterrupted flow of services, as it has for the past ten years, for an additional period of five years, including the preparation of a camera-ready copy of the next *Handbook-Directory*, as it did for the 1972 and 1976 editions, and other assigned duties.

The American Economic Association proposal, which was incomplete, provided for maintenance of addressing and membership lists but no accounting, secretarial, or management services. The estimated cost would be $30,000 per year with a one-time cost of $7,000 for processing the information.

The Iowa State proposal involved a total of $43,100 for personnel time and fringe benefits, and would include the secretary-treasurer for one-fourth time and a business manager for one-third time for a three year period. All other activities would be at cost. Nothing was said about the cost of producing a camera-ready copy of the *Handbook-Directory*.

The Janssen proposal was for six years and involved a one-time cost of about $16,000, plus annual personnel cost of about $30,000. This would be for two part-time secretaries and an honorarium for Janssen who is retiring from USDA. The ESCS-USDA was expected to provide space and certain other support, but details were less definite. After the first year, Janssen expected to provide approximately half to three-fourths time. All other activities would be at cost.

Hopkin suggested that the AEA proposal be eliminated and that Janssen and Farrell (ESCS) and Ebert and James (ISU) be present at a convenient time for a few questions. Discussions were delayed until the next day.

8. Rhodes reported as outgoing editor. His report will be given at the general business session. Based on experience, Rhodes noted that too much material had been allocated to the Newsletter and recommended that listing of Ph.D. dissertations be returned to the *AJAE*. The *Journal* also provides a

more permanent record. Stanton moved that the change be made effective in 1981, with a note as to availability of 1979 and 1980 lists. Seconded. Passed.

Houck reported as incoming editor. He announced his Editorial Board and that Martha Luzader would transfer to Minnesota to continue with the *Journal*.

9. King presented the facts on contractual and operational procedures with the University Microfilms. Over the past few years Johnson and Associates, a competing firm, had been contacting AAEA for a portion of the business. Tweeten moved that AAEA not pursue the Johnson and Associates proposals and remain with University Microfilms. Seconded. Passed.

10. Coffey reported for the Finance Committee, presenting a proposed budget and the financial transactions involving the portfolio. The decision on budget composition and approval was delayed until the end of the meeting.

11. Faris and Pittman, of Clemson University, gave a brief summary of the arrangements being planned for the 1981 meeting.

12. Redman reported that liability insurance coverage for AAEA was in effect. Redman presented a proposal received from the same insurance broker for group life insurance for AAEA members. Consensus was that AAEA had no interest in such a program.

13. Redman raised the point that AAEA did not have a positive policy statement concerning discrimination. Harl was requested to draft a suitable resolution to reflect the past and present policy of AAEA. The following was proposed:

Resolution

Whereas, the American Agricultural Economics Association, since the formation of its predecessor organization on or about 1910, has been a professional organization open and equall accessible to all persons without regard to age, race, color, sex, creed, ethnicity, or country of national origin, and,

Whereas, the American Agricultural Economics Association has had a strong commitment to extend membership, committee appointments, honors, awards, elective and appointed offices, and all rights of any type or kind whatsoever to persons affiliated in any manner with the American Agricultural Economics Association without regard to age, race, color, sex, creed, ethnicity, or country of national origin, and,

Whereas, the Executive Board of the American Agricultural Economics Association, acting for the Association, deems it to be advisable, desirable, and in the best tradition of the American Agricultural Economics Association to express formally and unequivocally its commitment to openess to all persons affiliated in any manner with said Association, and, therefore

Be it resolved that the American Agricultural Economics Association, acting through its duly elected Executive Board, does hereby affirm a policy of nondiscrimination to all persons affiliated with the American Agricultural Economics Association on the basis of age, race, color, sex, creed, ethnicity, and country of national origin.

Dated at Urbana, Illinois, this 27th day of July, 1980.

John C. Redman
Secretary-Treasurer
American Agricultural Economics
Association

Harl moved that the statement be accepted and be placed in the AAEA policy manual. Seconded. Passed.

14. Redman reported for the Post-War Literature Review Committee. He reported that 1,685 copies of volume 1 and 1,290 copies of volume 2 had been sold with about one-third of each going to nonmembers. To publish volume 3, the publisher proposed $10,000 subsidy instead of $7,500 for each previous volume and to change the royalty from 35% of sales to nonmembers to 22-½% of all sales. Discount to members would be 30% from the $35 list price.

Stanton moved that AAEA provide a $10,000 subsidy to University of Minnesota Press for volume 3. Seconded. Passed.

Babb, as chairman, will check with Harl regarding the legal aspects of the contract and the committee will develop the procedures for handling and processing orders for members.

15. Schuh reported for the Committee on Fellows Nominations. A concern was expressed about the lack of foreign member nominations, particularly since AAEA has a large foreign membership. Brown moved that the Bylaws be amended to have the committee report one month prior to the winter meeting. Seconded. Passed.

16. Schuh reported as the liaison representative to the National Bureau of Economic Research.

17. Tweeten provided a suggested list of members for the 1980–81 Nominating Committee, with Richard King as chairman, and asked for concurrence. Stanton moved the approval. Seconded. Passed.

18. King announced the dates for future AAEA meetings. They are 26–29 July 1981 at Clemson, South Carolina; 1–4 August 1982 at Logan, Utah; 31 July–3 August 1983 at Lafayette, Indiana; 5–8 August 1984 at Ithaca, New York; and 4–7 August 1985 at Ames, Iowa.

The Allied Social Science Associations, in which AAEA is a participator, will meet 28–30 December 1981 in Washington, D.C.; 28–30 December 1982 in New York; 28–30 December 1983 in San Francisco; 28–30 December 1984 in Dallas; and 28–30 December 1985 in New York.

19. Herr reported for the Resident Instruction Committee. The workshop sponsored by the

AAEA at Southern Illinois University was considered outstanding. Herr recommended that AAEA sponsor a teaching workshop every three years near the time of the AEA annual meeting. Coffey moved the acceptance of the idea. Seconded. Passed.

The bylaws of the Student Section had been out of date and King suggested a revision. The Student Section had some suggested revisions. The two were merged, with King providing a corrected copy. Tweeten moved to amend Article 13 of bylaws to reflect the changes. Seconded. Passed.

20. Meeting recessed at 5:00 p.m., 26 July 1980.

21. Meeting reconvened at 8:35 a.m., 27 July 1980.

22. The discussion on location of Secretary-Treasurer was resumed, with James and Ebert present to give an overview of facilities and cooperation expected from the administration at Iowa State. An account would be set up with ISU, and all receipts and expenses would be processed through that account to obtain audit control. Office would occupy 200 square feet, with an area $5' \times 8'$ for storage. Programming will be at no cost, but computer time will be paid. Questions were fielded.

Janssen and Farrell were present to elaborate on the Janssen proposal. Farrell indicated that the proposal was from Janssen, but ESCS will provide support as much as possible. Space would have to be found, the legality of use of FTS line would have to be determined, support staff cost would be on direct hire or on a reimbursement basis.

Redman indicated he had no further comments on the Kentucky proposal as he felt the Board had a complete understanding of the proposal which for the next five years would continue the uninterrupted flow of services as provided for over ten years, though perhaps on an increased level. The only major difference was that Kentucky was asking for $35,000 for partial reimbursement of professional time and services, and Redman officially would devote full time to AAEA activities. The expiration of the five-year period would coincide with Redman's planned retirement from the University.

The Board went into executive session.

Minutes of the Executive Session of the Board

The Board was convened in Executive Session at 10:05 a.m., 27 July 1980, by President King. Stanton was appointed secretary during this meeting. Harl excused himself from the meeting on the basis of potential conflict of interest because Iowa State University had submitted a proposal for Board consideration.

The Board members then discussed in detail the proposals presented, budget considerations associated with them, and the respective abilities of the institutions involved to process association data and accounts. A secret ballot was taken with each Board member listing his first preference for location of the office of secretary-treasurer and the business office of AAEA. The vote was eight in favor of locating at Iowa State University.

It was moved by Hopkin and seconded by Coffey that on the basis of the unanimous vote of preference obtained in secret ballot with all members of the Board present, excepting Harl who absented himself from both the discussion and final vote, the AAEA accept the proposal of Iowa State University to provide the services of the secretary-treasurer and the business office of the Association, to take effect not later than 1 January 1981, and that arrangements to effect this transfer be initiated immediately for the orderly and expeditious movement of the functions of the office and properties thereof. This motion was carried unanimously. Harl returned to participate in the balance of the meeting.

It was moved by Stanton, seconded by Schuh, that Sydney James be appointed secretary-treasurer of the AAEA for a term of one year, in accordance with Article VI, Section 2 of the Constitution, such appointment to be effective 1 January, 1981; and in accordance with the provisions of Article VI, Section 4 of the Bylaws, the Executive Board by this action confirms a commitment of three years to the appointment of Sydney James to the office of secretary-treasurer, subject to a performance evaluation each year preceding reappointment. The motion was carried unanimously with Harl abstaining from the vote.

It was moved by Schuh, seconded by Dennis that Sydney James, Secretary-Treasurer designate of the Association, be given the authority to create a business office for the Association at Iowa State University and to retain services of such individuals as shall be reasonably necessary to implement the establishment of the business office within the resource constraints of the Iowa State University proposal submitted and approved by the Executive Board on 27 July 1980. The motion was carried unanimously, with Harl abstaining from the vote.

It was moved by Coffey, seconded by Brown that a contingency fund of $15,000 be established from Association funds for the purpose of paying actual costs of the move of property and inventory of the Association, necessary travel costs, and other actual fees and costs incurred in the transfer of the office of secretary-treasurer from the University of Kentucky to Iowa State University and for the costs of services needed prior to 1 January 1981 to make operational the office of Secretary-Treasurer, including but not limited to reimbursement for wages, salaries, employee benefits, and other costs associated with the employment of necessary persons. The sum of $15,000 is to be deposited on account with the Business Office of Iowa State University, with amounts remaining to revert to the general funds of the Association after payment of all costs authorized in this motion. The motion was carried unanimously with Harl abstaining from the vote.

It was further moved by Schuh, seconded by Coffey that a three-person special committee be

created to formulate and implement plans for transferring the office of Secretary-Treasurer of the Association from the University of Kentucky to Iowa State University, with the appointment of members by the President of the Association. The motion was carried unanimously, Harl abstaining. Members appointed to this committee are John Hopkin, Tom Brown, and Earl Swanson.

It was moved by Schuh and seconded by Stanton that a Resolution of Appreciation and Special Commendation to John Redman for meritorious service to the Association be drafted and presented at the business meeting Tuesday morning, 29 July. This motion was carried unanimously.

The Executive Session was concluded at 12:15 p.m.

23. The Board resumed in a regular session with Mitchell reporting on the Selected Paper sessions. He indicated that 178 papers were received, from which 128 were selected, 28 more than last year.

24. Badger reported for the AAEA Literature Retrieval Committee. The committee recommended that (*a*) AAEA renew the cooperative agreement between AAEA and ESCS for fiscal year 1 October 1980–30 September 1981 and provide $19,000 to ESCS for operation of the literature retrieval service through the AAEDC; (*b*) an intensive public relations effort be undertaken to encourage the members to use the system; (*c*) the committee analyze the deficiencies in the system and make suggestions for correction; (*d*) the committee contact several major vendors of literature retrieval information to delineate and analyze alternatives; (*e*) AAEDC and ESCS explore the feasibility of contractor assistance to catch up in inputting literature into the file; (*f*) a Newsletter be initiated to improve the flow of services; and (*g*) hold a workshop to train reference librarians, computer specialists and library personnel to use the service.

Schuh moved the report be accepted and the committee be commended. Seconded. Passed.

Hopkin moved that AAEA allocate $19,000 as requested and to renew the agreement. Seconded. Passed.

25. Farrell reported for the task force on Operational Data Base for AAEA Activities. The report is rather comprehensive, listed the AAEA management and information requirements, information lending itself to automation, and discussed the feasibility of automation. Hopkin moved the acceptance of the report. Seconded. Passed.

26. Bromley reported for the Professional Activities Committee. He reported that the committee had recommended that AAEA sponsor (*a*) a teaching workshop with Herr as the organizer; (*b*) a symposium in cooperation with the American Meteorological Association on the value of weather information, with Eisgruber on the planning committee; and (*c*) a symposium in cooperation with the American Society of Agricultural Engineers on national energy issues, with Otto Doering on the planning committee.

The committee recommended that AAEA express an interest in becoming affiliated with a Federation of Scientific Agricultural Societies (FSAS) which would consist of the presidents of about forty professional societies. Stanton moved that AAEA become affiliated and allocate $400 for the membership fee. Seconded. Passed.

The committee also recommended that AAEA cooperate with seven or eight other societies in organizing a 1981 conference on research priorities in soil and water conservation and productivity. Hopkin moved that AAEA cosponsor the workshop with no financial support. Seconded. Passed.

27. Crowder reported for the Industry Affairs Committee. The committee recommended that an award for excellence in research relating to current business problems be established. It would be funded by the Industry Affairs Committee or private sources. Schuh moved that the report be accepted. Seconded. Passed.

28. Gardner reported on the Committee of Professional Associations on Federal Statistics (COPAFS), the Economics Statistics committee, and the Census Advisory Committee on Agricultural Statistics. Schuh moved the acceptance of the report. Seconded. Passed.

29. Mathia reported for the Membership Committee. A question was raised whether or not membership recruiters were violating the privacy of individuals regarding payment of dues. Harl moved that the President of the AAEA be authorized to commission members of the Association as local membership representatives and to make available to said individuals lists of members and nonmembers of the Association as needed in fulfillment of membership recruitment efforts. Seconded. Passed.

30. Extension Affairs Committee circulated a report indicating that it was in process of assessing its objectives and role in the profession. It was reported that a workshop was being explored. Tweeten moved that AAEA enthusiastically endorse and encourage the Extension Affairs Committee to develop the idea of a workshop and urge it to work with the Professional Activities Committee in preparing a proposal. Seconded. Passed.

31. King presented a report for the International Committee prepared by Nobe. A request was made to convert the committee to the status of a standing committee. No action was taken. Hopkin moved the acceptance of the report. Seconded. Passed.

32. King presented a report of the Professional Registries Committee prepared by Allan Johnson. The grant from Department of Labor was extended to 30 June 1981, with no additional funding. Hopkin moved acceptance of the report. Seconded. Passed.

33. Harl presented a letter from Lundeen concerning the status of women in AAEA. The Board considered various approaches to the problems of minorities. No action was taken, but the incoming President may wish to explore the concern further.

34. Anderson raised the possibility of closer cooperation with the regional associations with AAEA collecting and remitting dues. Coffey moved that the secretary-treasurer of AAEA be authorized

to cooperate with the regional associations by accepting payments of dues for membership in these associations and remitting the payment to them. Seconded. Passed.

35. King discussed the report circulated by CAST indicating the number of agricultural economists as AAEA representatives on various task forces. It was noted that AAEA will continue to assist in identifying agricultural economists who may have an interest in CAST activities as individuals but not as AAEA representatives.

36. Coffey presented the budget for 1981 incorporating the financial commitments made during the meeting. It showed a deficit of $12,728. Stanton moved the acceptance of the budget. Seconded. Passed.

37. It was suggested that the Board meet 9–11 December in St. Louis, to develop a joint program for 1981 with the Southern Agricultural Economics Association.

38. Board adjourned at 5:15 p.m.

Respectfully submitted,
John C. Redman
Secretary-Treasurer

Minutes of the Annual Business Meeting, Urbana, Illinois

The 69th annual meeting was called to order by President R. A. King on 29 July 1980, at 8:15 a.m.

1. King presented for approval the minutes of the annual business meeting held at Pullman, Washington, 31 July 1979, as published in the "Proceedings" issue of the *Journal*. Motion was duly made to approve the minutes. Seconded. Passed.

2. King announced the results of the election of officers. G. Edward Schuh was elected as President-Elect, and William E. Martin and Richard G. Heifner were elected as Directors.

3. King recognized the directors and ex-officio members of the Executive Board.

4. King gave his presidential report. The report will be published in the "Proceedings" issue of the *Journal*.

5. Redman presented the secretary-treasurer's report. Motion was made to accept the report. Seconded. Passed. The report will be published in the "Proceedings" issue of the *Journal*.

6. King presented the report of the certified public accountant on the financial condition of AAEA and indicated that a copy would be on file for anyone desiring to examine it. Motion was made to accept the report. Seconded. Passed.

7. Coffey reported for informational purposes some budgetary items for the 1981 budget, which will show a deficit of $12,718.

8. Rhodes reported as editor of the *Journal*. His report was accepted and will be published in the "Proceedings" issue.

9. No old business was noted.

10. Under new business, King recognized G. Edward Schuh for a resolution of appreciation and special commendation to John Redman for meritorious serivce as secretary-treasurer of AAEA since January 1970. Motion was made to accept the resolution. Seconded. Passed with a standing ovation. The resolution will be published in the "Proceedings" issue of the *Journal*.

Motion was made from the floor that AAEA Executive Board elect John Redman as a Fellow of AAEA. Seconded. After it was pointed out that the bylaws stated that Fellows Election Committee did the election, the motion was changed to the following: Move that the Executive Board nominate or submit and support the name of John Redman to the Fellows Election Committee to be elected as a Fellow. Seconded. Passed unanimously.

11. King announced that the next annual meeting will be on the campus of Clemson University on 26–29 July 1981.

12. King recognized Schuh again for Resolutions thanking the host, the University of Illinois, for a job well done; University of Missouri and especially editor V. James Rhodes, associate editor Stanley Johnson, assistant editor Martha Luzader, and Oregon State University, especially book review editor Herbert Stoevener for support and outstanding performance for the past three years; and the University of Kentucky for providing a home for AAEA for the past ten years. Motion was made to accept the Resolutions. Seconded. Passed. The Resolutions will be published in the "Proceedings" issue of the *Journal*.

13. King thanked the retiring members of the Executive Board—Stanton, Coffey, and Schuh—for their assistance and dedicated work.

14. King recognized and turned the chair over to Luther Tweeten as the new president. Tweeten announced the names of the Nominating Committee.

15. Meeting adjourned at 9:20 a.m.

Respectfully submitted,
John C. Redman
Secretary-Treasurer

Resolutions

Wishing to acknowledge the support given to the *American Journal of Agricultural Economics* during the past three years,

Be it resolved that the American Agricultural Economics Association expresses its appreciation to the Department of Agricultural Economics of the University of Missouri at Columbia for the support given the *American Journal of Agricultural Economics*. The special thanks of the Association are due the Editor, V. James Rhodes, the Associate Editor, Stanley Johnson, and the Assistant Editor, Martha Luzader, for their outstanding services. In addition, the Association wishes to express its deep

appreciation to Herb Stoevener of Oregon State University for his services as Book Review Editor.

Be it further resolved that a copy of this Resolution be sent to the appropriate administrative officials of the University of Missouri and Oregon State University.

Passed unanimously at the University of Illinois, Urbana, Illinois.

We wish to acknowledge the warm and cordial hospitality shown the members of the American Agricultural Economics Association, their families and guests, on the occasion of the annual meeting held at the University of Illinois on 27–30 July 1980. *Therefore,*

Be it resolved that the American Agricultural Economics Association expresses its sincere gratitude to President Stanley O. Ikenberry, to Daniel I. Padberg, Head of the Department of Agricultural Economics and his faculty, staff, and students and their families, and to Carole Holden, Conference Coordinator of the staff of the Conferences and Institutes division for their hospitality.

All of these, under the able and devoted leadership of Harold G. Halcrow, chairman of the Local Arrangements Committee, as constituted and reported on pages 45–47 of the program, have served us effectively and graciously.

Be it further resolved that a copy of this Resolution be sent to President Stanley O. Ikenberry, Daniel I. Padberg, Carole Holden, Harold G. Halcrow, and to each of the various committees and to others at the University of Illinois as appropriate.

Passed unanimously at the University of Illinois, Urbana, Illinois.

The University of Kentucky has been the home of the Secretary-Treasurer's office of the American Agricultural Economics Association for ten years. It has provided to the Association the services of one of its most able agricultural economists, Dr. John Redman. It has provided office space and general support for the Secretary-Treasurer and its staff.

In light of the above, *Be it hereby resolved* that the American Agricultural Economics Association expresses its deepest appreciation to the Department of Agricultural Economics of the University of Kentucky and its staff for the support of this important office and function of the Association.

Be it further resolved that a copy of this Resolution be sent to the appropriate administrative officials of the University of Kentucky.

Passed unanimously at the University of Illinois, Urbana, Illinois.

John C. Redman has been Secretary-Treasurer of the American Agricultural Economics Association for ten years. During that period he has served the Association and its members extremely well. To enumerate all the many things John has done would be difficult, if not impossible. But, those of you who know him, or are familiar with his activities, know that there is no request that is too small for him to attend to; you know the many hours of dedicated service he has given to the Association—in keeping up mailing lists, in keeping checks deposited and checks emitted, in preparing all the many certificates for the award ceremony each year, and in attending to numerous other aspects of the Association's business; and you know the inimitable style and grace with which he has done all of these things.

One of John Redman's important contributions over the years has been to the Executive Board of the Association. John has served as the institutional memory of the Board as outgoing members phased out and new members came on stream. He has oriented new members of the Board and Officers of the Association and saved many of us from missteps and even possibly major errors. His penchant for detail has been a help to us all. His penchant for orderliness has saved Board members countless hours, as he was able to retrieve bits and pieces of vital information from his well-organized and portable files. John has a rich knowledge of names and of people working in the profession, and has brought this knowledge to the meetings of the Board. John has a sensitivity for history, and in particular for what the Association and former Board members have done. All of these things John has combined with judgment and insight to contribute to the deliberations of the Board with ideas, suggestion and recommendations.

But John's contributions to the Association go much beyond his efforts on behalf of the ever-changing Executive Board. John has had a commitment to high standards for the Association. It has been largely due to John's efforts that the Award Ceremony each year comes off without a hitch. When statements for the presentation of the prestigious Fellows awards were not available, for example, John would sit up all hours of the night preparing them.

John also contributed importantly to the design of the present organizational structure of the Association. John's frugality has been both a bane and a blessing to members of the Board and incumbent presidents, but his honesty and integrity have set a standard for both the Board and members of the Association. John has saved the Association substantial expense through his ingenious use of resources, through the care with which he has searched out savings on things we needed to purchase, and through the inputs of his own personal time to activities of the Association. In the case of the San Diego meetings of a few years back, to cite only one example, John served as essentially a one-man local arrangements committee. Few people recognized this at the time.

Perhaps as important as any of these things that John has done, he has done it all with a cheerful and happy mien, and with style and good grace.

In light of the above, *be it hereby resolved* that the American Agricultural Economics Association

expresses its deepest appreciation to John C. Redman for the many hours of faithful, dedicated, and effective service he has given to the Association. *Be it further resolved* that a copy of this Resolution be sent to the appropriate administrative officials of the University of Kentucky.

In closing, we would like to take note of the fact that John Redman was a well-recognized and distinguished member of the profession at the time he took on the demanding job of Secretary-Treasurer of the Association. John, we all wish you well as you return to being a productive member of the profession in this next phase of your career. And, we look forward to your continued contributions to the activities of the Association.

Passed unanimously with a prolonged standing ovation at the University of Illinois, Urbana, Illinois.

Objective

The AAEA seeks to further the systematic development of knowledge of agricultural economics in order to improve agriculture and agriculture's contribution to the general economy. The activities of the AAEA include:

—publishing the *American Journal of Agricultural Economics;*
—planning and conducting two annual meetings of the membership;
—sponsoring annual awards for outstanding extension programs, distinguished teaching, and outstanding research;
—recognizing outstanding agricultural economists through a fellows program;
—supporting a literature retrieval system in cooperation with the U.S. Department of Agriculture;
—publishing periodically a biographical directory of the AAEA's members;
—supporting an employment registry for agricultural economists in cooperation with the U.S. Department of Labor.

Membership and Subscriptions

Membership in the AAEA is open to individuals having a professional interest in agricultural economics. Dues, payable at the beginning of each calendar year, are as follows: regular members, $25, senior members, $12.50, and junior members, $12.50. Senior membership is open to persons, upon written request, who are sixty-five years of age or older and have retired from active professional work. Junior membership is for students and is limited to three years; students should use application forms available from and signed by the head of the department in which they are studying. Members receive this *Journal*.

Any firm, corporation, association, or partnership may become an institutional member upon payment of $100 per year; institutional members receive three copies of each issue of the *Journal*. Library subscriptions are $35 per year. Individual issues of this *Journal* are $10.00.

Payment of membership dues, correspondence regarding subscriptions, orders for individual copies of the *Journal*, changes in address, or inquiries about the general affairs of the AAEA should be sent to John C. Redman, Secretary-Treasurer, American Agricultural Economics Association, Department of Agricultural Economics, University of Kentucky, Lexington, Kentucky, 40546.
